Biomedical postdocs: Salaries and population in the US.
A. Bankston1, C. Pickett2, G.S. McDowell1,3;
1Future of Research, Abington, MA, 2Rescuing Biomedical Research, Princeton, NJ, 3Manylabs, San Francisco, CA

The number of postdocs in the U.S. is elusive. Estimates of the postdoctoral population, of which the largest area of study is the biomedical sciences, are made difficult by the range of institutional policies and tracking efforts made. We have undertaken a study of the postdoctoral salaries, and therefore the population of postdocs at the time, at U.S. public institutions in response to recent changes to postdoctoral salary recommendations. This has been compared to the NSF’s Survey of Graduate Students and Postdocs (the “GSS”), which was itself evaluated to determine its ability to document postdoc population trends. In summary, while some institutions report postdoc data quite well, there are many caveats with the data that prevent making very clear pronouncements about postdoc data in general. However, it is clear that there are postdocs paid at a wide range of salaries, from the legal minimum of $23,660 to four times as much. We hope this evaluation will cause postdocs and institutions alike to reflect on the postdoctoral experience.

Outcomes From a Novel Online Course, Planning Your Scientific Journey.
A.M. Schnoes1,2, S. Behrman1,2, N. Griffin1,2, D. McQuillen1, E. Kirschner1, E. Cohn1, N. Green1,3, S. Goodwin1, R.D. Vale1,2,4;
1Biology, San Francisco, CA, 2Cellular and Molecular Pharmacology, University of California San Francisco, San Francisco, CA, 3Green Scientific and Educational Consulting, Oakland, CA, 4Howard Hughes Medical Institute, Ashburn, VA

Formulating a scientific question is an essential first step in doing research. So, how does one begin the daunting task of coming up with one? And, what makes a scientific question “good?” These are some of the complex questions we try to answer in a free online course called “Planning Your Scientific Journey.” The goals of the course are to have students (1) evaluate potential research questions and experimental approach with a set of criteria, (2) develop a plan for their research, and (3) prepare for a meeting to discuss their research project and plan with their mentor.
The course is run on the Open edX massive open online course (MOOC) platform. It is aimed at graduate students and postdoctoral researchers, but could be useful for undergraduates and other researchers. Designed with busy schedules in mind, it is 6-weeks long and is meant to take 1-3 hours of work a week.
Our online course is innovative in both curriculum design and video production. Because the topics are complex and somewhat subjective, we applied a unique approach to developing and presenting the content. Videos with “one lecture by one expert” wouldn’t sufficiently convey the diversity of ways to ask scientific questions and plan research. And so, we interviewed a variety of scientists on these topics. We edited the interviews into short documentary-style videos that each focus on one key learning objective with multiple perspectives represented.
We launched “Planning Your Scientific Journey” this past June (2017) and then ran the course a second time in October. Here we present course outcomes, examining both quantitative and qualitative measures to answer five important questions: (1) did we meet our course goals, (2) what was the level of engagement with the course, (3) what did students learn, (4) what is the level of course satisfaction, and, (5) what needs to be improved? Our evaluation includes the analysis of pre-, post- and follow-up course surveys, discussion forum posts, and quantitative data regarding student enrollment, completion rates, video analytics, and satisfactory completion of assignments.

Board Number: B3
Providing resources and strategies to enhance career training for junior scientists.
A. Bankston¹, G.S. McDowell¹,²;
¹Future of Research, Boston, MA, ²Manylabs, San Francisco, CA

Academia became the minority destination for junior U.S. biomedical scientists in the 1980s. In spite of this, early career researchers (such as graduate students and postdocs) are not being adequately equipped with the tools and resources needed to transition away from the bench into a non-academic job, and are not sufficiently trained in the mentoring and management skills required for academic positions.

Future of Research (FoR) is a nonprofit that helps early career researchers to organize local meetings to discuss problems they experience with science, and propose solutions to advocate for changes. Our aim is to improve the scientific research endeavor and scientists’ holistic careers. We advocate for improved training for early career researchers to help them achieve their desired career goals, as this has been an area of concern highlighted in our first junior scientist-organized conference in Boston in 2014 (see Shaping the Future of Research: A Perspective From Junior Scientists by GS McDowell et al. in F1000Research, 2015).

Our organization discussed this topic during recent workshops held at the American Society for Cell Biology Annual Meeting (ASCB 2016) and NatureJobs Career Expos in Boston (2015 and 2016). In this poster, we present a summary of the data we gathered at these meetings, including barriers to training identified by early career researchers; career development resources that they are aware of; and those resources which they have identified as still needed.

There is a clear gap in the training that early career researchers want, and what training they are able to receive. We call for collaboration in terms of career programming and resources among various stakeholders, for example by centralizing such information in an online database as suggested at the American Society for Biochemistry and Molecular Biology (ASBMB) Sustainability Summit (see Biomedical research workforce summit makes strides in implementing change for postdocs by Viviane Callier in Nature Biotechnology, 2016). Properly training the next generation of scientists for the roles they will play as future scientific leaders is critical to the future of the scientific enterprise.

Board Number: B4

‘Planting the seed of research in the undergraduate mind’: Conducting mentoring sessions on research opportunities and graduate school by INSPIRE/IRACDA fellows.
S. Borinskaya¹, H. Menon², S.M. Quartuccio³;
¹Pathology, Rutgers University, Piscataway, NJ, ²Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ, ³Department of Genetics, Rutgers University, Piscataway, NJ

A core mission of the IRACDA NIH-funded postdoctoral training program is to develop a diverse group of trained scientists in the fields of biomedical research by broadening participation at the undergraduate level. What better way to encourage participation of diverse groups than to have undergraduates experience first-hand early in their careers what science is all about? Student engagement in actual research improves their understanding of concepts, retention of information, problem solving skills and ability to apply knowledge to real world problems. However, many students are unaware of the research opportunities available to undergraduates or are intimidated by the application process. To encourage undergraduates to participate in research and pursue careers in biomedical science, we, fellows of INSPIRE (IRACDA program at Rutgers University), have developed mentoring sessions at our minority-serving partner institutions focused on summer research opportunities and graduate school. We provide students with information about local and national opportunities, answer questions, and mentor students through the application process. Our mentoring sessions are different from the conventional information sessions. We tailored the format of the session to foster conversations with students based on our and their personal experiences. These conversations promote development of mentor-mentee relationships between the fellows and the students at MSIs (minority-serving institutions). Here we present how we conduct mentoring sessions at our partner institutions, share student feedback, outcomes, reflections of the fellows and partner school coordinators. We hope that we will inspire others to conduct similar sessions at their institutions to enhance participation of diverse scientists in research.

Board Number: B5

Sustained teaching mentoring works—and benefits mentors as well as those mentored. An update on the Promoting Active Learning and Mentoring (PALM) Network.
S. Wick¹, A.J. Prunuske², M.J. Wolyniak³, M. Peifer⁴;
¹Biology Teaching Learning, University of Minnesota—Twin Cities, Minneapolis, MN, ²Medical College of Wisconsin, Wausau, WI, ³Biology, Hampden-Sydney College, Hampden-Sydney, VA, ⁴Biology, University of North Carolina, Chapel Hill, NC

Many instructors and instructors-to-be have heard of the value of using active learning to guide students to deep learning of course material. Some have attended workshops or several-day immersion experiences to learn how to employ effective active learning activities. In spite of best intentions, plans to actually implement active learning techniques often collapse once an instructor gets caught up in the academic year. To address this situation, ASCB, in cooperation with other professional societies and academic groups and with NSF funding, established the Promoting Active Learning and Mentoring (PALM) Network. This program provides PALM Fellows with a one-on-one teaching mentoring relationship for at least one semester with a mentor experienced in active learning. Participants to date have come from various partner societies within the Network. Analysis of teaching behavior before and after mentoring provides evidence that Fellows have been able to increase their use of active learning in
One faculty member and one graduate student at different institutions were paired by the Mentoring Active Learning and Teaching (MALT) program of the American Society for Cell Biology (ASCB). They worked together to create a Course-based Undergraduate Research Experience (CURE) centered on the research of the graduate student in the field of hematologic development, specifically exploring early embryonic red blood cell maturation. The faculty member had taught undergraduate courses in a flipped format threaded with active learning for years. However, one of the limitations of teaching at a primarily undergraduate institution (PUI) is the lack of access to cutting edge technology. The graduate student works in a large research lab at the forefront of imaging flow cytometry, a technology that combines flow cytometry with cell imaging to allow for analysis of immunophenotype and morphology simultaneously. Together, the faculty member and graduate student centered the class and lab on the use of this and other techniques to compare the maturation of primitive red blood cells to apoptosis in an established cell line, an important research question relevant to the graduate student. Importantly, this faculty member had expertise in adherent cell culture that the graduate student did not. As part of the MALT program, the graduate student travels to the faculty member’s institution, or uses assistive digital technology, to teach several lectures and labs. The faculty member worked with the graduate student on incorporating active learning techniques into his lectures and labs. Undergraduate students became research collaborators with the graduate student, conducting experiments they designed on adherent cell cultures they grew and maintained during the lab. In addition to conducting experiments at their PUI, the students traveled to the graduate student’s institution to conduct experiments at the flow cytometry core facility. Internal funding sources (faculty development funds, departmental funds, NSF funds, private endowments, course fees, and lab fees) from the both the faculty member and the graduate student paid for travel, accommodations, meals, equipment and supplies. Student comments from end of course evaluations revealed that they were motivated to and engaged in learning course content. This experience invigorated the faculty member’s teaching and gave the graduate student hands-on teaching experience in a PUI class and lab. Students presented a poster they created on their research at local and regional student conferences. The faculty member and graduate student were invited speakers for seminars and research panel discussions at each other’s institution. Overall, this MALT and CURE experience proved to be truly collaborative for all involved.

**Board Number: B7**

Mentorship for Developing course-based undergraduate research experiences (CUREs): The CUR/ASCB Mentorship for Integrating Research Into the Classroom (MIRIC) program.

M.J. Wolyniak¹, A.J. Prunuske², K.K. Resendes³;
¹Biology, Hampden-Sydney College, Hampden-Sydney, VA, ²Basic Sciences, Medical College of Wisconsin, Wausau, WI, ³Biology, Westminster College, New Wilmington, PA

The life science education community has responded to the recommendations of the American Association for the Advancement of Science (AAAS) Vision and Change document with several initiatives designed to improve the way in which undergraduates learn science. These initiatives have often taken the form of one-time workshops that generate awareness of and interest in developing authentic research experiences for undergraduate STEM classrooms. However, they have been less successful with respect to generating the sustainable change necessary to bring real reform to undergraduate science education. To create sustainable change, long-term faculty development initiatives focused on mentorship are needed so that instructors seasoned in developing and implementing course-based undergraduate research experiences (CUREs) can convey their experiences to mentees interested in using these pedagogical techniques as the centerpiece of their own teaching. The Council on Undergraduate Research (CUR) Biology Division and American Society for Cell Biology (ASCB) Education Committee are creating the Mentorship for Integrating Research Into the Classroom (MIRIC) program to provide a means for members with an interest in developing improved and sustainable active learning techniques to gain experience in this style of teaching through close, long-term interaction with a veteran teaching mentor.

Developed from the former ASCB Mentorship in Active Learning and Teaching (MALT) program, MIRIC focuses on the development of instructors who wish to develop a dynamic CURE. Current and future life science instructors pair themselves up with seasoned veterans of CURE development and work with them and their students over the course of a semester or longer to develop a CURE that will allow the mentee to bring authentic research into his or her classes.

In our pilot studies, we collected qualitative and quantitative data based on participant interviews and coding videos of student and instructor actions during classroom activity (Smith et al., 2013), respectively, that suggest that MIRIC/MALT mentorships have made positive gains in promoting sustainable active learning techniques among participants. Going forward, we wish to use instruments like the Laboratory Course Assessment Survey (Corwin et al., 2015) and Experimental Design Ability Test (Sirum and Humburg 2011) to assess the effectiveness of the MIRIC laboratory intervention.

It’s a small world: a cell biology outreach program for young learners.

E. García¹, A. Osimani¹, M. Lunde¹, N. Baudoin¹, M. Rosenzweig¹, D. Cimini¹;
¹Biological Sciences, Virginia Tech, Blacksburg, VA

In the Cimini lab, we strive to understand the intricate details that drive accurate cell division and what happens to a cell population when these details are perturbed. It is easy for us to see how important and beautiful cell division is, but this can be difficult to portray to a younger audience; therefore, we decided to develop an engaging and inspiring outreach program focused on cell division. In order to learn about cell division, one must first understand the cell, and to understand the cell, one must first comprehend the microscopic scale. Therefore, our program has two parts. The first part is designed to

---

Sunday-5
encourage visitors to explore the microscopic scale using various types of microscopes, such as a dissecting 'scope or a light microscope, and challenge them to “think small.” The second part of the exhibit consists of an animated tutorial that takes participants through a “microscope wheel”. It starts from something they can see with their eyes in nature, such as a beaver (or other leaving creatures they may be familiar with), and then moves to what is invisible to the eye (e.g., the beaver’s retinal cells). Next, they view videos of dividing cells to learn why cell division is important and discover how something as small as a single cell can create and sustain something as large as an adult animal! This outreach program includes a permanent exhibit housed at the local nature center, as well as a moving exhibit for science festivals or classroom settings. The goal of our outreach program is to provide activities for participants to see with their own eyes what the world looks like under a microscope and to help them understand how important cells and cell division are to perpetuating life. With this program we hope to impart excitement for cell biology onto the future generation.

P1009
Board Number: B9
Share your expertise and enthusiasm with teachers: Organize a workshop to build cheap, homemade microscopes.
B. Goldstein¹, K. Yoshino²;
¹Biology Department, UNC Chapel Hill, Chapel Hill, NC, ²-, Hamilton, NY

To get low-cost microscopes in front of as many children as possible, we have (1) shared freely a design for a homemade microscope (K.Y.) and (2) have run several workshops for elementary school teachers to build and take away their own microscopes (B.G.). The original microscope design was shared freely online in a 2013 Instructable entitled "$10 Smartphone to digital microscope conversion!" This is a design for a do-it-yourself microscope that takes advantage of ubiquitous smartphone cameras. We envision that like other inexpensive microscopes, these microscopes are likely to encourage children to explore microscopic worlds around them, encouraging curiosity-based learning within and beyond classrooms. This microscope design is relatively unique in that the microscope parts are mostly transparent, making usage intuitive to teachers and children without a need for written instructions. And the microscope parts for this design are readily available, mostly from hardware stores, so teachers or kids can build more microscopes when they want. Based on feedback from teachers, we’ve enlarged the original design to accommodate iPads and other tablets, which are available in many schools and which make it possible for groups of children to interact with each other around each microscope—a significant change from older, traditional microscopes in which only each individual child might know what he/she saw through an eyepiece. For the workshops with teachers, we prepare enough materials for each teacher to build one microscope to take away and use in a classroom. Each such workshop typically lasts 1.5 to 2 hours, during which three things happen: (1) each teacher assemblies a microscope and learns how to build more on their own if they’d like, (2) the teachers use the microscopes to take photos of objects they brought with them (for example, bugs, table salt, cloth, leaves, as well as petals at a resolution sufficient to see individual cells), and they email the photos directly into an online gallery that we project to everyone in the room and that remains online as a picture archive, and (3) teachers brainstorm about how they will use the microscopes with children to best match specific curriculum needs as well as children’s own interests. Current work includes development of outcome assessments with a collaborator, and work to expand the workshops to underfunded school districts. In this poster, we will share a protocol for anyone who would consider running your own workshop(s) with teachers at local schools or museums, and we will bring some microscopes for anyone to try.

Citizen scientists detect pathogens associated with tick-borne illnesses in Ixodes scapularis.
J.S. Alegria-Berrocal1, M. Alhalal2, C.N. Fisher3, R. Ragland4, J. van Westrienen5, A.J. Prunuske6;
1Biology, University of Wisconsin-Stevens Point, Stevens Point, WI, 2University of Minnesota- Duluth, Duluth, MN, 3Biomeme, Philadelphia, PA, 4Microbiology and Immunology, Medical College of Wisconsin, Wausau, WI

The *Ixodes scapularis* tick has been expanding its range across the upper Midwest and New England, which is likely to be increasing the risk to individuals of developing tick-borne illnesses. Ticks acquire pathogens from primary reservoir hosts like the white-footed mouse, *Peromyscus maniculatus*, and depending on the prevalence of the primary host in the environment there can be variability in the percentage of ticks carrying the pathogens associated with Lyme disease and Anaplasmosis. Public health data is limited by the number of samples that can be collected; however, with the advent of mobile technologies there are growing opportunities for the public to engage in citizen science. As part of a public education campaign to promote the adoption of behaviors that protect against Lyme disease, we have partnered with local middle school students in the extraction of tick DNA using Biomeme field sample preparation kits combined with portable real-time PCR analysis to test for the presence of pathogens. We have found that the students are able to successfully extract DNA that can be used in RT-PCR analyze and have found that 25% of ticks in Central Wisconsin carry *Borrelia burgdorferi* and 10% carry *Anaplasma phagocytophilum*. Importantly, we found a higher than random coincidence of the bacteria, which may impact disease transmission. Future work will involve pathogen strain analysis and a more in depth understanding of the benefits and challenges of engaging middle students in science.

P1011

Board Number: B11
A Five Week Cell Biology Laboratory Exercise: Characterization of Head and Neck Cancer Cell Growth and Invasiveness.
J.E. Hall1;
1Biology, Bucknell University, Lewisburg, PA

The complex nature of cell matrix interactions is a foundational concept of cell biology that proves challenging to teach in a traditional lecture setting. To give students real-world experience with studying this phenomenon, a laboratory exercise was designed utilizing current methods. One key concept is the interaction with and modification of the extracellular matrix (ECM) by cells. Cellular invasion into tissues is an important process for development and organismal homeostasis; this process is critical for the progression of disease states such as inflammation and tumor cell metastasis. In tumor cells, ECM degradation is accomplished by ventral actin-rich membrane protrusive structures termed invadopodia, the formation of which directly correlates with the ability to invade into local stroma. Having real world experience with the formation of invadopodia and corresponding ECM degradation helps learners connect these complex cellular phenomena to the basic principles of cell migration presented in lecture. Over five weeks lab pairs characterized the growth rate and invasiveness of several head and neck cancer cell lines. This laboratory exercise takes advantage of the highly invasive nature of these cell lines to introduce several techniques to undergraduate students: 1) culturing human tissue culture cells; 2) fluorescence microscopy; 3) establishment of a growth curve; and 4) data analysis. Students then presented posters with their results to their peers and two guest judges. Final exam
questions linked to laboratory material showed a significantly higher average score (p< 0.01) than questions that did not have accompanying laboratory exercises.

Board Number: B12
The yeast orphan gene project: Undergraduates finding a place for ORFans to GO.
M.J. Wolyniak1, J.B. Keeney2, E.D. Strome3;
1Biology, Hampden-Sydney College, Hampden-Sydney, VA, 2Biology, Juniata College, Huntingdon, PA, 3Biological Sciences, Northern Kentucky University, Highland Heights, KY

When the genomic sequence of the model eukaryote Saccharomyces cerevisiae was completed in 1996, the expectation was that an understanding of the integrated functioning of the collection of genes in this single-celled eukaryote would shortly follow. Despite almost 20 years of intense collaborative effort among yeast researchers, nearly 10% of open reading frames (ORFs) are considered uncharacterized. Determining the function of these orphan genes (ORFans) will require mining the current yeast genomic data, compiled in the Saccharomyces genome database (SGD), to most effectively design ORF-specific experiments in cell and molecular biology, and comparative genomics. A network of yeast researchers/educators with a focus on teaching experimental design could help overcome the challenges and absorb the risks of researching individual ORFans. The goal of the proposed Yeast Orphan Gene Project is to organize a consortium of undergraduate researchers and faculty at primarily undergraduate institutions (PUIs) to coordinate resources and design strategies to assign molecular functions to S. cerevisiae ORFan. Ultimately, the yeast orphan gene project aims to use the process of determining orphan gene function as a tool to teach undergraduate students key concepts in bioinformatics, genomics, molecular biology, and genetics and impart valuable experience in scientific collaboration and leadership. Based on analysis of SGD information, students will design and execute ORF specific experiments for defining gene function. The network will facilitate collaboration between students at different institutions so that students can share strategies and technique solutions while developing experience in on-line collaborations. These skills, including the ability to (1) apply the process of science, (2) use modeling and simulation, and (3) communicate and collaborate, are core competencies in “Vision and Change”. The proposed network will prepare undergraduates for careers in STEM, provide tools for faculty at PUIs to expand research experience for undergraduates, and incorporate research experiences into undergraduate courses. It will also be a mechanism to distribute a tested model of an authentic course-based research experience to a diverse set of institutions by providing workshop and assessment support. The networking activities will expand the expertise of faculty, as well as provide undergraduates tools and resources for collaboration. Defining the function of yeast ORFans will advance the goal of the yeast community to determine the function of the entire set of annotated yeast ORFs.

P1013
Board Number: B13
Steel City Blues: Leveraging a Legacy of Pollution for Research and Reflection in Introductory and Advanced Undergraduate Biology Courses.
K.M. Drace1, V.K. Gibbs1, M.L. Styers1, P.K. Hanson1;
1Biology, Birmingham-Southern College, Birmingham, AL

Place-based education (PBE) is a form of “in situ” science pedagogy that helps cultivate a sense of place among students as they interact with their local environment and community. PBE engages students
more effectively than traditional science curricula, promotes self-efficacy, and may play a role in identity formation. Despite these benefits, use of PBE has largely been confined to K-12 environmental education in rural settings. The goal of this project is to test the efficacy of PBE in three undergraduate biology courses at an urban liberal arts college. Specifically, heavy metal pollution from local industries is used to frame course-based undergraduate research and critical reflection. In an introductory cell and molecular biology course, students isolate and characterize bacteria from contaminated soils, looking for evidence of co-evolution of resistance to heavy metals and antibiotics. Quantification of interactions between microbes primes students for a subsequent course on evolutionary ecology. In an introductory organismal biology course, students use *Drosophila melanogaster* as a model organism to study the effects of heavy metals on development and behavior. They also develop and test hypotheses regarding the ability of diet to mitigate these effects. In an upper-level course on genetic engineering, students apply concepts from user-centered design to construct novel whole-cell bioreporters for chromate. Whereas the introductory labs will be implemented in Fall 2017, the 2016 pilot of the genetic engineering course suggests that this version of PBE is effective at engaging students. In pre-/post-surveys, 80% of students self-reported gains in “understanding how scientists work on real world problems” and 60% of students self-reported increased “ability to tolerate obstacles in the research process.” These gains are particularly notable, given that these students were all seniors, many of whom had prior undergraduate research experience. This cohort (*n*=10) also reported statistically significant gains in their readiness for more challenging research, their ability to contribute to science, and their understanding of the process of science (*p*<0.05). At the beginning and end of the term, students completed critical reflections addressing civic engagement. Rubric-driven analyses of these reflections suggest a possible increase in students’ abilities to articulate the relationship between their research and public interests, as the average score increased from marginal to proficient, and this difference approached statistical significance (*p*=0.1). Consistent with a limited number of reports in the literature, these preliminary data suggest that PBE can be adapted to engage urban undergraduates in STEM.

**P1014**

**Board Number: B14**

A semester-long cell biology research experience: from novice to project owner.

M.K. Dennis¹;

¹Biology, Marist College, Poughkeepsie, NY

Participation in authentic research experiences has been shown to increase student persistence, knowledge, scientific thinking and correlate with long-term career satisfaction. Incorporating authentic research into the undergraduate curriculum via course-based undergraduate research experiences (CUREs) is one mechanism for reaching a wider audience of students than classic apprenticeship models. Metrics for assessing student gains in research experiences include measures of experimental design ability and sense of project ownership. In this project, the lab component of a cell biology course was designed to introduce students to common methods used in molecular cell biology, and to encourage gains in scientific thought, understanding of the process of research and critical thinking through an extended independent project. In the first section of the course, students were introduced to key cell biology techniques via 1-2 week long modules, including mammalian tissue culture, transfection, immunofluorescence, Western blotting and data analysis and quantification. Each of these modules was designed as a scaffolded experience, with increasing independence as skills were gained and experimental design was understood to a greater degree. In the second section of the course, students worked in small groups to identify an extension of their preliminary data from the skills section, or to identify a new question related to course material, and to design and execute experiments to address this hypothesis. At the conclusion of the course, students presented their work in both oral and written
formats. To assess gains made in this research experience, the Experimental Design Ability Test (EDAT) and the Project Ownership Survey (POS) were used. Students who completed the course made large gains in their experimental design abilities, with EDAT scores of 3.7 (pretest) and 7.2 (posttest) on a 10-point scale. Additionally, students reported high degrees of ownership and satisfaction on both the POS and in written evaluations of the course. Together, these data indicate that this course improved scientific thought/experimental design abilities of students, and gave students a sense of place within the community, both of which are positive outcomes associated with undergraduate research experiences. Ideas for future iterations and improvements of the course will also be discussed.

Board Number: B15
CUREs for Everyone: Introductory Biology Lab Course Converted to Research Experience.
D.M. Thurtle-Schmidt¹, M. Prudencio¹, T.T. Eckdahl², A.M. Campbell¹;
¹Biology, Davidson College, Davidson, NC, ²Biology, Missouri Western State University, St. Joseph, MO

The seminal educational report Vision and Change calls upon scientists and educators to provide all their students with authentic research experiences in teaching laboratories. However, most laboratory courses do not simulate how real scientists conduct research. To provide students with a more genuine research experience in their first laboratory course, we have incorporated principles of iteration and relevance into an introductory course. We have expanded on our previous use of pClone (Campbell et al., 2014) so that students can design and test potential promoter sequences, ribosomal binding sites (rClone; Eckdahl et al., 2017), or modify promoters regulated by a transcriptional activator (actClone) or a transcriptional repressor (repClone). Students read research papers and design DNA sequences to test in one of four plasmids (pClone, rClone, actClone, or repClone). Each group clones an engineered DNA fragment and determines its function. Student groups present their results to the other three groups who have not worked with their particular plasmid. Based on the first round of results, all four groups can choose any plasmid for the second iteration and revise the DNA sequence to be tested. The students repeat the cloning and measuring procedures and then confirm the DNA by sequencing. To determine the effects of this course and the potential benefits of iteration on learning, student’s scientific self-efficacy, identity (Chemers et al., 2011), and career intentions (Estrada et al., 2011) will be measured before and after the laboratory course. Additionally, the Project Ownership Survey (Hanauer and Dolan, 2014) and Laboratory Course Assessment Survey (Corwin et al., 2015) will be administered at the end of the course to determine if potential gains are similar to those of Course Based Undergraduate Research Experiences (CUREs) that are usually restricted to upper level courses. We will present the results of this novel educational experiment that will be conducted in the fall of 2017 with first-term, first-year students. If successful, this model for introductory laboratory courses could be scaled to a national level at no additional costs to institutions.

Board Number: B16
Evaluating Cures as a Model for Persistence and Success in Science Majors and as a Model for Accelerating Departmental Curriculum Change.
A. Dasgupta¹, K.A. Marrs¹, J. Marrs¹;
¹office of vice chancellor for research, IUPUI, Indianapolis, IN

Research based learning taking place in biology laboratories had been identified an efficient way to engage students and to teach undergraduates about scientific research. Scientists make good teachers

Sunday-10
when they can guide student learning through discovery of information rather than its direct transmission (Boyer Commission, 1998). However, it is a challenge to provide laboratory access to a large number of students owing to the intense time commitment of mentored research and limited seats available across various institutions (Olson & Riordan, 2012; Wood WB, 2009). CUREs (Course Based Undergraduate Experiences) offer a solution to this issue by incorporating authentic research experiences in a course-based format accessible to large populations of undergraduates (Auchincloss et al., 2014; Brownell & Kloer, 2015, Rodenbusch et al., 2016). In this work, we present three CURE-based outcomes. First, we highlight efforts to implement semester-long CUREs with model organisms (Zebrafish, C. elegans) to study human disease and genomics (Sarmah et al., 2016). Starting first with freshman biology labs, we are now developing CURE modules using model organisms into cell biology, genetics and microbiology labs. Second, we present a plan to develop, coordinate, and build connections between lab courses to produce a comprehensive CURE experience across the curriculum via multiple biology courses from freshmen to senior level. This will include revising existing courses with CURE based learning outcomes using the participant perception inventory as well as measuring student learning gains with robust experimental design assessments. Third, we share a blueprint for implementing departmental transformation to enhance teaching and learning via CUREs. Creating integrated CURE experiences between courses supports a departmental teaching model where both faculty and students understand the benefits of developing a “researcher mindset” in undergraduate students, where key concepts, techniques, and modules introduced in one course become the foundation for additional learning and skill development in successive courses, from freshman year through the senior capstone. This department wide effort to progressively implement CUREs carries the potential to contribute significantly to the knowledge of the educational effects of CUREs as well as provides original research findings of interest to the scientific community.

Board Number: B17
Investigating the Role of Authentic Research Experiences on Science Identity of African American women.
I.A. Ero-Tolliver¹;
¹Biological Sciences, Hampton University, Hampton, VA

The President’s Council of Advisors on Science and Technology (PCAST) calls for a million more STEM professionals by 2022 to meet growing economic and global demands in the STEM fields (PCAST, 2012). In 2012, African Americans (AAs) accounted for only 7.5 percent of all STEM undergraduate degrees and only 4.5 percent of doctoral degrees awarded in STEM (NCES, 2014). In order to meet this need and to encourage diversity in these efforts, underrepresented populations that include women and AAs must be supported in their progress toward attaining STEM degrees. Women and (AAs) students are already underrepresented, and continue to leave STEM majors. Therefore, it is important to understand factors contributing toward under-representation and also to determine what elements help to promote attainment among under-represented students in order to create a strong and diverse workforce (National Science Board, 2007; Griffith, 2010). Previous literature shows that participation in authentic research experiences has positive influence on students’ level of engagement, interest in science, and retention in STEM majors and careers (Elaine, 2004; Eagen, 2013, Lopatto, 2007;Russel, 2007). Therefore, we have introduced undergraduate biology AAs female students to authentic research experiences in matrix biology. Their research involves investigating the role of the animal heme-peroxidase, Peroxidasin, in the cross linking of collagen IV molecules within the basement membranes. The goal of our research study is to identify factors within exposure to authentic, research experiences
that influence the career decision-making of AA women in the sciences. We will investigate the intersectionality of these factors between institutional cultures of predominantly white institutions (PWIs) and historically black colleges and universities (HBCUs).

**Student Retention using a Forensic Science Based Approach.**  
C.A. Jones¹;  
¹Biology, Lane College, Jackson, TN

Lane College is a historically black college committed to educating underserved minority students. My goal is to give students a diverse teaching and research experience that includes implementing course-embedded undergraduate research to aid the students in understanding the scientific process and incorporating a major active learning/inquiry based learning component and improve retention by engaging students through forensic sciences. Through the popularity of television shows like The First 48, CSI, NCIS, and Cold Case Files the study of forensic science has flourished and given teachers a method to teach biology, chemistry, and physics. To implement forensic science in General Biology I in the Spring 2018 semester first students will study and determine the items that need to be analyzed from a mock crime scene the first week of laboratory. Each additional week the students will participate in microscopic hair analysis, comparison of animal and human hair, fabric analysis, soil analysis, synthetic blood tests, and DNA fingerprinting. Secondly, the students will have active learning/inquiry based learning exercises in class with a forensic science focus. My objective is that in this environment it will foster the students to ask questions, research background information, design experiments, gather and analyze the data obtained leading them to understand the method of scientific discovery. Hopefully through this process the students will learn to collaborate and build their critical thinking skills while becoming self-learners. I will develop an assessment strategy and rubric to evaluate student learning outcomes that will include testing of hypotheses, recording observation in a laboratory notebook, and communication of results through written reports and oral presentations.

**A Peer-Led Team Learning Strategy for Course-based Undergraduate Research in General Biology.**  
M. Van Stry¹, U. Ugwu¹, K. Samuels¹, A. Gayle¹, T. Gladney¹, J. Smith-Levi¹, I. Tasie¹, D. Sklensky¹;  
¹Biology, Lane College, Jackson, TN

Lane College is a historically black college with a commitment to educating underserved minority students. Our overall goal for this project is to improve student retention in STEM through student-centered activities within our first year foundational courses. These approaches include course-based undergraduate research experiences (CURE) within the General Biology II laboratory course. The instructors who teach this course are developing a CURE project based on their research interests, including environmental microbiology and plant genomics. For our model, we are assigning a more experienced student to assist the instructor and serve as a peer mentor for students enrolled in each section of the course. During the Spring 2017 semester, we began training our first cohort of peer mentors through the traditional apprenticeship research model. Six students majoring in biology worked on research projects either in environmental microbiology or genomics. These students assisted with the development of protocols and obtained baseline data for the CUREs to be implemented in the Fall.
2017 semester. For our environmental microbiology project, each student cultured bacteria from the Lane College campus, performed gram staining, and completed initial antibiotic resistance screens. They isolated three different bacteria strains that are resistant to penicillin, ampicillin, and amoxicillin. These strains included a gram-negative coccius, a gram-negative bacillus, and a gram-positive bacillus. In addition, the students optimized the amplification of the 16s rDNA gene and the beta-lactamase TEM1 gene from Escherichia coli transformed with the pUC19 plasmid using polymerase chain reaction (PCR). For our plant genomics project, our students will amplify and sequence the GAPC gene from Tennessee native plants, as well as the model organisms Arabidopsis thaliana and Ceratopteris richardii. We are currently developing assessment strategies and rubrics to evaluate student learning outcomes of the process of science, such as development and testing of hypotheses, recording observations within a laboratory notebook, and communication of results through oral presentations and written reports. We plan to fully implement these CURE laboratory exercises in General Biology II laboratory courses during the 2017-2018 academic year.

Assessment of Mapping the Brain, a research and neurotechnology based approach for the modern neuroscience classroom.
S.D. Robertson1, Z.A. Johnson1, N.R. Sciolino2, N.W. Plummer1, P. Jensen2;
1Biotechnology Program, Department of Molecular Biomedical Sciences, North Carolina State University, Raleigh, NC, 2Neurobiology Laboratory, National Institute of Environmental Health Sciences, Research Triangle Park, NC

Neuroscience research is changing at an incredible pace due to technological innovation and recent national and global initiatives such as the BRAIN initiative. The BRAIN initiative, launched by the White House in 2013, rivals the Human Genome Project in scale and is propelling the field forward through the development of novel neurotechnologies. This transformation of modern neuroscience requires that we reflect on our current approach to neuroscience education, identify best practices, and consider new strategies in the classroom. Given the wealth of data supporting the value of course-based research experiences for students, we developed and assessed a neurotechnology- and inquiry-based course: Mapping the Brain. The goal of the course is to immerse undergraduate and graduate students in research and to explore emerging technologies in neuroscience. In the laboratory portion of the course, students pursue a hypothesis-driven, collaborative National Institutes of Health research project. Using chemogenetic technology (Designer Receptors Exclusively Activated by Designer Drugs-DREADDs) and a recombinase-based intersectional genetic strategy, students map norepinephrine neurons and their projections, and explore the effects of activating these neurons in vivo. In lecture, students compare traditional and cutting-edge neuroscience methodology, analyze primary literature, design hypothesis-based experiments, and discuss technological limitations of studying the brain. We evaluated this course over two consecutive years in the Biotechnology Program at North Carolina State University, assessing achievement of student learning outcomes and knowledge of Society for Neuroscience’s (SfN) core concepts and essential principals of neuroscience. Using analysis of student assignments and pre/post content- and perception-based course surveys, we found student’s attained the course-learning outcomes. Next we assessed whether the course improved student primary literature analysis and neurotechnology assessment. Our analysis revealed the course increased student confidence in their ability to analyze primary research articles and methodologies. Students also report greater focus on data while reading articles post course. In summary, through the integration of authentic research and a neurotechnology focus, Mapping the Brain provides a unique model for an introductory
neuroscience course. Students finish the course with new technical and intellectual skills along with knowledge of SfN’s core concepts and essential principles of neuroscience. We hope that Mapping the Brain and similarly designed courses, which actively engage students in the scientific process and cutting edge research, will inspire a new cohort of innovators in the field of neuroscience.

Integrating Cell Biology Concepts: Comparing Learning Gains And Self-Efficacy In Live And Virtual Undergraduate Lab Experiences.
L. Goudsouzian1, P. Riola2, K. Ruggles2, P. Gupta2, M.A. Mondoux2;
1Natural Science, DeSales University, Center Valley, PA, 2Mathematics and Computer Science, DeSales University, Center Valley, PA, 3Biology, College of the Holy Cross, Worcester, MA

Multiple pedagogical approaches, such as experimental experiences or computer-based activities, have been shown to increase student learning and engagement. We have developed a laboratory module that includes both a traditional “live” experimental component and a student-designed “virtual” computer simulation component. This laboratory employs the mating pathway of the model yeast Saccharomyces cerevisiae to demonstrate four fundamental cell biology concepts: cell signaling, cytoskeleton, cell cycle, and cell cycle checkpoints.

In the live laboratory, students add mating pheromone to yeast cultures, then measure the rate of cell division and changes in morphology characteristic of the S. cerevisiae mating response. The “virtual” complement to this laboratory was designed using the principles of Design Thinking in collaboration with an undergraduate Computer Science course. The students generated two computer simulations which can support the live laboratory or provide a virtual laboratory experience.

We assessed the live and virtual laboratories at two undergraduate institutions by measuring student learning gains for three learning objectives: applying fundamental cell biology content, developing laboratory skills, and predicting novel experimental outcomes. Students who completed the live lab and the simulation, or the simulation alone, demonstrated gains across all three objectives, with greater gains for students who completed the live lab. Students who performed neither the live nor virtual lab had no significant learning gains. In a student attitudinal survey, students reported positive perceptions of their learning gains, engagement, and self-efficacy after performing the live and virtual labs.

Our data demonstrate that students at both campuses achieved learning gains in key cell biology topics and acquired an improved sense of self-efficacy as a result of performing this laboratory. We believe that the successful implementation of this laboratory at two institutions of varying selectivity indicates that this exercise has a broad appeal for a wide variety of students. The virtual laboratory simulation provides an opportunity for students not enrolled in a laboratory course to achieve some of the learning gains observed with the live laboratory; however, our data underscore the value of a hands-on experimental experience.

Board Number: B22
Fine-tuning summer research programs to increase underrepresented students’ scientific identity.
M. Ghee¹, M. Keels², C.N. Spence³, E. Baker⁴, E.B. Evans¹, C. Poston¹;
¹The Leadership Alliance, Brown University, Providence, RI, ²Department of Comparative Human Development, University of Chicago, Chicago, IL, ³Department of Sociology, Spelman College, Atlanta, GA, ⁴Meyerhoff Scholarship Program, University of Maryland, Baltimore County, Baltimore, MD

The Leadership Alliance, a consortium of leading PhD-granting and minority-serving institutions (MSIs), leverages partnerships to place underrepresented (UR) students from MSI and non-MSI institutions in competitive research environments through its national Summer Research Early Identification Program (SR-EIP). Here, we sought to identify components of this summer program that increased students’ awareness of and commitment to research careers and enhanced research knowledge and skills. Using longitudinal pre/post data collected from student surveys, we applied social cognitive career theory as a conceptual framework to examine how research engagement, skill development, and mentorship aspects of this program affect students’ pursuit of research careers. Self-reported knowledge of research skills, time engaged in research activity, and students’ understanding of and attitudes toward pursuing graduate study were measured in relation to the classification of students’ home undergraduate institution, level of students’ pre-existing research experience, and demographic factors. All research skills knowledge items evidenced significant positive post-program change. The highest degree of mean rating increase change included bibliographic software (49.8%), statistics software (30.2%), and approaches to quantitative data analysis (26.7%). Pre-survey respondents were most likely to agree that they understood the careers available in their discipline (72.9%), and least likely to agree that they had an understanding of graduate school life (60.4%) or the graduate school application process (62.0%). The majority of post-survey respondents (96.0%) agreed that they understood the graduate school application process, understood graduate school life (91.8%), and understood the careers available in their discipline (90.4%). Regression analyses show that time spent on research preparation, learning activities, professional development, data gathering, and analysis was positively associated with significant gains on career pathway variables and the research skills index. Mentor quality was positively associated with significant gains in research skills and knowledge of graduate school life index. While student demographics and institutional characteristics were not significantly associated with pre-program measures, modest significant differences were observed post-program with regard to research skill development and academic career planning. Our results provide evidence of specific programmatic components that positively impact students’ research skills and career planning. The acquisition of research skills and increased awareness of graduate programs and careers contribute to the ongoing formation of motivational behaviors that shape subsequent career pursuits.

Board Number: B23
A short authentic research module increases complexity in student thinking about research without sacrificing student experience or content knowledge.
L.L. Dahlberg1, S.R. Lee1, B. Wiggins2, H. Jordt3, L. Lily2, D.S. Leaf4;
1Biology, Western Washington University, Bellingham , WA, 2Biology, University of Washington, Seattle, WA

The AAAS Vision and Change (2011) for undergraduate biology students identified the Ability to Apply the Process of Science as a core competency. We embedded an authentic research module in an existing introductory Cell and Molecular Biology course to provide practice in experimental design, experimentation, and analysis to a large number of students. The three-week laboratory module addresses the fundamental cell biological question of how cell cycle is regulated using the model organism Tetrahymena thermophila. The protein CDT1 is required for licensing origins of replication, and its mutation has clear human health impacts. Students used a strain of Tetrahymena that can overexpress the protein CDT1 to determine what role CDT1 plays might play in Tetrahymena. Our research module runs during part of an academic quarter, and students draw on their existing knowledge from the classroom and from previous laboratory sessions to engage with the process of science during the relatively short timeframe. In-class and take-home activities prompt students to actively reflect upon the information they are using to design their experiments and to draw their conclusions. This short authentic research module serves as a model for introducing authentic research into large, diverse, introductory courses.

We used pre-post surveys, task-based questions, and focus group discussions to assess how the authentic research module affected the student experience. Pre-post survey responses of students who did and did not participate in the authentic research module suggest that participation did not change student opinions of their engagement with the process of science, and in particular with problem solving in Biology. However, students who participated in the authentic research module gave more, and more sophisticated, responses to a task-based question that required practice in self-direction and self-reflection. Focus group interviews with students at a variety stages of their undergraduate Biology education support our assertion that short authentic research module succeeded in providing choice to students, which helped them feel engaged and invested in the research experience. These findings will help inform the how we study students’ engagement with the process of science, and how best to enhance course-based research at the undergraduate level.

Design-based and Interdisciplinary Strategies for Learning in Laboratory Sciences.
J. Fornaglio1, Z. Sheffler1, D. Hull2, A. Bobak3;
1Biology, Seton Hill University, Greensburg, PA, 2Greensburg Central Catholic High School, Greensburg, PA

We developed a model curriculum for interdisciplinary STEM teaching and learning utilizing a collaborative and inquiry-based approach to Cell Biology laboratory. The pedagogical goals were to develop, adapt, and refine design-based inquiry approaches to laboratory experiences using real-world student-developed research studies; incorporate learning technologies -- such as interactive and video tutorials -- into the curriculum; and assess the impact of this approach on student understanding of scientific concepts and processes and attitudes toward science and research. To most effectively model
active learning and the collaborative nature of science, students in Cell Biology worked alongside students in Biochemistry and Mathematics courses throughout the semester. The differences between pre- and post-Participant Perception Indicator (PPI) survey responses in each question in the categories understanding, skills, attitudes, integration of learning, and meeting learning objectives (relative to the baseline semester) indicated that, when paired with like students, high-performing students are more likely to report improvements in the areas of skills, integration of learning, meeting learning objectives, and understanding, while mid-level performing students report significant improvements in the categories of understanding, attitudes, and meeting learning objectives. Low-level performing students report regressions in these areas. Performance task quiz data reveal improvements in critical thinking through our pedagogical approach to teaching laboratory sciences.

Inquiry-based cell culture course improves student conceptual and practical understanding of biomedical research.

A. Krufta¹, M. Dittmar¹, G.J. Eaton¹, C. Iftode²;
¹Department of Biological Sciences, Rowan University, Glassboro, NJ, ²Department of Molecular and Cellular Biosciences, Rowan University, Glassboro, NJ

In order to develop strong scientific thinking abilities in the context of cell biology experimentation, we have developed a laboratory-intensive undergraduate cell culture course for acquisition of a broad technical skill set along with inquiry skills necessary to conduct scientific research. Our “Fundamentals in Cell Culture Technology” course engages students in hands-on projects that require them to develop hypotheses, design and conduct experiments, analyze their results, and present their conclusions to their peers. Proliferation, viability, and differentiation modules promote the gaining of cell culture skills including aseptic technique, mammalian cell line maintenance, cryopreservation, condition optimization, and critical thinking in the scientific method. We hypothesized that the course would produce technically competent students who are confident in conceptual knowledge, capable of scientific inquiry, and interested in pursuing areas of biomedical research. To assess the students’ growth in these key areas, we administered pre- and post-course self-efficacy and career aspirations surveys and conducted the Experimental Design Ability Test (EDAT) for each of the three semesters that the course has been offered. Our analyses show a positive effect on the students’ confidence in their ability to design and conduct experiments and to present their conclusions from those experiments. Students indicate a better understanding of biomedical research and a slight increase in their interest in biomedical research above the already high level observed at the beginning of the course. Post-course evaluation of experimental design ability did not demonstrate significant improvement. Our future work includes assessment of experimental design ability in the specific context of cell biology as well as the development and assessment of new modules to teach flow cytometry, gene expression analysis, and primary explant culture.

Implementation and assessment of an intensive 7 week summer CURE designed for incoming freshmen.
G. Stein1, H. Thieringer2;
1McGraw Center for Teaching and Learning, Princeton University, Princeton, NJ, 2Molecular Biology, Princeton University, Princeton, NJ

MOL152 is an intensive summer course-based undergraduate research experience (CURE) that is part of the Freshman Scholars Institute (FSI) program at Princeton University. The program allows first generation and low-income students an opportunity to take two courses during the summer preceding their freshman year. This CURE was designed with the goals to increase the conceptual knowledge and technical and analytic skills of the students, while also promoting a sense of belonging, identity and self-efficacy in research. The specific research project was designed to allow for a parallel project structure which gives the students project ownership. Working in the C. elegans model system, the roles of serotonin receptors in modulating behaviors such as pharyngeal pumping, egg laying and locomotion were investigated. Student pairs were assigned a specific serotonin receptor gene target and used feeding RNAi to knockdown expression of their target gene in either neuron cells or all tissues except neurons through the use of tissue specific RNAi sensitive strains. The curriculum is designed so that students have the chance to critically evaluate experimental data, formulate hypotheses, and design follow up experiments. Integrated into the course are opportunities for guided reading of primary literature related to the project. Students write lab reports and deliver oral presentations to report their results and the course culminates with the publication of a Princeton version of the Worm Breeder’s Gazette. Pre and post surveys were implemented to the measure the impact of the CURE on student concept knowledge, skills, attitudes and mindset. Analysis of the survey results indicates that the course has enhanced student content knowledge and writing and data analysis skills based on their own assessment of their learning. The course also resulted in changes in student attitudes and mindsets. The course has had a positive impact on student learning and identity as a STEM major. Further analysis of the survey data will help determine the ability of this course to impact the success and satisfaction of first generation and low-income students interested in pursuing STEM majors.

Board Number: B27
An Inquiry-Driven Optical Tweezer Experiment for Upper Division Physics Lab.
J.Y. Sheung1, D.L. Nall2, P.R. Selvin2;
1Physics and Astronomy, Vassar College, Poughkeepsie, NY, 2Physics, University of Illinois, Urbana, IL

Medical physics and biophysics graduate programs have become attractive next steps for physics undergraduates. To better serve such students, an inquiry-driven optical tweezer experiment was developed as part of an upper division biophysics lab course offered by the physics department at the University of Illinois. We supplemented the inexpensive and well-supported kit from Thorlabs with an E. Coli mutant strain (KAF95) acquired from Howard Berg at Harvard University. The eight hour lab was taught in two four-hour parts. In the first, students learned basics on the biology, capabilities of the instrument, and analysis techniques. During the second, students came up with and conducted their own experiments in groups of four. While the lack of experiment time meant none of the datasets were large enough to draw clear conclusions, students received points on clarity of their hypotheses and
effective use of the instrument. Post-lab surveys were extremely positive: nearly all students indicated a preference for more labs in the course to be taught in a similar style.

*A bioinformatics curriculum that teaches gene structure is associated with learning gains for beginning college students.*

L.V. Paliulis¹, M.M. Laakso², M.S. Santisteban³, S. Silver Key¹, R.C. Burgess⁵, J.S. Sanford⁶, A. Rosenwald⁷, C.W. Bazinet⁸, W. Leung⁹, S.C. Elgin⁹;

¹Biology Department, Bucknell University, Lewisburg, PA, ²Department of Biology, Eastern University, St. Davids, PA, ³Biology Department, University of North Carolina at Pembroke, Pembroke, NC, ⁴Biology Department, North Carolina Central University, Durham, NC, ⁵Department of Biological Sciences, Stevenson University, Fine School of the Sciences, Stevenson, MD, ⁶Department of Biological Allied Health Sciences, Ohio Northern University, Ada, OH, ⁷Biology Department, Georgetown University, Washington, DC, ⁸Department of Biological Sciences, St. John's University, Queens, NY, ⁹Department of Biology, Washington University, St. Louis, MO

The related features of eukaryotic gene structure, transcription, alternative splicing, reading frames, and translation are complex molecular biology concepts that are often taught to beginning biology college students using a lecture format in a traditional classroom setting. Computer-based bioinformatics tools, such as a genome browser, can be used in an active learning strategy to provide a hands-on approach for students to visualize and understand these challenging concepts. One of the major barriers to using such an approach has been the lack of available curriculum for faculty who are not experts in bioinformatics. We have created a series of six teaching modules that make use of a UCSC Genome Browser mirror maintained by the Genomics Education Partnership (GEP) to illustrate these biological concepts. The genome browser allows one to see the “big picture” for multi-exon genes, provides translation to exhibit the alternative reading frames, and lets the student zoom in to find specific signals such as the start codon. These teaching modules and associated videos are available through the “Introducing genes” section of the GEP website (http://gep.wustl.edu). The modules have been used in a variety of classroom settings at diverse institutions, and have been shown to be associated with learning gains for this molecular biology content, as well as helping students develop familiarity with a genome browser, a basic bioinformatics tool. The knowledge gains achieved through the use of this introductory curriculum provide students with the skills needed to participate in classroom-based research experiences in genomics that build on careful gene annotation. The GEP is collaborating with Galaxy to create G-OnRamp, a tool that creates a genome browser (in UCSC or JBrowse formats) for newly sequenced genomes, thereby allowing students to participate in a variety of genomics research projects. [The GEP is currently supported by NSF IUSE grant #1431407, while development of G-OnRamp is support by NIH grant R25 GM119157, both to SCRE.]

Bioinformatics Core Competencies for Undergraduate Life Scientists.
1Life Sciences, Arizona State University, Tempe, AZ, 2Biology, San Diego State University, San Diego, CA, 3Biological Sciences, St. Edwards University, Austin, TX, 4Biology, College of Wooster, Wooster, OH, 5Biology, Georgetown University, Washington, DC, 6Bioinformatics Program, St. Vincent College, Latrobe, PA, 7Biology, University of Nebraska-Omaha, Omaha, NE, 8Microbiology and Cell Science, University of Florida, Gainesville, FL, 9School of Interdisciplinary Informatics, University of Nebraska-Omaha, Omaha, NE

Bioinformatics is becoming increasingly central to research in the life sciences. Despite its increasing importance, however, there is a general lack of integration of bioinformatics skills and knowledge into undergraduate biology education. This curricular gap prevents biology students from harnessing the full potential of their education and limits their career opportunities. In order to advance the integration of bioinformatics, a framework of evidence-based core bioinformatics competencies is needed. To that end, the Network for Integration of Bioinformatics in Life Sciences Education (NIBLSE; “nibbles”), an NSF Research Coordination Network for Undergraduate Biology Education, recently conducted a survey about the teaching of bioinformatics to undergraduates. The survey was targeted to life sciences faculty in the United States (n = 1,260). Results indicate widespread agreement that bioinformatics knowledge and skills are critical for undergraduate life scientists and considerable agreement about what specific bioinformatics skills are necessary. Perceptions of the importance of some skills varied with the respondent’s degree of training, time since degree earned, and/or the Carnegie classification of the respondent’s institution. To assess which skills are currently being covered in curricula nationwide, we analyzed syllabi submitted by survey respondents. Finally, we used the survey results, the analysis of the syllabi, and our collective expertise and experience in both teaching bioinformatics and applying it to research to develop a set of bioinformatics core competencies for undergraduate life sciences students. NIBLSE is supported by a Research Coordination Network for Undergraduate Biology Education grant from the National Science Foundation (DBI 1539900).

Application of DNA Sequence Analysis Software in Undergraduate Biology Curriculum.
L. Kee1, J. Pieczynski2;
1Biology, Stetson University, Deland, FL, 2Biology, Rollins College, Winter Park, FL

Providing inquiry-based tools to students as they actively learn to link concepts in molecular biology and genetics is an important way to help students develop critical thinking and analyses skills. The challenge in undergraduate curriculum at a primarily undergraduate research institute, where resources are limited, is developing easily accessible tools that are both authentic and engaging for students, all while being applicable to both lecture and laboratory components of the course. Here, we describe how open source DNA sequence analysis software, such as A Plasmid Editor (ApE), which is used by many Research-1 labs, is integrated into Genetics and Molecular Biology courses at two different PUs. The learning objectives for using molecular biology software as an integrated instructional tool is for students to become competent in the functionality and applications of such tools, and then use these tools when applying genetic and molecular biology principles in research-based setting. To achieve
these learning objectives, we have developed exercises where students use open source software in both class and lab work, in both guided instruction and inquiry-based experiences. During the instruction phase students are taught to use this software in lab, using these tools to build plasmid maps and annotate features, determine restriction enzyme sites, and DNA fragment sizes, while concurrently performing the corresponding guided experiment. Once familiarity is gained, students then apply these skills and tools to inquiry-based experiments including the analysis of single nucleotide polymorphisms in alleles for a gene isolated from their own DNA and or generating homology directed repair templates for CRISPR-based gene edits. In class, these software platforms become an active instructional tool where students use molecular biology software as a complement to traditional didactic instruction. Using such software allows for more inquiry-based assessment such as analysis of DNA sequencing data, identification of mutations, and determining how the molecular lesion affects the reading frame and translation. Pre-and post-assessment of utilization of the application of open source molecular biology software in coursework reveals the effectiveness of this approach in promoting higher order thinking in undergraduate biology students and confidence in ability to understand experimental design and analyze data.

Incubators: A community based model for improving the usability of bioinformatics learning resources.

1Biology, College of Wooster, Wooster, OH, 2Biological Sciences, University of Pittsburgh, Pittsburgh, PA, 3Biology Biotechnology, Worcester Polytechnic Institute, Worcester, MA, 4Bioinformatics Program, Saint Vincent College, Latrobe, PA, 5Biology Teaching and Learning, University of Minnesota, St. Paul, MN, 6Biology, Georgetown University, Washington, DC, 7Biology, San Diego State University, San Diego, CA, 8Microbiology and Cell Science, University of Florida, Gainesville, FL, 9Interdisciplinary Informatics, University of Nebraska, Omaha, NE, 10Biology, University of Nebraska, Omaha, NE

The Network for Integrating Bioinformatics into Life Sciences Education (NIBLSE) is an NSF-funded Research Coordination Network that aims to establish bioinformatics as an essential component of undergraduate life sciences education. As part of that effort, NIBLSE is working to make existing bioinformatics learning resources more accessible to non-specialists and to increase their use across undergraduate biology courses. To this end, NIBLSE has partnered with the Quantitative Undergraduate Biology Education and Synthesis (QUBES) project and CourseSource to develop and implement a novel model for supporting the refinement, publication, and dissemination of high quality bioinformatics teaching resources. NIBLSE Incubators are small, short-lived, online communities that work with an existing learning resource to (1) improve its usability across diverse life sciences classrooms, (2) introduce and teach important bioinformatics learning outcomes, and (3) move the learning resource toward publication and broader dissemination. Incubator pilots have highlighted the opportunities and challenges of this approach and led to the refinement of the development process. NIBLSE and QUBES are supported by grants from the National Science Foundation (DBI 1539900 and DUE 1446269, respectively). Any opinions, findings, and conclusions or recommendations expressed in this material are those of the author(s) and do not necessarily reflect the views of the National Science Foundation.

New NIGMS Funding Opportunities: Collaborative Program Grants for Multidisciplinary Teams (RM1); Maximizing Investigators' Research Award (MIRA) (R35); Technology Development (R21, R01).

P.J. Sammak1, K. Willis1, S. Gregurick1;
1National Institute of General Medical Sciences, National Institutes of Health, Bethesda, MD

The National Institute of General Medical Sciences (NIGMS) has initiated several research grant funding announcements Collaborative Program Grant for Multidisciplinary Teams (RM1). Contact: Paul Sammak The Collaborative Program Grant (PAR-17-340), has replaced the Program Project Grant (P01). The first receipt date is January 25th, 2018. It is intended to support complex and challenging research within the NIGMS mission that require multidisciplinary teams from 3 to 6 investigators and between $700,000 and $1,500,000 direct costs. Research questions should need the integrated efforts from different areas of intellectual and technical expertise. Projects should have a unified scientific goal that will produce convergent, lasting scientific benefits or produce major advances in their fields. The description of the research program is limited to 30 pages. A separate 6-page section on team management is required. Leadership structures should be designed to match the research program goals and to enhance Interdisciplinary team performance. An additional $250,000 for an early stage investigator pilot program may optionally be included. Maximizing Investigators' Research Award (MIRA) (R35). Contact Kris Willis The MIRA (PAR-17-094, and for Early Stage Investigators, PAR-17-190) provides support for the NIGMS mission-relevant research and provides support for the research program rather than a project with defined specific aims. The goal of the MIRA program is to increase the efficiency of NIGMS funding by providing investigators with greater stability and flexibility, thereby enhancing scientific productivity and the chances for important breakthroughs. Another aim of the program is to help distribute funding more widely among the nation’s highly talented and promising investigators. Technology Development without Biomedical Hypotheses. Contact Paul Sammak Projects should be focused on technical questions that aim to develop and validate novel research tool including instruments, devices, algorithms and software, chemical reagents and processes for modified molecule production, and the manipulation of biological systems. The eventual biomedical significance of the technology should be apparent, but the work plan must not include testing of unknown biological questions. The R21(PAR-17-046: Exploratory Research for Technology Development) is a high-risk feasibility test of a concept that has not been evaluated with preliminary data. The R01 (PAR-17-045: Focused Technology Research and Development) is for later stage project that are feasible but where technological obstacles remain.

After the infection, viruses plunder the system of the replication, transcription and translation, and grow proliferously in host cells. Finally, host cells were burst by viruses were grown in cells. Therefore, some viruses are cause of lethal diseases. Knowledge of the 3D structure and distribution of viruses in cells play very important role of elucidation of mechanism of these diseases and developments of their therapies. However, the size of viruses is too small to observe by the optical microscopy. Scanning electron microscopy (SEM) can observe only surface structure, and Transmission electron microscopy (TEM) can observe only thin 2D area. Thus, little is known about the 3D structure and distribution of viruses in cells. Recently, some 3D imaging methods with SEM were developed, and some study reported that these methods were applied to biological sample. In this study, we analyzed the 3D structure and distribution of phages (T4, λ, Φ174) in E.coli with these new SEM methods. We used four methods in this study, and compared these methods. All methods required for samples that were stained by heavy metals and embedded by resin. First method is Serial block-face SEM (SBF-SEM) method. This method uses the SEM that has ultra-microtome in the specimen chamber; samples are able to slice in specimen chamber. This method repeats to slice the sample and observe the new surface. Finally, we can obtain 3D image to stack serial slice images. Second method is FIB-SEM. This method uses the instrument that combine with focus ion beam (FIB) and SEM. This method ablates the sample surface by FIB, and new surface is observed too by the SEM. In this result, we can obtain serial image series, and reconstruct the 3D image. Third method is array tomography. In this method, we prepare the serial section ribbons by ultra-microtome, and these ribbons are mounted on the conductive base like a silicon wafer. Finally, we obtain image series in order, and stack these images on to one another. Forth method is TEM tomography. In this method, we obtain the serial tilt projection image by TEM, and 3D image was calculated by Computerized-tomography. In these results, SBF-SEM, FIB-SEM, and array tomography can observe the 3D morphology of infected E.coli, and 3D distribution of
phages in cells. On the other hand, TEM tomography is required to observe the 3D morphology of phages in cells.

Unlocking the distribution of fluorescent-labeled albumin in zebrafish through correlative microscopy.
D. Cheng¹, M. Morsch², G. Shami¹, R. Chung², F. Braet¹,³;
¹School of Medical Sciences, The University of Sydney, Sydney, Australia, ²Faculty of Medicine and Health Sciences, Macquarie University, Sydney, Australia, ³Sydney Microscopy Microanalysis, The University of Sydney, Sydney, Australia

In the past decades, the zebrafish model has become increasingly popular in many research disciplines for their unique genetic and functional resemblances with that of humans. The animal small size, translucent nature and ease of manipulation and observation as a whole, make them an attractive experimental model. However, only a few publications related to drug delivery into the digestive system of zebrafish, and particularly the liver, have been reported, resulting in limited information on the ultrastructural architecture and drug behavior/pathways. The efficacy of a therapeutic drug relies on the accumulation of the drug at the site of action at therapeutic levels. Hence, it is important to understand the drug behavior, rate of uptake and site of accumulation of prospective drugs to better tailor drug targeting studies and set a limit of confidence in the use of the zebrafish as a model for drug delivery studies. The study presented herein reports on the widely-used protein-based drug carrier, albumin. Fluorescent-tagged albumin was injected into the liver of 12 days post-fertilisation zebrafish. At this age, previous studies have shown that the zebrafish presented a mature digestive system, resembling closely in structure and function to that of human. By applying the concept of correlative microscopy, functional and structural information were provided on the distribution of albumin in the zebrafish larvae liver. Live confocal imaging was used to follow fluorescent-labelled albumin. At different time points, the zebrafish were fixed and processed for electron microscopy using a protocol whereby the fluorescence is retained. Sections across and throughout the liver were then produced and imaged using both fluorescence-and electron microscopy. Correlation of the acquired data provided insights on the site of accumulation, being the liver sinusoidal endothelial cells, the space of Disse and the hepatocytes as well as respective rates of accumulation. Albumin was found to be taken up within the liver sinusoidal endothelial cells as early as 5 min after injection. After 10 min, the accumulation rate stagnated and further incubation up to 15 min indicated post-uptake processing taking place at the cellular level. The workflow established herein allowed to demonstrate the albumin pathway in zebrafish liver which is in line with that in rodents and human. Not only can this experiment form the basis for future albumin-based drug-complexes experiments, it also validates the zebrafish as a suitable animal model for drug delivery studies.

Development of a new type of low-voltage cryo-electron microscope enabling simultaneous imaging of STEM and SEM in biological samples.
J. Usukura1, A. Narita1, T. Matsumoto1, E. Usukura1, T. Sunaoshi2, Y. Tamba1, J. Azuma2, Y. Nagakubo2, T. Mlzu2, M. Osumi3, K. Nimura2, R. Tamochi2, Y. Ose2;
1Graduate School of Science, Nagoya University, Nagoya, Japan, 2Hitachi High-Technologies Corporation, Tokyo, Japan, 3Japan Women's University, Tokyo, Japan

We developed a new type of cryo-electron microscope by attaching a newly developed cryo-transfer holder and anti-contamination trap to a scanning electron microscope (SEM: SU9000) equipped with a cold field emission gun (FEG: Acceleration voltage of 30 kV). The new cryo-transfer holder and anti-contamination trap were cooled with liquid nitrogen slash, resulting in ultimate temperatures of −190 °C and −210 °C, respectively. The SEM also works as a scanning transmission electron microscope (STEM) because it is equipped with a detector that catches transmitted electrons. For this reason, simultaneous measurement of a transmission electron image and the secondary electron image is possible. In STEM, an image is formed as a bit map of an electron, and is therefore not affected by contrast transfer function. Moreover, low acceleration voltage acts to increase contrast. When enough contrast is created, the images are produced without defocus, meaning that the original resolution of the microscope is maintained. These characteristics in a low-acceleration-voltage STEM (LVSTEM) are very useful for single particle analysis. Practically, when compared with a conventional 100-kV TEM, LVSTEM showed more detailed structures in single particle analysis of actin filaments. In the case of cells, cells cultured on carbon-coated grids were unroofed by weak sonication and used as samples. Because some soluble components were eluted upon unroofing, the spatial architecture of the cytoskeletal actin filaments and microtubules were observed at extremely high contrast. Many ribosomes and an endoplasmic reticulum were found in the cytoplasm despite the cells being unroofed.

Graphene-oxide as a substrate for high-resolution single-particle cryo-EM.
E. Palovcak1, F. Wang1, D. Bulkley1, S. Zheng1,2, D.A. Agard1,2, Y. Cheng1,2;
1Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA, 2Howard Hughes Medical Institute, University of California San Francisco, San Francisco, CA

Specimen preparation is a substantial remaining challenge for single-particle cryo-EM. While elegant, the traditional blot-and-plunge procedure for creating thin, free-standing films of vitrified buffer is actually quite harsh to macromolecules and requires orders of magnitude more sample than theoretically necessary. Adsorbing the specimen to a substrate film on the grid before vitrification can concentrate and protect fragile macromolecular complexes. Monolayer sheets of graphene oxide (GO) are a promising substrate, but we found that available methods for coating grids with GO were hard to reproduce.

In this study, we developed a simple and robust method for coating EM grids with thin films of GO and then evaluated the suitability of such GO grids for high-resolution single-particle cryo-EM. We report that GO grids produced by a simple Langmuir-Blodgett technique can be used for high-resolution single-particle cryo-EM and that background images of the GO lattice may serve as high-resolution fiducial markers for image quality assessment and motion correction.

An adaptive optical, structured illumination, lattice light sheet microscope for isotropic 100 nm resolution imaging of living specimens.

W.R. Legant1, E. Betzig1;  
1Howard Hughes Medical Institute, Ashburn, VA

I will discuss recent efforts to push both spatial resolution and imaging depth in light sheet microscopy. We have designed and constructed a new 5-objective system to obtain a 2X isotropic resolution improvement via structured illumination through a triad of excitation lenses mounted at 120 degree angles, increase imaging depth via adaptive optics and direct wavefront sensing, and double the collection efficiency and triple the axial resolution by combining lattice light sheet excitation with widefield interferometric imaging through opposed detection objectives. Axially structured light sheet excitation patterns fill the gaps in the optical transfer function that are associated with interferometric detection of fluorescence emission. Our ultimate goal is to perform isotropic 100 nm spatial resolution imaging in living specimens at high speed and with minimal phototoxicity.

A high resolution, tomography-compatible electron microscopic method for assessing subcellular distribution of membrane proteins.

R. Sengupta1, S. Mattoo1;  
1Biology, Purdue University, West Lafayette, IN

Localization of membrane proteins via electron microscopy (EM) at high resolution is dependent on a robust detection technology and a sample preparation method that confers superior ultrastructural preservation of membranes. Current methods for precise localization rely on chemical fixation of the sample followed by alcohol dehydration at room temperature. Such traditional methods, however, exhibit poor preservation of the membrane, induce membrane artifacts and diminish resolution. In contrast, high pressure freezing (HPF) of cells followed by heavy metal staining via freeze substitution (FS) in acetone at sub-zero temperatures offers the best possible membrane preservation, but this method has not been exploited for protein localization at subcellular resolution. Here, we report the development of a hybrid method that combines high pressure freezing with an existing peroxide-based detection technique typically used with chemical fixation methods. As proof of concept, we assessed the localization of a fusion protein consisting of the N-terminus of HMG CO-A fused with a peroxidase tag that faces the cytosol. We exploited the induction of OSERs (organized smooth endoplasmic reticulum) in cells by the over-expression of this N-terminal fragment as a metric for specific staining and membrane preservation. We next extended our studies to assess the localization of the sole human Fic (filament induced by cyclic AMP) protein, HYPE/FicD. HYPE resides in the ER lumen, but global proteomic studies have identified cytosolic proteins that interact with HYPE, suggesting alternate cellular locations for HYPE. Using our hybrid methodology, we provide strong evidence that HYPE is compartmentalized within various subdomains of the ER only. We further demonstrate via serial sectioning that our technique enables the localization of membrane proteins through a large volume of the cell. Our work, thus, aligns well with the three-dimensional mapping of membrane proteins in large organelles using EM-tomography in a near-native cellular context.

Imaging Live Uterine Smooth Muscle Modulation.
B. Obayomi1, S.M. Peck1, D.P. Baluch1;
1School of Life Sciences, Arizona State University, Tempe, AZ

The use of immunohistochemistry or histological staining to identify localization of specific receptors and general morphology in sectioned tissue are the most widely used imaging techniques in endocrinology and reproduction. A major drawback of these methods is that physiological events, such as smooth muscle contraction, is a complex system that contains dynamic feedback mechanisms. Without observing the live tissue, the researcher would be making interpretations based on random snapshots in time. We are interested in expanding our imaging capabilities to visualize uterine smooth muscle contractions using confocal and light sheet microscopy in order to observe live tissue receptor mediated modulation. In this study, uterine tissue from GFP Lifeact mice enabled visualization of F-actin during live smooth muscle contraction. Antibodies to specific receptors, conjugated to a fluorescent probe, were co-incubated with the tissue to visualize the actual response and timing of receptor recruitment during tissue stimulation. Initial imaging was conducted using a dipping lens on a Leica SP5 confocal microscope. This technique allowed the tissue to be imaged while alive and as a complete functional unit so that contractile activity could be observed. This technique was further explored using the Leica SP8 Lightsheet system. This system utilizes TwinFlect mirrors that align on both sides of the tissue expanding the observable area to greater than 180 degrees around the uterine horn. By imaging live tissue and stimulating the tissue with various hormones, peptides and amines, we were able to observe the dynamic response of both agonist and antagonist receptor recruitment. Utilizing this whole tissue-imaging technique has proved to be very useful in understanding the modulation and feedback mechanisms in response to various biological stimuli and helps in correlating the results found using standard techniques on fixed tissues.

LITE imaging: a high numerical aperture, low photobleaching fluorescence imaging technology.
1Biology, UNC-Chapel Hill, Chapel Hill, NC, 2Chemistry, UNC-Chapel Hill, Chapel Hill, NC, 3Biomedical Engineering, North Carolina State University, Raleigh, NC, 4Biomedical Engineering, UNC-Chapel Hill, Chapel Hill, NC

The dynamics of cellular processes demand visualization with fluorescence microscopy at high spatial and temporal resolution with; however, conventional fluorescence microscopy techniques are very light-intensive and introduce unwanted photobleaching, phototoxicity, and out-of-focus fluorophore excitation. Light sheet fluorescence microscopy decreases these issues by selectively illuminating the focal plane of a detection objective using an orthogonal excitation objective.1 However, existing light sheet microscopes are physically limited in the numerical aperture (NA) of the detection objective, which decreases both the microscope’s efficiency and the native image resolution.1-4 We present a novel light sheet illumination method: Lateral Interference Tilted Excitation (LITE), in which a sheet of light is generated at the focal plane of the imaging objective without a sterically limiting illumination objective. This allows the use of practically any detection objective, including oil immersion, with no upper NA limit. Thus, LITE achieves the low photodamage of light sheet imaging while exploiting the
benefits of high spatial resolution, high efficiency, coverslip-based objectives. We demonstrate the efficacy of LITE in imaging animal, fungal, and plant model organisms over many hours at high spatiotemporal resolution. Specifically, we are now able to generate multigenerational nuclear pedigrees in Ashbya gossypii over the course of more than 7 hours of continuous imaging, allowing us to study nuclear asynchrony at high spatiotemporal resolution over long developmental times.

A new method for large-volume high-resolution intravital imaging using multiphoton microscopy identifies microenvironment-driven tumor cell phenotypes leading to metastasis. D. Entenberg1,2,3, Y. Wang1,2,3, J. Pastoriza4, M.H. Oktay1,2,3, J.S. Condeelis1,2,3;
1Department of Anatomy and Structural Biology, Einstein College of Medicine/ Montefiore Medical Center, Bronx, NY, 2Gruss-Lipper Biophotonics Center, Einstein College of Medicine/ Montefiore Medical Center, Bronx, NY, 3Integrated Imaging Program, Einstein College of Medicine/ Montefiore Medical Center, Bronx, NY, 4Department of Surgery, Einstein College of Medicine/ Montefiore Medical Center, Bronx, NY

We report, for the first time, a new approach to intravital imaging that successfully stabilizes tumors in living animals and isolates them from imaging artifacts associated with living tissue. This allows the capture, over days, of many high-magnification, sub-cellular resolution images in a mosaic pattern that maintains their spatial relationships. These images are then stitched together to produce a low-magnification, but high resolution, large volume image over time: a process we call Large-Volume, High-Resolution Intravital Imaging (LVHR-IVI). LVHR-IVI does not suffer from the magnification and spatial resolution artifacts inherent with mesoscopic and light sheet intravital imaging. LVHR-IVI is applicable to many different tissues, which includes soft tissues such as the mammary fat-pad, lymph nodes, and salivary gland which are particularly challenging as they are extremely compliant and easily transmit motion and vibrations from the animal's involuntary movements. Furthermore, using permanent imaging windows in mice in combination with LVHR-IVI extends imaging sessions from hours to multiple days over several weeks.

We have used LVHR-IVI to identify and quantitate modes of tumor cell motility, invasion and systemic dissemination in transgenic breast tumors which maintain the clinically observed histology presented by patients. High-resolution time-lapse imaging of these tumors identify the tumor microenvironment of metastasis (TMEM) - mediated transient vascular permeability events as the mechanism of tumor cell intravasation and hematogenous dissemination.

Furthermore, we used LVHR-IVI to evaluate the percent contribution of each of the proposed origins of circulating tumor cells and tumor cell clusters in vivo. Potential mechanisms of migration toward blood vessels include: 1) single cell migration; 2) streaming migration; 3) collective migration. Potential mechanisms of intravasation of blood vessels include: 1) Cell crowding of individually arriving tumor cells at sites of intravasation; 2) Collective vascular invasion by collectively migrating tumor cells; 3) Single cell intravasation followed by cluster formation in the blood.

The results indicate streaming migration resulting in cell crowding at TMEM intravasation sites are the major mechanisms associated with intravasation. Furthermore, the arrival of single tumor cells at distant sites in close temporal proximity can result in cluster formation within blood vessels there. Finally, the survival of single cells during metastatic seeding is 10-100 fold greater than previously believed. These new insights narrow the targets associated with metastatic progression and allow for better prognostic markers, treatment strategies and associated companion diagnostics.

Innovative measuring methods of optical transparency of the cleared brains by various newest tissue clearing technique.
J. Woo¹,², E. Lee³, Y. Cho¹,²;
¹The Spine and Spinal cord Institute, Department of Neurosurgery, Gangnam Severance Hospital, Yonsei University of Medicine, Seoul, South Korea, ²Brain Korea 21 PLUS Project for Medical Science, Yonsei University, Seoul, South Korea, ³College of Physicians and Surgeons, Columbia University, New York, NY

The advent of methods for achieving optical transparency in neuronal tissue, in conjunction with optical imaging techniques, has allowed for a refined, 3D visualization of structures and cellular networks in the brain with great resolution. Numerous efforts have been made to improve clearing by reducing light scattering and absorption in the tissue; however, little has been done to quantify the efficacy of clearing.

In this study, we designed a novel PACA (Punching-Assisted Clarity Analysis) assay, which quantifies levels of light attenuation in order to analyze the efficiency of tissue clearing. PACA was used to assess regional transparencies in the rat brain, as well as the efficacies of previously reported tissue-clearing techniques including PACT (PAssive Clarity Technique). Results were then confirmed by imaging luminous-light permeation. Compared to standard methods that measure refractive indices as a proxy for tissue clarity, PACA yielded results with significantly greater precision and accuracy. With its innovative approach and superiority over existing quantification methods, PACA shows great promise in future analyses of tissue transparency.

Detection of PI(3,4,5)P3 on cellular endomembranes using fluorescence correlation spectroscopy.
M. Ebner¹,², I. Yudushkin¹,²;
¹Dept. of Medical Biochemistry, Medical University of Vienna, Vienna, Austria, ²Dept. of Structural and Computational Biology, Max F. Perutz Laboratories, Vienna, Austria

Methods for the detection of cellular phosphoinositide lipids are based on using protein lipid-binding domains, antibodies or LC/MS. While the latter method is arguably the most sensitive, it cannot be used in the context of live cells, whereas the other reagents provide little quantitative information. Here, we report use of fluorescence correlation spectroscopy to monitor the concentration and dynamics of phosphoinositide lipid PI(3,4,5)P3 on cellular endomembranes.

Pleckstrin homology (PH) domain of Akt1 is widely used as a genetically encoded probe to detect accumulation of PI(3,4,5)P3 at the plasma membrane. Detection of PI(3,4,5)P3 on the endomembranes, however, is non-trivial. The surface area of endomembranes has been estimated to be as much as 200 times larger than that of the plasma membrane (Schmick et al, 2014), indicating that internal membranes occupy much of the perceived cytoplasm. Combined with the low steady-state fraction of the membrane-bound PH domain, these factors make it difficult to discriminate between the membrane-bound and cytosolic probe using conventional, diffraction-limited imaging.

As an alternative approach, we monitored the diffusive behavior of eGFP-tagged PH domain in live cells using fluorescence correlation spectroscopy with pulse-interleaved excitation (PIE-FCS). FCS allows discriminating between cytosolic and membrane-bound eGFP-PHWT pools by their respective fast (8.21±1.10 μm²/s) and slow (0.06±0.01 μm²/s) diffusion. In contrast, the mCherry-PH¹⁴Δ point mutant
that does not bind PI(3,4,5)P₃, displayed a single fast diffusive component (7.83±0.58 μm²/s), demonstrating that the slower component corresponds to PI(3,4,5)P₃-bound PH domain on cellular endomembranes. Additionally, FCS allows the precise determination of concentration of membrane-bound eGFP-PHWT domain in different cell compartments. To avoid overestimation of the slow-diffusing population, we used a de-trending algorithm (Wachsmuth et al, 2015), benchmarked using a small GTPase Rab7. We show that ~45% of PI(3,4,5)P₃-bound PH domain is found at the plasma membrane, whereas endomembranes account for up to 15% of cellular PI(3,4,5)P₃ (or PI(3,4)P₂), as measured by FCS. PI3K inhibition by GDC-0941 resulted in rapid decrease of the membrane-bound PHWT both at the plasma membrane and in the cell interior. Our results demonstrate the utility of FCS for detecting lipids and intracellular dynamics of peripheral membrane proteins within the complex environment of live cells.

Methodology to uncover a 100-year-old mystery, how does ploidy affect cell volume?
R. Suman¹, A. Glen¹, R. Kasprwicz¹, P. O'Toole²;
¹Phasefocus Ltd, Sheffield, United Kingdom, ²Technology Facility, The University of York, York, United Kingdom

How cells coordinate their growth and division are fundamental homeostatic cell biology questions impacting normal and pathological cellular functions. For the latter, one well established phenomenon that has remained poorly understood and often ignored, is that which correlates ploidy with cell volume. To interrogate such fundamental biological processes, we utilized real time ptychographic imaging to determine the volumes of karyotypically abnormal (A549) and normal (NIH-3T3) cell lines. Ptychographic imaging (Livecyte, Phasefocus, UK) is a label free quantitative phase imaging (QPI) technology ideally suited to cellular segmentation which enables label free, low toxicity, real time imaging of cellular dynamics. QPI permits the acquisition of many parameters including cell size, shape, roughness, dry mass with the potential to derive a measure of cell volume by measuring the phase delay of coherent light. This phase delay is dependent on intrinsic properties of the cell including thickness and refractive index. Utilising the average cell RI, the optical volume can be translated into actual cell volume. Correlative QPI and confocal fluorescence image datasets of dye-loaded cells demonstrated a one-to-one relationship between the average cell volume derived via each method. This minimally perturbing multiparametric live cell imaging methodology could help unlock the mechanisms of the one-hundred-year-old fundamental mystery of why ploidy correlates with cell volume and what effect it has on cells thereby contributing to a fundamental understanding of how cancer develops.

Dual-Color Metal-Induced and Förster Resonance Energy Transfer for Cell Nanoscopy.
A.M. Chizhik¹, C. Wolnik¹; D. Ruhlandt¹, N. Karedla¹, A.I. Chizhik¹, D. Hähnel¹, I. . Gregor¹, J. Enderlein¹, F. Rehfeldt¹;
¹3rd Institute of Physics - Biophysics, University of Göttingen, Göttingen, Germany

We report a novel method, dual color axial nanometric localization by Metal Induced Energy Transfer (dcMIET), and combine it with Förster Resonant Energy Transfer (FRET) for resolving structural details in cells on the molecular level. We demonstrate the capability of this method on cytoskeletal elements and adhesions in human mesenchymal stem cells (hMSCs). Our approach is based on Fluorescence-Lifetime-
Imaging Microscopy (FLIM), and allows for precise determination of the 3D architecture of intracellular structures, here in particular, stress fibers anchoring at focal adhesions, thus yielding crucial information to understand cell-matrix mechanics. In addition to resolving nanometric structural details along the z-axis, we use FRET to gain precise information on the distance between actin and vinculin at focal adhesions. Both measurements combined can give an unprecedented insight into the nano-structure of the linkage between stress fibers and focal adhesions. Here, we will present data where we use our method to follow the maturation of focal adhesions and acto-myosin fibers in hMSCs over time and show that actin fibers are nearly parallel to the substrate yielding an inclination angle of only 0.2°.

Hybrid phasor unmixing for hyperspectral fluorescence imaging.
H.R. Chiang1,2, E.S. Koo1,2, L.A. Trinh2,3, J. Unruh4, S.E. Fraser1,2,3, F. Cutrale1,2,
1Biomedical Engineering, University of Southern California, Los Angeles, CA, 2Translational Imaging Center, University of Southern California, Los Angeles, CA, 3Molecular and Computational Biology, University of Southern California, Los Angeles, CA, 4Stowers Institute for Medical Research, Kansas City, MO

Fluorescence labels enable the visualization of proteins or peptides as indicators for biological dynamics. With growing needs from fluorescent biological imaging, multicolor labeling techniques have been widely proposed. However, the spectra of fluorescence labels are often overlapping, making the analysis more complicated. Hyperspectral fluorescence imaging adds a new dimension to microscopy imaging and enables unmixing of the overlapping spectra. With the continuously growing size of datasets, there is a need for fast and robust software to analyze the complicated data. In our previous study, we proposed an algorithm that tackles this problem based on the Fourier transform method, Hyper-Spectral Phasors (HySP). In this research, we provide a new solution hybrid unmixing combining traditional linear unmixing and HySP. This method combines both techniques’ advantages—it can denoise data, reduce computational time and solve spatially overlapping spectra with more than three labels. In this preliminary test, we apply this method’s enhanced sensitivity and robustness to observe liver metabolism reporters in zebrafish. Fluorescence signals could be separated easily, allowing observation of dynamic cellular interaction. In addition, we identify multiple autofluorescence signals spectra and extract their contribution from the biological activity.

Enhancing visualization of hyperspectral data with Phasor-Maps.
W. Shi1,2, E.S. Koo1,2, L.A. Trinh1,3, S.E. Fraser1,2,3, F. Cutrale1,3,
1University of Southern California, Translational Imaging Center, Los Angeles, CA, 2University of Southern California, Department of Biomedical Engineering, Los Angeles, CA, 3University of Southern California, Molecular and Computational Biology, Los Angeles, CA

Hyperspectral fluorescence imaging is gaining popularity, for it enables spectral separation of fluorophores whose spectra overlap by extending the acquisition dimension into spectral domain. This imaging modality produces large datasets generally complex and lengthy to analyze. In this work we present a visualization tool based on Hyperspectral Phasors, that provides a quantitative insight on the dataset prior to performing the full-scale analysis. Hyperspectral Phasors approach is a powerful tool for separating different fluorescent labels based on their spectral signature. The fluorescent spectral cube is
Fourier-transformed into a 2D plot where vector logic and histogram statistics provide an enriched and simplified insight into the data. However, visualization of hyperspectral images into tristimulus displays still proves to be a complex dimensionality reduction problem, where numerous hyperspectral bands are reduced to only three bands. Here we propose a fast and comprehensive approach to interpret hyperspectral fluorescent dataset based on similarity of spectral properties by designing multiple spectral maps aim at preserving much spectral information as well as enhancing spectral properties of the relevant pixels. We apply these phasor maps to multiple transgenic fluorescent zebrafish embryos of ubi:zebrabow, H2B-venus as well as wildtype AB/TL. Our results show enhanced visualization of spectral properties, separating fluorescent signal from autofluorescence and highlighting differences within intrinsic signals during live imaging. Phasor-Maps provide an image representation that is easy to interpret for human eyes and that quantitatively highlights different spectral characteristics of the sample.

Higher spatial resolution of overlapping gene expression achieved through a combination of multiplexing in situ Hairpin Chain Reaction and Hyperspectral Phasor analysis.

V. Thomas1,2, H.R. Chiang2,3, F. Cutrale1,2, S.E. Fraser1,2,3, L.A. Trinh1,2;

1Molecular and Computational Biology Department, University of Southern California, Los Angeles, CA, 2Translational Imaging Center, University of Southern California, Los Angeles, CA, 3Biomedical Engineering, University of Southern California, Los Angeles, CA

Development requires integration of distinct gene regulatory networks (GRNs) that coordinate patterning, growth, and morphogenesis. GRNs are defined by overlapping expression patterns of key cell fate determinants, forming a molecular code that specifies different populations of cells for unique roles during development. The ability to spatially resolve overlapping gene expression at single cell resolution in the context of the whole embryo is critical for dissecting GRNs. However, spatially resolving multiple overlapping gene expression remains a significant challenge. The recent development of multiplexed in situ Hybridization Chain Reaction (HCR) has met some of these challenges by allowing the simultaneous detection of multiple genes within a single sample. The approach uses sequence-specific DNA probes coupled to a hairpin-based amplification system that are labeled with Alexa-fluors for fluorescent detection of target genes. However, the spectral overlap of Alexa-fluors limits the multiplexing capability of in situ HCR. Here, we combine multiplexing in situ HCR with Hyperspectral imaging and Phasor (HySP) analysis to characterize the overlapping expression of transcription factors critical for establishing the molecular code within the lateral plate mesoderm (LPM) for cardiac fate specification. HySP imaging and analysis allows the identification of multiple fluorescence spectra by capturing the full spectrum of wavelengths and segmenting the pixel data by Fourier transformation provides an efficient representation of the hyperspectral data without data loss. The combination of these approaches allows for better multiplexing capabilities of in situ HCR, leading to the identification of novel non-overlapping patterns of hand2 and gata5 gene expression in the LPM. Importantly, the higher signal-to-noise allows for more accurate modeling of the GRNs controlling early cardiac specification. Our results show that multiplexing in situ HCR in combination with HySP imaging analysis provides the resolution needed to better understand the dynamics of GRNs, shedding light on the molecular mechanisms of development.

Unraveling combinatorial labels in vivo with Voronoi Hyper-Spectral Phasor.
F. Cutrale1,2, B. Steventon3, M. Kitano1,3, W. Shi1,4, E.S. Koo1,4, Y. Chai5, L.A. Trinh1,2, S.E. Fraser1,2,4, 1Translational Imaging Center, University of Southern California, Los Angeles, CA, 2Molecular and Computational Biology, University of Southern California, Los Angeles, CA, 3Department of Genetics, University of Cambridge, Cambridge, United Kingdom, 4Biomedical Engineering Department, University of Southern California, Los Angeles, CA, 5Center for Craniofacial Molecular Biology, University of Southern California, Los Angeles, CA

Increasing the number of labels in samples is becoming a common step in biology for distinguishing, tracking and revealing function of cells complexes, bundles of neurons or cells and perform lineage analysis. The recent blooming of transgenic strategies for combinatorial expression of fluorescent proteins provides formidable tools for tackling the problem of multicolor labeling such as Brainbow. This multicolor toolbox, however, shifts the problem from biology to image acquisition and analysis, providing a complex problem of stochastic combination of fluorescent labels to be acquired first and then unraveled after imaging. Multiple approaches have been used for tackling these issues, mostly using standard confocal microscopy approaches in combination with tristimulus color image processing. However, these image analysis approaches face difficulties when translated to fluorescence data. Limiting factors such as bleed-through, instrument noise, photo-bleaching and toxicity greatly compromise signal quality and consequently the quantitative results. In this work, we report a method for rapidly acquiring and analyzing Zebrabow samples base on parallel multispectral confocal fluorescence and Hyperspectral Phasors. We extend acquisition in the spectral dimension, acquiring a full spectrum for each pixel to overcome bleed-through effects. Using Hyperspectral Phasors, we enable lossless denoising and obtain a graphical representation of the dataset that can be easily interpreted. The linearity of phasors proves ideal for detecting linear combination of fluorescent labels. We then apply Voronoi segmentation in phasor space to successfully quantify and segment 3D and 4D datasets of ubi-Zebrabow samples at multiple developmental stages.

Nanophotonics and Optogenetics – A Novel Combination towards Precise Stem Cell Regulation.
A. Desai1, C. Handelmann1, K. Harikrishnan1, B. Decker1, A. Sangwan1, P. Miao2, M.K. Stachowiak1, J. Jornet2, L. Feng3, Y. Bae3; 1Pathology and Anatomical Sciences, State University of New York at Buffalo, Buffalo, NY, 2Electrical Engineering, State University of New York at Buffalo, Buffalo, NY

Major breakthroughs in the field of genomics, stem cell biology, optogenetics, and biophotonics are enabling the control and monitoring of biological processes through light. By incorporating light-actuated/light-emitting proteins into cells, key biological processes at the sub-cellular level can be controlled and monitored in real time. In this direction, we will be taking the first steps towards the control of stem cell regulation processes with real-time operation through the development of novel nanophotonic devices. More specifically, the objective of this study is to demonstrate the feasibility of controlling genomic functions in multipotent Neural Progenitor Cells (NPCs) by activation and deactivation of protein expression/interaction using novel nano-actuators. The first stage of the project is to develop nano-actuators at 480 nm (blue) that allow light-controlled molecular toggle switch to control the nuclear fibroblast growth factor receptor-1 (nFGFR1). As an intermediate step prior to the
design of blue-light nano-lasers, we have designed and fabricated an opaque mask with an array of micro-hole openings on a blue-light laser diode to mimic an array of micrometric lasers able to illuminate individual neurons. Each opening is 5 micrometer long and wide, and the spacing between holes is also 5 micrometers. A 3D printed support was designed and built to facilitate the positioning of the laser infinitesimally close to the NPCs (to limit the amount of light diffraction), but not in contact (to prevent electrical damage to the laser). Secondly, we are developing optogenomic constructs that can be activated and deactivated using nano-actuators. Preliminary experiments were performed by transfecting NPC’s with the channelrhodopsin-Chr2 (green) plasmid, and observing the effects of exposing it to 480 nm light with a flash of light occurring every 2.5 min for 15 min. NPCs were then allowed to recover for 90 min and were immunostained. We observed light-induced Chr2-dependent upregulation of cFos, nuclear FGFR1 and FGF2. In addition, we have also performed double transfection of Chr2 and CMV-R-GECO1 (GECO) (red), a Ca2+ indicator plasmid. Initial experiments were performed using KCl to activate GECO and observe Ca2+ release to test the efficacy of the plasmid. Currently, we are in the process of using We have also successfully used the 480 nm light to activate Chr2 plasmid which in-turn will activated GECO resulting in Ca2+ release. This is the first steps towards using nano-actuators for precise control of optogenetic system. The eventual goal of the project is to develop a nanophotonic - optogenetic system that will function as light-based switches for creating or decoupling protein-protein interactions for photo-regulation of stem cells.

Liquid Tunable Microscopy to study Chromatin-DNA.
A. Diaspro\textsuperscript{1,2};
\textsuperscript{1}Nanophysics, Istituto Italiano di Tecnologia, Genoa, Italy, \textsuperscript{2}Physics, University of Genoa, Genoa, Italy

Taking inspiration from the philosophical and sociological speculation by Zygmunt Bauman (Z. Bauman, Liquid Modernity, Polity Press, Cambridge, 2000) a new paradigm for optical microscopy is proposed regarding design, implementation, and applications. The current advances in optical microscopy related to the accessibility of data at the nanoscale in living systems or matter physics studies make super-resolved microscopy, label-free approaches, time and space encoding and decoding strategies, single molecule imaging and tracking approaches impregnated with a liquidity capable of condensing in itself the most significant aspects of the status of the art: a dimension in which the lasting gives way to the transient, the need to the discovery, and the necessity to the utility. This approach appears suitable to study chromatin-DNA at different temporal and spatial resolution scales. Phase contrast, confocal and multiphoton microscopy were a prelude for the super-resolved approaches. Today, in the era of super-resolution, we have a continuous growth of variations on the theme (Diaspro A. and van Zandvoort M.A.M.J. (eds) 2016. Superresolution Imaging in Biomedicine. CRC Press). Super-resolved Fluorescence Microscopy offers incredible performances and unlimited spatial resolution. (Diaspro A. 2014. Il Nuovo Saggiatore). Moreover, the modern methods allow tuning on the needed resolution in a direct, simple and efficient way. (Viciodini G. et al. 2014. Methods.) (Lanzanò et al. 2015 Nat. Com.). Different optical platforms can be used (Scipioni et al. 2016 Biophysical Journal; Castello et al. 2017. Rev.Sci.Instruments), and label-free methods (Bianchini and Diaspro, J.Biophotonics, 2008). (Mazumder et al. 2017 J.Optics) (Diaspro et al. 1990 IEEE Trans.Biomed. Eng.) become integrated modules of the modern liquid tuneable microscope. The microscope of the future, combining different converging technologies, is a liquid tunable microscope able to provide a scalable insight in the sample. It is liquid because it overlaps in an efficient and optimised way different mechanisms of contrast and it is tunable because it offers a real time tunability regarding spatial and temporal resolution like a radio tuned to the preferred radio station. It is smart because can adapt its architecture to the current scientific question

Sunday-34
and is open to additional light-matter interaction modules. The case study of interest here is related to study high order chromatin-DNA organisation in a scalable way with special attention to label free approaches coupled to high precision fluorescence mapping.

CRISPR/Cas 9 generated knockout cell lines for antibody screening and validation.
X. Hu\(^1\), W. Zhang\(^2\), H. Wei\(^1\), J. Li\(^1\), M. Liu\(^1\), L.J. Fang\(^2\);
\(^1\)OriGene Technologies, Inc., Rockville, MD, \(^2\)EdiGene Inc., Beijing, China

While antibodies are among most commonly used reagents in biomedical research, they have been blamed for the main causes of reproducibility crisis of biological experiments. To find a solution to improve the specificity, sensitivity and reproducibility of antibodies, we tested CRISPR/Cas 9 generated knockout (KO) cell lines for antibody screening and validation of different antibodies. First, we used PITPNB KO cell lysate to screen different hybridoma clones and the Western blot (WB) results showed three clones had specific bands in parental cell lysates but two of them also showed bands in KO cell lysates, which indicated potential cross-reactivity with similar size protein(s). Second, we cross tested KRT7 and KRT8 KO antibodies against KRT7 or KRT8 KO cell lysates, the WB results indicated that the KO lysates could clearly identify the specificity of KRT7 and KRT8 KO antibodies. Finally, we compared HER2 knockout cell line and its isotype control for HER2 antibody specificity analysis in flow cytometry, the results indicated that the KO cell line is a better control than traditional isotype control for antibody specificity analysis. The study concludes that KO cell lines and their lysates are extremely useful tools for antibody screening and validation.

Pooled screening in an insect cell-line.
R. Viswanatha\(^1\), Z. Li\(^1\), Y. Hu\(^1\), N. Perrimon\(^1\);
\(^1\)Genetics, Harvard Medical School, Boston, MA

Forward genetic pooled screening using shRNA or genome-editing approaches in mammalian cultured cells is a powerful method for the systematic identification of fitness-essential genes and genes conferring resistance to drugs. Despite the existence of numerous established insect cell-lines, a pooled screening method had not been possible due the absence of high-diversity gene delivery techniques. First, we report the development of a \( \phi C31 \)-based method allowing diverse pool delivery in insect cells. Next, we combine the method with CRISPR-Cas9 knockout screening and identify approximately 50 known and novel genes conferring resistance to the mTor-inhibitor rapamycin (positive selection). Finally, we use the technique to identify \(~1450\) fitness-essential genes (negative selection) with a false-discovery rate of 15%. Of these, 30% are uncharacterized in the fly; 85-95% have human orthologs; and 70% of the orthologous genes map to essential pathways in mammalian CRISPR knockout screens. Together, these results extend pooled screening to insect cell-lines as a rich source for discovering novel genes and pathways regulating basal and context-specific cell proliferation control.

Designing an imaging pipeline for gene edited hiPSC-derived cardiomyocytes.
R. Gunawardane; 1Allen Institute for Cell Science, Seattle, WA

The Allen Institute for Cell Science is creating an imaging pipeline to study the changes in cellular organization during the differentiation of human induced pluripotent stem cells (hiPSCs) into cardiomyocytes. Using CRISPR/Cas9 we have fluorescently tagged ~15 target genes which localize to and thereby identify key cellular organelles, including adhesions, actin and microtubule cytoskeleton, mitochondria, nuclear envelope, desmosomes, endoplasmic reticulum, and the Golgi. In addition, we have initiated editing of several cardiomyocyte-specific genes including ACTN2, ssTNNI1, TNNI3, MYL2, MYL7, and TTN to study the organization of the cardiomyocyte contractile apparatus. To study these structures in iPSC-derived cardiomyocytes we have developed an optimized, scalable, and robust protocol for both cardiac differentiation and for live, high-resolution 3D fluorescence imaging. This was achieved by evaluating established cardiomyocyte differentiation protocols that use either small molecules or a combination of cytokines and small molecules, and optimizing parameters such as cellular density, dissociation enzyme, and substrates for imaging the edited cardiomyocytes. Here, we present our results along with the quantitative and qualitative assays used to determine the efficacy of differentiation, including cellular morphology, myofibril contraction, cardiac protein expression, transcriptome profiling, and localization of cardiac proteins such as troponin T and alpha-actinin to the myofibrils. We will also present images of the structural organization of cardiomyocytes using these gene edited iPSC-derived cardiomyocytes. This imaging pipeline will be used to perform high-resolution live cell fluorescent imaging of these gene-edited cardiac-specific structures in addition to the major intracellular organelles to build a predictive and interactive model of the cell from pluripotency and extending throughout the cardiac differentiation process.

Board Number: B57
Systematic gene tagging to illuminate stem cell organization.
R. Gunawardane; 1Allen Institute for Cell Science, Seattle, WA

We are generating a collection of genome-edited clonal hiPS cell lines (WTC line) for studying cellular organization and dynamics. At present, we have ~15 GFP-tagged structures (www.allencell.org) that include major organelles, like the nucleus and mitochondria, as well as other key organizational structures that include microtubules, actin bundles, and cell-cell and cell-matrix adhesions. We have validated these cell lines for genomic, cell biological, and stem cell integrity and made them available to the research community. Here we present our newest iPSC lines with GFP-tagged structures; they include the ER, golgi, centrosomes, lysosomes and endosomes, along with some key observations of these structures in hiPS cells using live 3D microscopy. Our approach uses CRISPR/Cas9 gene editing to introduce fluorescent tags via homology driven repair (HDR) into genomic loci whose expressed products localize to specific organelles. Editing yields isogenic hiPSC lines expressing fusion proteins unique to each cell line under endogenous regulation. Most often these lines contain mono-allelic tags; but we have now also generated two tagged lines containing both mono- and bi-allelic tags. These gene-edited diploid cells display great consistency in GFP-tagged protein levels and cell behavior, greatly facilitating imaging and analysis. We have also developed strategies and workflows for successfully
tagging structures with red fluorescent proteins, generating dual structure tagged lines, and introducing fluorescent tags at the safe harbor (AAVS1 locus) for cytoplasmic and membrane localization. We present genomic and imaging data representing these newest gene-editing efforts and discuss the utility of these cell lines for generating image-based integrated models of cell organization and dynamics.

Eyes in the cell: Visualizing active kinases using genetically encodable fluorescent biosensors.
A. Mukherjee1,2, R. Singh1, S. DilipKumar3, P. Pothula1, S. Udayan1, R. Das3, B. Rao4, A. Gulyani1; 1technology for the advancement of science, institute for stem cell biology and regenerative medicine, bangalore, India, 2school of chemical and biotechnology, SASTRA University, thanjavur, India, 3National Centre for Biological Sciences, bangalore, India, 4Department of Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC

Cell fate and physiology are regulated by cell signaling wherein signaling proteins play a central role. On receiving cues (internal and/or external) proteins are known to form complex interactomes thereby regulating many processes with immense specificity. Very often the same protein/family of proteins gives rise to very different cellular outcomes and responses downstream of these cues. Therefore, to understand a given cellular pathway, understanding the stringent spatio-temporal regulation of these signaling proteins becomes essential. One such approach is to selectively detect and report the "active" state of the protein. Using this approach, our lab has generated a toolbox of fluorescent biosensors for the Src family of kinases. Src kinases are a family of non-receptor tyrosine kinases and signals emanating from these kinases are known to feed into multiple pathways. Fyn kinase (an SFK member) is ubiquitously expressed in all cell types wherein it controls a myriad of functions ranging from control of myelination of neurons by oligodendrocytes to regulation of adhesion structures in keratinocytes making it an interesting candidate protein. However, a better understanding of its role in this process has been lacking due to the paucity of specific tools available owing to the high degree of homology amongst the Src kinases. By adapting a stable scaffold based high through-put screening regime we have been able to generate a very specific FRET based "biosensor" for Fyn kinase. Using this sensor we find that cells plated on fibronectin (an integrin ligand) are highly polarized with respect to Fyn activity and that on addition of Platelet-derived growth factor (PDGF), an amplification in this polarized signal is achieved. This is the first conclusive evidence showing involvement of Fyn in mediating cross-talk between different types of receptors and such an approach could help uncover a general mechanism for Fyn's biological action.

Sensitive biosensor imaging based on membrane-permeant, environment-sensing dyes.
T. Watanabe1, C.J. MacNevin5, M. Weitzmann1, A. Gulyani1, S. Fuehrer1, F. Liu1, J. Jin5, K.M. Hahn1; 1Pharmacology and Lineberger Cancer Center, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC, 2Center for Integrative Chemical Biology and Drug Discovery, University of North Carolina at Chapel Hill, School of Pharmacy, Chapel Hill, NC

Biosensors with environment-sensitive fluorescent dyes have proven useful to study the spatio-temporal dynamics of protein activity in living cells. When dyes are attached to proteins or protein-binding reagents, they can report protein conformational changes or posttranslational modifications. The utility of dye-protein conjugates has been limited by the difficulty of loading them into living cells. They are
unusually are unable to pass through cellular plasma membranes so must be mechanically loaded or introduced using protein translocation approaches that can generate fluorescent vesicles and obscure fluorescent signals. To take advantage of recent techniques enabling protein labeling within living cells, we have developed solvent-sensitive dyes that are water soluble, use acetoxymethyl esters to pass through the plasma membranes, and show minimal staining of internal cellular structures. These dyes are bright (ε > 100,000 M-1cm-1, φ = 0.23), reducing the amount of labeled protein required in cells, and fluoresce at long wavelengths (excitation ~560 nm, emission ~590 nm), avoiding cellular autofluorescence. Reactive groups were incorporated for attachment of the dyes to either expressed proteins or small molecules. We utilized an unnatural amino acid (UAA) incorporated in the WASP CRIB domain to successfully extend the application of the novel dye to biosensor imaging of endogenous Cdc42 activity in living cells. When the dye mero166 was conjugated to an inhibitor of histone methyl transferase, the dye-conjugate translocated into nuclei, consistent with the biological functions of the transferase. The novel environment-sensitive dye with in cell labeling by UAA provides a generalizable strategy to access dye-based biosensors for a variety of protein or signaling components in living cells, and to trace the intracellular behavior of small molecules.

The development of non-FRET ratiometric ATP indicator “QUEEN-37C” and its application for single-cell metabolism analysis.
H. Yaginuma1, Y. Okada2;
1QBIC, RIKEN, Osaka, Japan

Adenosine triphosphate (ATP) provides energy to intracellular reactions. It is still unclear how the ATP concentration is maintained. Two pathways are known to supply the ATP: glycolysis and oxidative phosphorylation (OxPhos). Recent studies have clarified that some cells such as ES cells and cancer cells are rather dependent on glycolysis, but some other cells are more dependent on OxPhos. The relations between this metabolic switching and the cell differentiation are actively studied. FRET-based ATP indicators have been developed to measure concentration of ATP at single cell level. These probes enabled to visualize the relative temporal or spatial changes within in a same cell. However, the apparent FRET efficiency is biased by the heterogenous maturation of fluorescent proteins that constitutes the FRET pair, which has been the hurdle for the quantification of the absolute concentration of ATP. To circumvent this problem, we have developed “QUEEN”, a non-FRET ratiometric fluorescent ATP indicator protein for quantification of ATP inside bacterial cells. Here we developed an improved version, “QUEEN-37C”, for visualization of ATP concentrations in mammalian cells at 37°C. We first validated the accuracy of ATP concentration measurement by using QUEEN. The ATP concentration was measured from the ratio image of Madin-Darby canine kidney (MDCK) cells stably expressing QUEEN-37C. Then, the average concentration of ATP of the same cells was determined by using luciferase. The results agreed within the experimental errors, demonstrating that QUEEN-37C can be used for quantitative analysis of absolute ATP concentrations in mammalian cells. In this presentation, we will show our latest results using QUEEN-37C. For example, we expressed QUEEN-37C in co-cultured neuron and astrocytes. Perturbations with inhibitors of glycolysis or OxPhos showed that neurons are heavily dependent on OxPhos, but glial cells can maintain ATP concentration by glycolysis alone. More interestingly, we have noticed that metabolic switching stochastically and transiently occurs in MDCK cells when cultured at high densities.

Tool-box of Fluorescent Biosensors for Visualizing Protein Kinase Activation Dynamics in Live Cells.

R. Singh¹, A. Mukherjee², P. Pothula³, S.O. Raja³, R. Das², B. Rao³, A. Gulyani¹;

¹Technologies for the Advancement of Science, Institute for Stem Cell Biology and Regenerative Medicine, BANGALURU, India, ²Biochemistry, Biophysics and Bioinformatics, National Centre for Biological Sciences, BANGALURU, India, ³Department of Chemical and Biomolecular Engineering, North Carolina State University, Raleigh, NC

Cell behavior is governed by complex interconnected networks of signaling proteins that tightly regulate whether on the cellular context. Classical biochemical and protein depletion approaches are limited in deciphering spatio-temporal regulation of these molecules. Therefore, fluorescent biosensors and probes that can report on cellular dynamics of specific-signaling proteins are extremely valuable. Here, we describe generally applicable, high throughput strategies to build new biosensors for the activity of Src family kinases (SFKs), using tailored protein mono body libraries. Protein activity biosensors are limited by the availability of reagents that specifically recognize the active forms of signaling proteins. We use high throughput, yeast surface display screening to generate protein mono body binders that recognize the active form of Src family kinases. In this approach, the surface residues of DNA-binding protein Sso7d (~7 kDa protein from Sulfolobus solfataricus) has been randomized to generate combinatorial libraries of scaffold proteins, which can express the mutant proteins as fusions to a yeast cell-wall protein. We screened the yeast surface display library to fish-out the specific binder for Fyn SH3 domain using magnetic selection followed by FACS. The isolated Fyn binder ORF was sub-cloned in to expression vector and purified using biochemical methods. We performed in-vitro binding analysis as well as pull down assays to determine its specificity towards Fyn SH3 domain. The binder has a strong affinity towards the Fyn SH3 domain and is capable of pulling-down the full-length kinase from mammalian-cell lysate. The structure of binder-SH3 domain interacting complex was resolved using solid state NMR and further validated using structure-function studies. Using this binder we built a genetically encodable FRET-biosensor that could help in visualizing Fyn kinase activity in living cells. The new biosensor reveals that Fyn, downstream of integrin receptor engagement, has a highly polarized and pulsatile activity pattern. Growth factor stimulation experiments further provide a dramatic illustration of how signalling via multiple receptor classes can be modulated by spatio-temporally localized Fyn action. These results not only provide the first visual insights into Fyn activation dynamics in cells, but also provide a cellular framework to address the role of Fyn kinase in cell migration and metastasis. We will also showcase exciting new strategies to make highly sensitive, fluorogenic, genetically encoded sensors for endogenous, unmodified kinases. These strategies can be used to study signaling targets that have been difficult to study using conventional techniques due to limitations of size, post-translational modification etc.

Use of orthogonal binding interfaces to develop small GTPase biosensors with greatly reduced cellular perturbation.
E.C. O'Shaughnessy1, T.M. Jacobs2, X. Ma3, D. Tsygankov4, B. Kuhlman2, G. Danuser3, K.M. Hahn1;
1Department of Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Department of Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC, 3Department of Cell Biology, UT Southwestern Medical Center at Dallas, Dallas, TX, 4Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA

Specificity of cellular signaling pathways can be achieved in part through precise spatio-temporal control and recent advances in biosensors have enabled an unprecedented view of these mechanisms in vivo. While these tools have proven invaluable in capturing the spatio-temporal dynamics of protein activation, most are based on protein fragments, inhibitors and/or use overexpression methods that can perturb the cell physiology being studied. To overcome these significant limitations in biosensor development, we have used multistate interface design to engineer biosensors for the small GTPase Rac1 which bind to upstream regulators (and therefore properly reflect Rac activation) but do not interact with downstream components. These dual-chain biosensors consist of a GTPase fused to a donor fluorophore and an acceptor fluorophore fused to a polypeptide that binds specifically to the activated form of the GTPase. Taking binding domains from endogenous effector proteins as a starting point we used Rosetta to computationally randomize the binding interface between the GTPase and polypeptides and then scored the mutations with three objectives: 1) to stabilize the interaction between biosensor components, 2) to destabilize the interaction between sensor components and endogenous downstream binding partners and 3) to minimize perturbation of interactions with upstream regulators. We selected approximately 25 computationally predicted orthogonal pairs for experimental screening and, through high-content screening, identified two mutational pairs that confer tight binding between sensor components and show greatly reduced interactions with endogenous binding partners. In fibroblasts we found a substantial decrease in perturbation of edge motility dynamics, and confirmed modeling results indicating that the use of orthogonal interfaces could increase the concentration range over which biosensors can be expressed without significant cell perturbation. Using this approach can lead to biosensors that minimally perturb normal signaling, opening a window to the behavior of low abundance proteins and processes affected by subtle changes in activation.

Luminescent metabolite detection assays to monitor cancer cell metabolism in real-time.
D. Leippe1, T. Riss1, J. Vidugiriene1;
1Promega Corporation, Madison, WI

Studying the role of metabolism in cancer has presented challenges in developing reliable rapid and miniaturized homogeneous methods for measuring changing levels of metabolites to understand the changes in metabolic pathways. We have developed highly sensitive luminescent assays to detect metabolites such as glucose, lactate, glutamine, glutamate, and NAD(P)/NAD(P)H and have applied them to monitor changes in levels of metabolites over time in vitro. The assays are based on a common core technology that uses selective dehydrogenases and a coupled enzymatic assay approach to generate a luminescent signal from luciferase. Sample deproteinization is not required thus enabling the
measurement of kinetic changes in metabolite levels by removing very small aliquots of culture medium at defined time intervals from the same population of cells. We demonstrate the utility of the assays to study glycolysis and glutaminolysis using two ovarian cancer cell lines: OVCAR-3 (considered to be low invasive) and SKOV-3 (considered to be highly invasive and glutamine addicted). Both cell lines showed comparable glucose consumption (0.5pmol/h/cell) and lactate secretion (0.9pmol/h/cell) rates. However, differences in glutamine metabolism were observed. The glutamine consumption rate was higher in the more invasive SKOV-3 cells (0.2 pmol/h/cell versus 0.15 pmol/h/cell for the OVCAR-3 cells and the glutamate secretion rate was 20-fold higher. A difference was also reflected in intracellular metabolite levels. Intracellular glutamine was not detected in lysates of the more invasive SKOV-3 cells while OVCAR-3 lysates had 28 mM glutamine. Both cell lines contained significant amounts of glutamate (20 mM for SKOV-3 and 41 mM for OVCAR-3). In addition, we have applied these luminescent assays to validate an approach for screening for modulators of lactate and glutamate production utilizing known inhibitors (2DG and BPTES). These simple homogeneous luminescent assays will enable greater understanding of how various treatments affect the metabolic state of tumor cells in real-time.

**Deep Cell: Deep Learning in Biological Image Analysis and Phenotypic Profiling.**

J.J. Nirschl\(^1\), A.S. Moore\(^2\), E.L. Holzbaur\(^1\);

\(^1\)Department of Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, \(^2\)Neuroscience Graduate Group, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

Advances in fluorescent probes and light microscopy have revolutionized imaging in biological research, generating large, multidimensional datasets. However, image analysis tools accessible to biologists have not scaled with the increased volume of data, creating a bottleneck. Large image datasets require automated, data-driven analysis. We are developing machine learning tools that use deep neural networks or ‘deep learning’ to fill this need. We have developed convolutional neural network (CNN) based pipelines for biological applications including unsupervised phenotypic profiling for high-throughput microscopy and image segmentation. The hypotheses driving our study are: 1) pre-trained CNNs can be used as feature extractors to discover novel relationships in biological data and 2) CNNs will outperform conventional machine learning at segmenting objects in complex biological assays. We trained our networks on a large, diverse set of fluorescent micrographs of >600,000 cells from 22 cell lines labeled for 20 compartments, curated from The Human Protein Atlas and our lab. We use this dataset to train deep residual networks for phenotypic profiling. First, we trained our networks to classify 22 different cell lines based on staining for DNA, ER, and microtubules (94% accuracy). After training, we removed the classification layer to extract a high-dimensional vector representing image phenotypes, which can be visualized with dimensionality reduction techniques. We show that these “deep features” can be applied to new datasets with different acquisition settings, cell types, and fluorescent labels while retaining useful semantic information about biological phenotypes. We find that image features extracted from a network trained to classify cell type accurately cluster subcellular organelles without additional training, supporting the strength and flexibility of this approach. Future applications include phenotypic profiling in microscopy screens, where clustering genetic or drug treatments by image phenotypes may reveal novel relationships among genetic or pharmacologic pathways.

Next, we develop image segmentation pipelines for assays that require specific and precise measurements. We compared the performance of CNNs to a Random Forest classifier in the task of segmenting GFP-LC3 engulfed mitochondria to quantify mitochondrial autophagy. The CNN classifier is...
highly accurate (95% sensitivity, 83% specificity) and significantly outperforms the Random Forest classifier (93% sensitivity, 5% specificity). Together, these results demonstrate the power and promise of computer vision and deep learning in biological image analysis. We will open source and distribute code and trained networks to the biological community to expedite application and discovery.

A machine learning framework for kinetic phenotypic prediction of neurological disease states in patient-derived cell models.

M. Jones¹, C. Huang¹, H. Sasaki¹, T. Cheng¹, T. Sugawara², Y. Shi², J. Ichida², J.S. Lee¹;
¹DRVision Technologies LLC, Bellevue, WA, ²Eli and Edythe Broad Center for Regenerative Medicine and Stem Cell Research, University of Southern California, Los Angeles, CA

Patient-derived cell models coupled with long term imaging microscopes and state-of-the-art live cell fluorescent reporters provide a powerful platform to study dynamic morphological and biomolecular events and infer kinetic phenotypes to predict the states of the neurological diseases.

We are developing a machine learning based kinetic informatics discovery (KID) framework. It is applied to induced motor neurons (iMN) culture of amyotrophic lateral sclerosis (ALS) patient populations, to detect subtle differences underlying disease states. A machine learning enabled soft-matching detects somas and neuritis of iMNs. A tracking function tracks all iMN-like objects. Trajectory features for tracked objects are used to filter out non-iMN tracks. The states of the remaining true iMNs are inferred by measuring the responses of fluorescent reporters. A field inference stage uses random-forests classifier to infer the disease states at the field level. Like the field inference step, a patient inference stage uses random-forests classifier to infer the disease states at the patient level.

The KID tool is validated by rigorous tests at each stage using testing movies of iMN conversion and degeneration processes acquired on a Nikon BioStation CT. Both motor neuron reporter and neuronal firing reporter channels were imaged every 6 hours for 27 days, each patient in triplicate in 96 well plates. Neurotrophic factors were withdrawn and iMN survival was then imaged for 20 days.

The detection, tracking and state inference accuracies were tested by 12 movies, 4 from healthy controls and 8 from diseased patient lines. The detection accuracy is 94.6% ± 0.287% and the tracking accuracy is 94.5% ± 1.387%. The state inference accuracy is 87.9% ± 0.408%. The field inference accuracy was tested using 10 movies, 5 from healthy controls and 5 from diseased patient lines. The field inference accuracy is 90%. The patient inference accuracy was tested using 8 movies, 3 from healthy controls and 5 from diseased patient lines. The patient inference accuracy is 87.5%.

To further validate the KID tool, we used a masked test set consisting of 5 healthy and 5 patient lines to compare Z factor between KID score and survival alone. The KID tool showed Z factor of 0.5056 (good separation). The Z factor of the conventional survival assay using iMN survival metrics was -19.43 (very poor separation). These results provide a strong evidence of analyzing dynamic molecular events using time-lapse microscopy for discovering the pathogenic mechanisms underlying disease phenotypes. We will multiplex additional biomolecular reporters for spatial-temporal functional dynamics and cell fate readouts in the future.

Board Number: B66

Automated novel neuronal type discoveries by machine learning.
M. Jones¹, H. Sasaki¹, C. Huang¹, J.S. Lee¹;
¹DRVision Technologies LLC, Bellevue, WA

The structures of neuronal dendrites and axons play fundamental roles in synaptic integration and network connectivity. The neuron morphological characterization enables comparative anatomical investigations, morphometric analysis of cells, or brain modeling. Advancement in neurobiology, microscopy, and imaging software are rapidly transforming the three-dimensional (3D) reconstruction of neuronal morphology into a mainstream technique. However, classification and quantitative characterization of morphologies from 3D microscopy neuronal reconstruction is challenging since it is still unclear how to delineate a neuronal cell types and the best features to define them. There is a critical need for analytical tools to enable the discovery of novel neuronal patterns and cell types automatically.

We developed a machine learning framework for robust automatic object classification. The machine learning-enabled classifier allows the teaching of classification algorithms to look for specific phenotypes (e.g. developmental stages, disease states and cell types.) present in the data. The framework supports neuron classification and classification of individual dendrite segments, dendrite branches, spines, and other 3D objects such as cells and nuclei.

We are extending the machine learning framework for novelty detection to identify new or unknown types that the framework has not been taught. Three different methods are supported: one class random forest (OCHR), one class support vector machines (OCSVM) and kernel null Foley-Sammon (KNFS).

The novelty detection tool is applied to neuronal type discoveries. It is tested on several data sets to validate the tool and to help direct improvement and compare strengths of different methods. The test data sets include a human set (101 neurons, 4 types), a mouse set (287 neurons, 6 types) and a rat set (354 neurons, 6 types). The tests were performed by training different number of types and evaluating the untaught types as novel types. 80% of the data were used for training and 20% were used for testing. We evaluated detection accuracy, precision and recall. In the novelty detection, the precision is the most important metric. For one type training and detection, the achieved precisions are 88% (human), 97% (mouse) and 94% (rat) for OCRF. They are 75% (human), 91% (mouse) and 90% (rat) for OCSVM. Finally, they are 84% (human), 92% (mouse) and 94% (rat) for KNFS.

These results indicate that OCRF is a good machine learning method for the neuron applications. The results also provide a promising direction of automated novel neuronal type discoveries using machine learning. We will further test and improve the methods using additional data sets including dendritic spine classifications.

Identification of genes involved in CAR-T therapy using CRISPR screening.
P. YUAN¹, F. WANG¹, M. JIN¹;
¹Business Development Department, EdiGene Biotechnology Inc, Beijing, China

Chimeric antigen receptor (CAR)-engineered T cells (CAR-T cells) have yielded unprecedented efficacy in B cell malignancies. However, somatic gene mutations can alter the vulnerability of cancer cells to T-cell-based immunotherapies. Here we describe a rapid high-throughput CRISPR-based screening
approach that allows a comprehensive identification of genes in human cancer cells that involved in CAR-mediated tumor cell killing. A membrane specific CRISPR/Cas9 library that consisted of 3279 genes was used in Raji cells. After co-cultured with CD19-CAR-T, genes involved in CAR-T resistance were profiled by deep sequencing. A set of genes whose loss impaired CD19-CAR-T efficacy, including CD19, were identified. This method allows a rapid and comprehensive determination of immune-modulatory genes in CD19 and any other target based CAR-T therapy.

The CRISPR (clustered regularly interspaced short palindromic repeats)-Cas9 (CRISPR-associated 9 proteins) system derived from Streptococcus pyogenes has been adapted to upregulate any gene in its endogenous context, enabling gain-of-function or gene activation experiments while avoiding the use of exogenous over-expression plasmids. For CRISPR activation (CRISPRa), the guide RNA forms a complex with a nuclease-deactivated Cas9 (dCas9, D10A and H840A), which is in turn fused to transcriptional activators. The machinery then acts upstream of the transcription start site to up-regulate expression of a target gene. CRISPRa provides new tools to identify gene functions that might otherwise go undetected using loss-of-function studies down through-regulation of gene expression or gene knockout. Here we demonstrate a strategy to conduct CRISPRa experiments using chemically synthesized crRNA and tracrRNA molecules. We examine the functionality and advantages of using the synthetic approach for CRISPRa in multiple cell lines. Additionally, we show how the transcriptional activation leads to a significant increase in the target protein level, which in turn causes phenotypic effects by inhibiting or activating downstream genes. The methods presented are broadly applicable as a strategy to up-regulate any gene including systematic functional gene analysis in arrayed screening format.

Establishing Ubiquitylation Patterns in Cells: Efficient Monitoring of Cancer Biomarkers and Drug Activity.  
X. Lu\(^1\), P.K. Foote\(^1\), R. Singh\(^1\), C. Song\(^1\);  
\(^1\)LifeSensors, Malvern, PA

Cells regulate their functions by altering the ubiquitylation status of many key proteins, especially oncoproteins. As a result, ubiquitin proteasome system (UPS) substrates and the relevant UPS enzymes have been identified as attractive anti-cancer targets. However, to date, the only effective ways to measure ubiquitylation patterns has been by immunoprecipitation coupled with immunoblot analysis (IP/IB) or by mass spectrometry methods, which are either insensitive, low throughput, or highly intensive. Here, we describe two Tandem Ubiquitin Binding Entity (TUBE) based assays, UbiQuant S and UbiTest, which provide a platform to efficiently detect ubiquitylation of anti-cancer targets. UbiQuant S is a high throughput assay to quantify ubiquitylation status in a cells or tissue. Ubiquitylated proteins are identified by energy transfer between AlphaLISA bead-labeled TUBE and antibody against the endogenous protein of interest in a homogenous plate-based assay. In the case of extremely low-abundance or otherwise challenging target proteins, a TUBE-based isolation followed by two-antibody
While applications published multicellular prominent treatment (CRISPR), immunoblot We has shown important K48 ubiquitin linked vessels). Engineering, 1Molecular P1070 Inc., 1Cellecta, 1Genetic 1Genome loss of function screening is a fundamental method to identify genes responsible for driving biological processes. Complex pooled lentiviral-based libraries expressing large numbers of genetic disruptors, such as shRNAs (RNAi) or sgRNAs (CRISPR), make large-scale cell screening practical. While RNAi-based approaches have proven to be an effective strategy for these screens, recent work has showed CRISPR-based technologies offer not only an effective alternative, but distinct advantage. We will present unpublished data from genetic screens in human Cancer cell lines using CRISPR-KO, CRISPRi and CRISPRa technologies, as well as RNAi. Although loss-of-function shRNA and sgRNA pooled library screens are similar in concept, the gene loss of function is achieved by different mechanisms (mRNA degradation with RNAi, full gene disruption with CRISPR-KO, transcriptional inhibition with CRISPRi), so some divergences are expected and indeed observed when comparing results obtained using one method versus the other. Furthermore, contrary to RNAi, CRISPR technology can be modified to activate gene expression (CRISPRa), thus enabling the use of genome-wide gain-of-function screening in gene function studies.

Metastatic tumor cells exit circulation as multicellular clusters augmenting secondary tumor formation ability in melanoma cancer.

T.A. Allen¹, D. Asad¹², E.O. Amu¹, J.A. Yoder¹, K. Cheng¹²;
¹Molecular Biomedical Sciences, NC State University, Raleigh, NC, ²Joint Department of Biomedical Engineering, NC State University University of North Carolina at Chapel Hill, Raleigh, NC

Metastasis remains the leading cause of cancer-related mortality worldwide. Accumulating data suggests metastatic primary tumor cells disseminate through the circulation and seed distant sites as multicellular clusters. However, whether these clusters must first dissociate to extravasate (exit blood vessels) and form secondary tumors remains largely unknown. We hypothesized that circulating tumor cells (CTCs) could maintain adherence to each other while exiting blood vessels through a recently published alternative method of cell extravasation, termed angiopelosis.
To test this, we used an in vivo transgenic zebrafish larvae model, tg(fli1a:egfp), in which blood vessels exclusively fluoresce. We infused fluorescent human and mouse melanoma tumor cells directly into the circulation of the larvae and used intravital imaging to observe the circulating tumor cells in real-time. Next, using an RNA silencing approach, we knocked down the cell adhesion-related protein plakoglobin (gamma-catenin), and determined the effect of varying conditions on CTC cluster migration and extravasation in vivo. Additionally, we used a mouse metastasis model to evaluate whether circulating tumor cell clusters formed metastatic nodes more efficiently than individual circulating tumor cells. Here, by studying metastasis in murine and transgenic zebrafish larvae models, we show circulating tumor cell clusters possess the ability to exit blood vessels while maintaining a multicellular phenotype, through the recently identified mechanism of extravasation, angiopeliosis. We discovered tumor cells which extravasate as multicellular clusters exhibit an augmented ability to proliferate while individually-extravasating cells remain characteristically dormant. Furthermore, we found that silencing of cell adhesion molecule plakoglobin was sufficient to decrease the clustering ability of tumor cells in vivo, diminishing their ability to extravasate and establish secondary foci. Our results challenge the hypothesis that circulating tumor cell clusters must first disassociate to exit the circulation, and posits an alternative model. We propose tumor cells both travel and exit the circulation while maintaining a multicellular phenotype. Our results suggest CTCs’ ability to form secondary tumors and speed at which these tumors arise is directly proportionate to the number of extravasating cells in an aggregate; this is known collectively as the Cancer Exodus Hypothesis. We anticipate our findings to provide a starting point for more complex in vivo studies understanding the dynamics of group extravasation on tumor clusters ability to establish secondary tumors. We also expect the results to prompt development of clinical targets specifically to mitigate tumor cell clusters in circulation.

Pseudophosphatase MK-STYX regulates neurite outgrowth and alters the morphology of primary neurons.
D.A. Banks¹, A. Dahal¹, A. McFarland¹, B.M. Flowers¹², C.A. Stephens¹, A. Gugssa³, W.A. Anderson³, S.D. Hinton¹;
¹Biology, College of William and Mary, Williamsburg, VA, ²National Cancer Institute, National Institutes of Health, Bethesda, MD, ³Biology, Howard University, Washington, DC

Mitogen-activated protein kinases (MAPKs) are essential players in important neuronal signaling pathways including neuronal development, plasticity, survival, learning, and memory. The inactivation of MAPKs is tightly controlled by MAPK phosphatases (MKPs), which also are important regulators of these neuronal processes. There is compelling evidence that a unique catalytically inactive member, MK-STYX (mitogen activated kinase phosphoserine/threonine/tyrosine binding protein), is a regulator in neuronal differentiation such as neurite outgrowth. We previously reported that MK-STYX dramatically increases the number of primary neurites in rat pheochromocytoma (PC-12) cells through the RhoA signaling pathway. MK-STYX decreases RhoA activation, whereas knockdown of MK-STYX increases RhoA activation. Furthermore, MK-STYX increases phosphorylation of coflin, a RhoA downstream effector, whereas coflin phosphorylation decreases when MK-STYX is knocked down with shRNA. Throughout the course of these experiments, we noticed that cells overexpressing MK-STYX developed more neurites, which often branched. Here, we report that microtubules and actin, components of the cytoskeleton that are involved in the formation of neurites, are present in MK-STYX-induced outgrowths. In addition, in response to nerve growth factor (NGF), MK-STYX-producing cells produced more actin growth cones.
than non-MK-STYX-expressing cells. Transmission electron microscopy confirmed that MK-STYX-induced neurites form synapses. Furthermore, the expression of Tau-1 and MAP2 (microtubule associated protein) in MK-STYX-induced neurites suggests that they have both axonal and dendritic properties. Further studies in hippocampal primary neurons demonstrated that MK-STYX altered their morphology. A significant number of primary neurons overexpressing MK-STYX had more than the control number of primary neurites. Taken together these data provide evidence that MK-STYX causes cytoskeletal rearrangement. It also highlights that this unique member of the MKP subfamily has the potential to have a major role in neuronal signaling.

The sarcomere is the basic contractile unit within cardiomyocytes driving heart muscle contraction. Mechanisms governing sarcomere assembly, however, are poorly understood. Complicating this, there are no manipulable assays to test mechanisms of de novo sarcomere assembly. Here, we develop a novel assay using human cardiomyocytes to test de novo sarcomere assembly. Using this assay, we report non-muscle like stress fibers (NMLSFs) are essential sarcomere precursors, and evolutionarily conserved mechanisms drive sarcomere assembly in human cardiomyocytes. We show sarcomeric actin filaments arise directly from NMLSFs, which requires formin-mediated actin polymerization and non-muscle myosin IIB (NMIIB). We demonstrate formin-mediated sarcomere assembly is driven by the formin FHOD3, knockdown of which stops the NMLSF to sarcomere transition. Interestingly, we show NMIIB is required for the assembly of de novo sarcomeres but not maintenance of existing sarcomeres. We confirmed NMIIB is required in vivo for sarcomere assembly, as Zebrafish NMIIB knockdown animals fail to form sarcomeres. Furthermore, we show muscle myosin II filaments concatenate to form the A-band through a mechanism that is completely dependent on organized actin filaments. Thus, we provide a robust model of de novo cardiac sarcomere formation based on evolutionarily conserved mechanisms between non-muscle and muscle cells. This model offers new insight into the mechanisms governing sarcomere formation in human cardiomyocytes, and provides a testable platform to investigate normal sarcomere assembly during development or aberrant sarcomere assembly during disease states, such as cardiomyopathies.

**EhRho1 regulates cell motility and phagocytosis in *Entamoeba histolytica***.

R. Bharadwaj\(^1\), R. Arya\(^3\), A. Bhattacharya\(^3\), S. Bhattacharya\(^4\), S. Mohanty\(^1\);  
\(^1\)Stem cell facility, AIIMS, New Delhi, India, \(^2\)School of Biotechnology, Jawaharlal Nehru University, New Delhi, India, \(^3\)School of Life Sciences, Jawaharlal Nehru University, New Delhi, India, \(^4\)School of Environmental Sciences, Jawaharlal Nehru University, New Delhi, India

*Entamoeba histolytica*, a protozoan parasite causes amoebic dysentery or amoebiasis by invading colonic mucosa of host tissue. Phagocytosis and motility of parasite have often been associated with virulence behavior of *E. histolytica* and are essential factors responsible for pathogenesis. During tissue invasion, *E. histolytica* cells display high degree of blebbing due to high friction surfaces of gut epithelial cell lining which tend to employ blebbing as a mode of migration over pseudopods. After invasion, parasites may reach to liver, brain or lung and cause abscess in the tissues. Rho GTPases have been shown to play an important role in regulating actin polymerization and phosphoinositide kinases to regulate cytoskeleton dynamics in phagocytosis and cell motility in many model systems. In the present study, an attempt has been made to understand the role of EhRho1 in blebbing dependent motility and phagocytosis in *E. histolytica*. EhRho1 is a small GTPase that resides in the plasma membrane and enriches in the membrane, forming blebs. We have shown a novel mechanism for regulation of bleb formation in *E. histolytica* by EhRho1 through PI3 kinase pathway. Overexpression of mutant EhRho1 defective for GTP-binding or lowering expression by anti-sense RNA, in trophozoites results in reduced blebbing and motility. Also, Serum replenishment or LPA (Lysophosphatidic Acid) treatment was observed to induce high levels of GTP-EhRho1 in trophozoites resulting in increased blebbing while treatment with wortmannin, a known PI3K inhibitor reduced the bleb formation by reducing the PIP2 (Phosphatidylinositol 4,5-bisphosphate) levels in plasma membrane. Our study indicates the role of EhRho1 in bleb formation by amoebic cells that may contribute to the motility during host cell invasion. On the other side, our results show that EhRho1 regulates actin dynamics and localizes in the phagocytic cups during erythrophagocytosis and remain associated with the newly formed phagosome. Binding of activated EhRho1 (GTP bound) with Rho bind domain of EhFormin1 releases it from intermolecular autoinhibitory state and recruits to phagocytic cups. Expression of dominant negative mutant or lowering expression of EhRho1 by anti-sense RNA in trophozoites cause mislocalization of EhFormin1 from phagocytic cups which results in impairment of phagocytic processes and decrease F-actin content. The overall results concluded that EhRho1 regulates bleb based motility of parasite by regulating PIP2 level in plasma membrane through PI3 kinases pathway. Activation of EhFormin1 is required for progressions of phagocytic processes through the EhRho1 pathway in *E. histolytica*.

**XMAP215 is important for coordination between actin filaments and microtubules in embryonic neuronal growth cones.**

P.G. Slater\(^1\), A. Magee\(^1\), A. Samuelson\(^1\), L.A. Lowery\(^1\);  
\(^1\)Biology, Boston College, Chestnut Hill, MA

During neuronal development, neurons coordinates the actin and microtubule (MT) cytoskeletons present in the axonal growth cone to determine growth cone shape and generate an axonal morphological response. The family of plus-end tracking proteins (+TIPs) binds to and regulates MT behaviors, and can couple MTs to F-actin dynamics. Our lab has demonstrated that the +TIP and MT
polymerase, XMAP215, participates in certain MT behaviors that appear to be dependent on F-actin regulation, yet the mechanism by which this occurs is unknown. Our goal is to determine the XMAP215 contribution to growth cone morphology and to MT/F-actin coupling. We used genetically-manipulated \textit{Xenopus laevis} spinal cord explants, in addition to high and super resolution microscopy. We find that knockdown of XMAP215 results in: 1) larger growth cones with longer filopodia; 2) an increase in the looped morphology of MTs; 3) MTs that are more spread within the growth cone; and 4) an increase of dynamic MTs in the growth cone. Finally, even though we find that the MT/F-actin co-alignment is not altered, we observe an increase in the number, orientation and length of MTs advancing into the periphery that are not coupled to F-actin bundles. These results show that XMAP215 could have a role in the regulation of spatiotemporal guidance of MTs, a function that is attributed to the actin cytoskeleton. Thus, XMAP215 could be an important participant in MT/F-actin coupling within embryonic growth cones.

**Functional Behavior of Overexpressed Fusion Proteins in Melanoma Cells Under Confinement Mediating Leader Bleb Based Motility.**

G. Adams Jr$^1$, M. Preciado-Lopez$^2$, R.S. Fischer$^4$, M.A. Baird$^1$, J. Logue$^3$, C.M. Waterman$^4$;  
$^1$Cell Biology and Physiology Center, National Institute of Health, Bethesda, MD, $^2$Regenerative and Cancer Cell Biology (RCCB), Albany Medical Center, Albany, NY

Cell movement is mediated by a remarkably plastic array of morphologies. Cancer cells migrating in confined 3D environments mimicking tissue microenvironment can switch between modes of migration depending on the degree of confinement and the availability of adhesive ligand. Under high confinement and low adhesion, cells undergo a mesenchymal-to-amoeboïd switch and take on a highly stereotypical morphology with fast, persistent movement termed ‘leader bleb-based migration’ (LBBM). The morphology is characterized by formation of a large ($\sim 20.5$ um) sausage-shaped bleb that points in the direction of movement (the “leader bleb”) separated from a smaller ($\sim 12.5$ um) spherical cell body by a contractile neck. LBBM has been shown to be driven by actin and myosin II assembly and retrograde flow along the bleb, however, how actin binding proteins organization mediate motility is not elucidated, nor has the fundamental organization of cellular organelles necessary for various functionalities of cancer cell motility in this unusual cellular morphology. We performed a survey of the localization of 16 actin associated proteins including nucleators, bundlers, crosslinkers, and stabilizers, as well as various organelles in metastatic human A375 melanoma cells undergoing LBBM. We expressed fluorescent fusion proteins in cells confined to a 3um space under an agar pad and imaged by time-lapse spinning-disk confocal microscopy, and analyzed the spatial distribution within the cell body and leader bleb, as well as the effect of overexpression on the frequency of mesenchymal-to-amoeboïd transition and cell motility parameters. Our results indicate that nucleators Arp2/3 and mDia2 localizes towards the leader bleb tip, while $\alpha/\beta$-spectrin and FMN2 are confined to the cell body and $\alpha$-actinin and filamin are found exclusively in the bleb. All membranous organelles examined are localized in the cell body; however, cisternal endoplasmic reticulum and some Golgi is also found in the bleb; peroxisomes and mitochondria are found along the base of the bleb closer to the neck; and the nucleus and centrosome translocate between body and bleb. Of all proteins examined, only over-expression of $\alpha$-actinin or filamin induces alterations in leader bleb morphology. Our study provides the first description of a group of actin binding proteins and organelle dynamics during LBBM, and suggests an important possible role of actin crosslinkers in establishing LBBM morphology, thus enhancing our
understanding of cancer cell morphology and migration, which may lead to better treatment options for inhibiting cancer metastasis.

Uncovering the developmental functions of nuclear actin.
D.J. Kelps1, D.M. Wineland1, C.M. Jamie1, T.L. Tootle1;
1Anatomy and Cell Biology, University of Iowa, Iowa City, IA

Several decades of nuclear actin research implicate it in the regulation of transcription, chromatin remodeling, nuclear organization, replication, cell cycle, and the DNA damage response. However, what functions nuclear actin play in development and how the structure of nuclear actin impacts its functions remain largely unexplored. We have identified three reagents to examine nuclear actin during Drosophila oogenesis, i.e. follicle development. Follicles are composed of roughly 1000 somatic follicle cells and 16 germline cells, including 15 nurse or support cells and a single oocyte. Follicles progress through a series of 14 morphological stages, from the germanium to Stage 14 (S14). We find that monomeric actin (G-actin) is present in all cells and fairly uniform levels throughout oogenesis. Conversely, one actin antibody (C4) recognizes nuclear actin during early oogenesis (germarium-S9), including germline and somatic stem cells, mitotic follicle cells, and in transcriptionally silent nurse cells. These data suggests C4 nuclear actin promotes stemness, regulates the cell cycle, and inhibits transcription. This nuclear actin appears to be largely monomeric, and does not localize to the chromatin. As C4 nuclear actin decreases with follicle development, another actin antibody (AC15) begins to label nuclear actin. Specifically, the nurse cells exhibit AC15 nuclear actin starting at S8 and this increases with development; the follicle cells exhibit AC15 nuclear actin weakly at S9 and highly starting at S10. AC15 nuclear actin appears to be polymeric and localizes to the DNA; this and other data suggest it promotes transcription in both the nurse cells and the follicle cells. To further explore the roles of nuclear actin, we manipulate nuclear actin levels by blocking its nuclear import (Importin 9) and export (Exportin 6). Knockdown of Importin 9, results in female sterility and defects within the germarium, supporting a role for nuclear actin in stemness. Additionally, reduced Importin 9 levels cause chromatin defects. Loss or knockdown of Exportin 6 results reduced female fertility, distinct chromatin defects, heterochromatin issues, and alterations in the nuclear envelope. These data indicate nuclear actin regulates nuclear organization, and we predict such a function impacts transcription. Together these studies reveal nuclear actin plays critical roles in Drosophila follicle development. Considering the evolutionary conservation of actin structure and function, these studies will also provide insight into the roles of actin in the nucleus in the development of other tissues and organisms, and during tissue homeostasis and disease.

Nuclear actin interactome links actin to novel functions inside the nucleus.
T. Viita1, M. Varjosalo1, M.K. Vartiainen1;
1University of Helsinki, Institute of Biotechnology, Helsinki, Finland

Although actin is still best known from its actions in the cytoplasm, current studies have strengthen the importance of nuclear actin. Inside the nucleus actin has been linked in various functions from gene expression to chromatin remodeling, but still the molecular mechanisms behind these functions remain unclear. To tackle this problem, we have used two mass spectrometry (MS) based techniques: Strep-HA
Thus, Fabrogates DNA degranulation modifier. Here, cell actin checkpoint interactions. As remodeling down complexes. Our requirement for Manchester, Pediatrics and Human Immunobiology, Baylor College of Medicine, Houston, TX, MCCIR, University of Manchester, Manchester, United Kingdom.

As essential players of the innate immune system, Natural Killer (NK) cells are responsible for the targeted lysis of virally infected or transformed cells. Upon activation, they establish a specialized cell-cell interface called the immunological synapse (IS). Activation-induced F-actin remodeling at the lytic IS is a critical requirement for cytotoxic function but neither the dynamic regulation of synaptic actin nor its specific function have been determined at a nanoscale level. Here, live cell super-resolution microscopy is used to define nanoscale F-actin dynamism as well as its requirement for NK cell lytic granule secretion. Although total branched F-actin content at the mature lytic synapse is stable, the displacement of individual filaments enables stochastic formation and disappearance of clearances. And while we have previously shown that lytic granules undergo degranulation within minimally sized regions of actin hypodensity, we found here that clearance formation occurs independently of lytic granule positioning. This F-actin dynamism depends upon branched network formation by Arp2/3 and contractility by myosin IIA. Inhibition of F-actin dynamism abrogates lytic granule exocytosis, underscoring the importance of this previously undefined nanoscopic F-actin architecture.

Thus, NK cell lytic secretion is dependent upon the multimodal generation of nanoscale F-actin dynamism at the immunological synapse, which is thereby delineated as a complex and novel regulatory checkpoint for cytotoxic activity.

Differential effect of M-CSF vs. GM-CSF on macrophage morphology and phagocytic ability.
Z. ROTH1, J.J. Lim1, S. Grinstein1,2,3,
1Cell Biology, The Hospital for Sick Children, Toronto, ON, 2Biochemistry, University of Toronto, Toronto, ON, 3Keenan Research Centre for Biomedical Science, St. Michael’s Hospital, Toronto, ON

Macrophages are innate immune sentinels, capable of eliminating pathogens while also maintaining homeostasis by clearing apoptotic cells. Phagocytosis is central to both of these processes. Not all macrophages are equally competent in the performance of these roles, displaying specialized phenotypes that favor anti-microbial or anti-inflammatory homeostatic functions. Acquisition of such phenotypes is influenced by exposure to defined cytokines, notably macrophage colony stimulating factor (M-CSF) and granulocyte macrophage colony stimulating factor (GM-CSF). M-CSF is abundant in healthy human serum and is constitutively secreted by a variety of cell types including epithelia, fibroblasts, endothelial cells and even by the macrophages themselves. It is needed for the proper development of most tissue resident macrophages. In contrast, GM-CSF is rarely detectable in healthy tissues and is upregulated during injury, inflammation and in certain tumors. In-addition, GM-CSF is expressed in the lung, where it is necessary for the proper development of alveolar macrophages. In vitro, exposure to these cytokines differentially affects the appearance of macrophages: M-CSF-treated cells appear elongated and ruffle extensively, while GM-CSF-treated cells adhere more tightly to the substratum and show minimal dorsal ruffling. Because these morphological features suggest differential cytoskeletal organization, we compared also the phagocytic ability of the cells polarized with either M-CSF or GM-CSF. M-CSF-treated cells engulfed phagocytic targets much more effectively than did GM-CSF-treated cells. Differential engulfment was observed using bacteria, zymosan particles, as well as red cells coated with either IgG or complement, suggesting an overall attenuation of phagocytosis in the GM-CSF-treated macrophages, regardless of the receptors involved. The molecular basis of these differences is under investigation and will be discussed in detail.

Targeting mechanoresponsive cytoskeletal proteins to inhibit pancreatic cancer cell metastasis.
A. Surcel1, E.S. Schiffhauer1, D. Thomas1, Q. Zhu1, K. DiNapoli1,3, M. Herbig4, O. Otto5, P. Iglesias1,3, J. Guck1, R. Anders2, D.N. Robinson1;
1Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, 2Pathology, Johns Hopkins University School of Medicine, Baltimore, MD, 3Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, 4Biotechnology Center of the TU, Dresden, Germany, 5University of Greifswald, Greifswald, Germany

Metastatic disease is characterized by increased cellular contractility and deformability, lending cells and groups of cells, the flexibility to navigate through different microenvironments. This ability to alter cell shape is predicated on the structural elements of the mechanobiome – the cytoskeletal proteins that sense and respond to mechanical stimuli. Here, we present findings that the expression of known mechanosensory proteins in the mechanobiome, specifically non-muscle myosin IIA, IIB, and IIC, α-actinin-1 and 4, as well as filamin A and B, are altered in pancreatic ductal adenocarcinoma (PDAC) patients. We demonstrate that these proteins directly impact cellular mechanics using knock-down and overexpression cell lines. We further quantify the non-muscle myosin II family members in patient-derived cell lines and identify a role for myosin IIC in actin-band formation, using tissue spheroids and
computer-assisted image analysis. Additionally, we have previously shown that the targeting of myosin IIC by the small molecule mechanical modulator 4-hydroxyacetophenone (4-HAP) affects PDAC mechanics. 4-HAP decreases dissemination and induces cortical actin belts in spheroids, likely affecting retrograde flow. Mice treated with 4-HAP show a reduction in metastasis to the liver, suggesting that the mechanobiome is an effective, new drug space that can be exploited to improve the 5-year survival rate of pancreatic cancer patients, currently at ~6%, with a median survival time of <6 months.

Structure-based virtual screening to identify first-generation inhibitor of profilin1:actin interaction with anti-angiogenic property.
D. Gau1, T. Lewis2, L. Mcdermott3, P. Wipf2, D. Koes3, P. Roy1;
1Bioengineering, University of Pittsburgh, Pittsburgh, PA, 2Chemistry, University of Pittsburgh, Pittsburgh, PA, 3Computational and Systems Biology, University of Pittsburgh, Pittsburgh, PA

Profilin1 (Pfn1) is an important regulator of actin cytoskeleton that plays a vital role in many actin-based cellular processes. Previous studies have shown that profilin1’s interaction with actin is important for endothelial cell (EC) migration and angiogenesis, suggesting that this interaction is a suitable target for an anti-angiogenic strategy. In this study, we performed structure-based virtual screening of small molecules that can disrupt the hot spots of the Pfn1:actin interaction followed by a biochemical assay to identify two hit compounds with similar structures that can reverse Pfn1’s effect on actin polymerization in vitro. A proximity-ligation assay further confirmed compound-induced inhibition of direct Pfn1:actin interaction in EC. Treatment with these compounds had potent anti-angiogenic effects on EC both in vitro and ex vivo. Consistent with the importance of Pfn1:actin interaction in the regulation of actin polymerization and cell migration, treatment of these compounds also led to a reduced overall level of cellular F-actin and slower EC migration. In summary, this study provides the first proof-of-principle of small-molecule-mediated interference of Pfn1 function that may have a potential to serve as a novel anti-angiogenic strategy in the future.

ARAP2 suppresses Akt signaling through APPL1.
R. Luo1, P. Chen2, C.M. Waterman3, X. Jian1, J.C. Kuo4, P.A. Randazzo1;
1LCMB, NCI|NIH, Bethesda, MD, 2Biology Department, Williams College, Williamstown, MA, 3LCTM, NHLBI, Bethesda, MD, 4The Institute of Biochemistry and Molecular Biology, National Yang ming University, Yamin, Taiwan

ARAP2 is an Arf GAP that controls the dynamics of focal adhesions. The Arf GAP activity is necessary but not sufficient to explain the effects. Because ARAP2 binds APPL1, a regulator of Akt and Akt has been reported to regulate FA dynamics, we hypothesized that ARAP2 regulates FAs in part by controlling Akt. We discovered that ARAP2 can affect Akt levels through interaction with APPL1, but the effect was independent of effects on FAs. Reducing ARAP2 increased pAkt and overexpressing ARAP2 decreased pAkt in U118 cells; however, ARAP2 affected FAs but had no effect on Akt in MDA-MB-231 cells. Furthermore, an Akt inhibitor did not block the effect of reduced ARAP2 on FAs in U118. Altering FAs by other means also did not affect Akt in U118 cells. Thus, ARAP2 induced changes in Akt were not directly linked to FAs in U118 cells. The effect of ARAP2 on pAkt may be mediated by ARAP2 binding to APPL1. APPL1 had similar effects as ARAP2 on pAkt in U118. The effect of ARAP2 knockdown on pAkt was not
reversed by overexpression of APPL1 whereas the effect of APPL1 knockdown was reversed by overexpressing ARAP2. The effect of ARAP2 on Akt required binding to APPL1 but not Arf GAP activity. We conclude that Akt signaling is not involved in ARAP2 regulation of FA and that ARAP2 may have function outside of FA regulation in the regulation of Akt signaling in some cells.

Nuclear actin and actin regulated transcription factors in heat shock responses.
B. Prajapati¹, M. Sokolova¹, M.K. Vartiainen¹;
¹Institute of Biotechnology, University of Helsinki, Helsinki, Finland

Actin is an essential protein both in the cytoplasm as part of the cytoskeleton and in the nucleus, where it has been linked to transcription, RNA processing, and chromatin remodeling. Interestingly, actin also seems to play a role in different cellular stress responses, including the evolutionarily conserved heat shock response (HSR). It is well established that HSR is essential for preventing proteotoxic or cytotoxic damage to cell during stress, and it requires transcriptional activation of heat shock protein (hsp) genes for this process. Previous studies have shown that in rat fibroblast cells, the actin cytoskeleton is altered and actin is localized inside nuclei as actin/stress bars upon heat shock. MAL (also known as MRTF-A/MKL1) is an actin-regulated transcription coactivator of serum response factor (SRF), and heat shock has been shown to induce expression of MAL/SRF target genes. On the other hand, MAL seems to bind to hsp genes at least in *Drosophila* ovaries. However, the molecular mechanism and functional significance of actin accumulation in nuclei, MAL/SRF transcriptional activation upon heat shock or binding of MAL to hsp genes upon heat shock are unknown. Here we have investigated the role of actin and MAL in transcription using heat shock responses in *Drosophila* and mammalian cell lines as model systems. By using chromatin immunoprecipitation followed by deep sequencing (ChIP-seq), we have shown that in *Drosophila* ovaries, actin co-occupies most transcription start sites together with RNA polymerase II. Interestingly, actin is also highly enriched on hsp genes, binding throughout the gene body. Also, ChIP-seq in a *Drosophila* cell line showed high accumulation of actin on the hsp70Aa gene upon heat shock. Further manipulation of nuclear actin and MAL activities will reveal their relevance and molecular interplay in hsp gene transcription under heat shock conditions.

Optogenetic stimulation of Ras-RalGEF-Ral axis promotes cell migration through recruitment of Exocyst-Wave complexes at the plasma membrane.
G. Zago¹, M.C. Parrini¹, J. Camonis¹, M. Coppey¹;
¹Research, Institut Curie, Paris, France

The Ral GTPases (RalA and RalB) are key players in the transduction of oncogenic signals down-stream Ras. Direct activators of Ral, the RalGEFs (Guanine nucleotide Exchange Factors), are direct effectors of Ras. Even though it is well known that activation of Ras-RalGEF-Ral signaling is crucial for human oncogenesis, it remains very difficult to establish how at molecular level a particular event (for example a Ras mutation) causes the acquisition of a particular malignant phenotype (for example invasiveness). To dissect these cause-effect mechanisms we took advantage of an innovative approach, optogenetics, which is a novel discipline that combines genetics and optics to control well-defined events in living cells. We developed an Opto Ral system, based on a light-gated dimerization system that upon
illuminated recruits the GEF domain of Ral to a specific subcellular domain of the plasma membrane, leading to a localized and specific activation of Ral signaling pathway with no crosstalk activation of other Rho GTPases. Coupling Opto Ral system with TIRF microscopy technique, we observed that a primary consequence of Ral activation at the plasma membrane is the stimulation of cell edge protrusion events. A possible mechanistically explanation of this phenotype came from previous work in our lab (Biondini et al, J Cell Sci. 2016, 129:3756-3769) where we established a direct link between the Ral-exocyst pathway and the Wave Regulatory Complex (WRC), a crucial regulator of actin polymerization and protrusion formations. Indeed, we found that the optogenetic activation of Ral leads to a subsequent recruitment at the plasma membrane of WRC complex, supporting the following mechanistic model: under the control of Ral, exocyst and WRC complexes associate and exocyst works as "molecular taxi" physically transporting WRC from cytoplasm to leading edge. We are currently using an exocyst point mutant, deficient in WRC-exocyst association, to evaluate the impact on protrusion efficiency upon uncoupling Ral, exocyst and WRC recruitment and . This novel optogenetic approach revealed the mechanistic relationship between Ral activation, "the cause", and WRC recruitment to the front, "the effect", and provided an example of the power of optogenetics in untangling the molecular mechanisms at the base of cellular processes.

Matricellular Protein Cysteine-Rich Angiogenic Inducer 61 (CCN1/CYR61) – A Potential Therapeutic Target to Lower Intraocular Pressure.
P.P. Pattabiraman1;
1Department of Ophthalmology, Case Western Reserve University, Cleveland, OH

Purpose: Well-documented corroborations link actin cytoskeleton and extracellular matrix (ECM) proteins in the trabecular meshwork (TM) of aqueous humor (AH) outflow pathway and the regulation of intraocular pressure (IOP). Decreasing cell-cytoskeleton and -matrix interactions decrease the tissue stiffness to decrease IOP, which is a major risk factor for glaucoma. This study investigates the role of CCN1, a secreted matricellular protein that binds to and signal via integrins, in the regulation of the contractile properties of TM and IOP homeostasis. Methods: Using immunofluorescence and immunoblotting analyses, we assessed - a) cellular distribution, basal expression and secretion of CCN1 in primary human TM (HTM) cells and culture media, b) regulation of CCN1 by factors that regulate TM cytoskeleton and IOP including lysophosphatidic acid (LPA), dexamethasone, transforming growth factor-β2 (TGFβ2), and vascular endothelial growth factor (VEGF), c) effects of recombinant human CCN1 (rhCCN1) alone or in the presence of TGFβ2 on the changes in actin cytoskeletal organization and fibrogenic markers including α-smooth muscle actin (α-SMA) and collagen1A, and d) changes in cell stiffness after treatment with rhCCN1 using atomic force microscopy. All experiments described had sample size >3. Paired Student's t-test used to calculate statistical significance and results were significant if p<0.05. Results: Immunoblotting analysis confirmed CCN1 (40kDa) expression in HTM cells and its secretion in conditioned media. Cellular distribution by immunofluorescence showed predominantly cytoplasmic localization. Serum-starved HTM cells when treated with TGFβ2 (10ng/ml) and VEGF (20ng/ml) significantly increased intracellular CCN1 expression (≥1.5 folds) within 5h whereas LPA (10μM) for 24h and dexamethasone (500nM) for 5 days did not. Further, treatment with rhCCN1 (20ng/ml) for 5h led to decreased actin stress fibers and expression of the fibrotic markers - α-SMA and collagen1A as visualized by immunofluorescence and a 2.6 fold decrease in α-SMA compared to 0.1% BSA treated control HTM cells as detected by immunoblotting. Treatment of TM cells with rhCCN1 significantly attenuated TGFβ2-mediated induction of α-SMA and Collagen1A (>1.5 fold). On the other
hand, knockdown of CCN1 using shCCN1 led to a significant increase in α-SMA levels (1.7 fold). Atomic force microscopy studies revealed significant decrease in Young’s Modulus (cell stiffness) 1h post CCN1 treatment and reversed back to baseline by 4h. Conclusions: Taken together, CCN1 decreased the cytoskeletal integrity and the cell stiffness and negatively regulated the fibrogenic responses in AH outflow pathway making it an attractive and a novel mechanism-based therapeutic target to lower the IOP.

Anillin regulates epithelial cell mechanics by structuring the medial-apical actin network.
T.R. Arnold¹, R.E. Stephenson¹, K.M. Dinshaw¹, T. Higashi¹, A.L. Miller¹;
¹Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI

Anillin is a scaffolding protein with a well-characterized role in cytokinesis and a novel role in regulating cell-cell junction structure. Anillin knockdown in the Xenopus laevis epithelium results in domed cells with wavy cell-cell junctions and reduced phospho-Myosin II light chain at junctions, hallmarks of reduced junctional tension. Additionally, Vinculin, which is recruited to adherens junctions under tension, is reduced when Anillin is knocked down and increased when Anillin is overexpressed. Contractility of the epithelium after the addition of ATP is also reduced when Anillin is knocked down and increased when Anillin is overexpressed. Based on these findings, we hypothesized that junction recoil following laser ablation would correlate with Anillin expression levels – that is, increased recoil when Anillin is overexpressed and reduced recoil when Anillin is knocked down – indicating that Anillin promotes line tension parallel to the junction. Surprisingly, recoil inversely correlates with Anillin expression: when Anillin is knocked down, cell vertices recoil faster than controls, and when Anillin is overexpressed, the vertices separate more slowly. We attribute this result to the changes in the medial-apical actin network that spans the apical surface of the cell. In control cells, the medial-apical actin network is dense and dynamic. Anillin knockdown reduces medial-apical actin accumulation, while Anillin overexpression results in a stable network of thick actin cables. We propose that loss of Anillin results in reduced medial-apical actin integrity, and cells are not able to maintain their shape after ablation causing the vertices separate rapidly. In contrast, when Anillin is overexpressed, the robust actin cables provide an apical support network that helps maintain cell shape after laser ablation of the junction. This work reveals a novel role for Anillin in regulating epithelial mechanics through the medial-apical actin network and could be important for understanding Anillin’s potential roles in tissue homeostasis, morphogenesis, and disease processes such as cancer metastasis.

Asymmetrical distribution of actin and endocytic proteins provide differential mechanical forces to propel myoblast fusion.
Y. Liu¹, M. Chuang¹, S. Lin¹;
¹Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

Cell-cell fusion is critical for the development of syncyial tissues in multicellular organisms, including muscle, trophoblasts and osteoclasts. Although actin cytoskeleton has been known as the main driving force to overcome the energy barrier of intercellular membrane fusion, recently endocytic machinery and the membrane fission GTPase dynamin are reported to be essential for myoblast and osteoclast fusion. To understand the detailed roles of actin and endocytic proteins in cell-cell fusion, we utilized
mouse myoblast C2C12 to recapitulate myogenesis and observe the distribution of actin and endocytic proteins during myoblast fusion. We found that actin, but not tubulin, is asymmetrically coordinated in two fusing myoblasts that one cell protrudes actin-rich, protrusive structure to attack, and the other cell possess prominent cortical actin and stress fiber to receive. Furthermore, we found both actin and endocytic proteins are asymmetrically distributed in two fusing myoblasts that they are enriched at the fusion site of attacking cell. Intriguingly, the actin- and dynamin-enriched membrane protrusion can be observed in both of first phase myoblast fusion, fusion between two single nuclear myoblasts, and second phase fusion, fusion between two multinuclear myoblasts. Together, our results suggest that intercellular membrane fusion is orchestrated by actin and endocytic machineries in attacking and receiving myoblasts to provide invasive and resistance forces respectively.

Differential regulation of the axonal cytoskeleton by glycolysis and mitochondrial respiration. 
S.M. Holland¹, A. Ketschek¹, G. Gallo¹; 
¹Temple University School of Medicine, SHPRC, Philadelphia, PA

The bioenergetics of axon extension are poorly understood. Actin is an ATPase and ATP loading of actin is required for filament polymerization. We used chicken embryonic neurons to address how glycolysis and mitochondrial respiration regulate the axonal actin cytoskeleton. While mitochondria distribution in axons and growth cones has been previously detailed, the distribution of glycolytic enzymes has not been addressed. Through immunocytochemical analysis, we observed glycolytic enzymes for both the preparatory and pay off phases in axons and growth cones. Acute inhibition of respiration and glycolysis with Antimycin A and glucose free medium with 2-deoxy glucose, respectively, both blocked axon extension. However, inhibition of glycolysis also resulted in axon retraction, which is an active process requiring actomyosin contractility. Measurements of ATP levels in growth cones using the fluorescent reporter PercevalHR indicate that inhibition of glycolysis or respiration results in a decrease of about 25% and in combination in a 50% decrease. Inhibition of glycolysis, but not respiration, resulted in the formation of axonal filament bundles. Similarly, the growth cone also exhibited bundles through the central domain at the expense of lamellipodial structures. In contrast, inhibition of respiration resulted in greatly simplified and collapsed growth cones. Moreover, the density of growth cone actin puncta/foci, structures considered to be reflective of substratum attachment points, was decreased by inhibition of glycolysis but not respiration. Collectively, these data suggest the hypothesis that glycolysis may provide energetic support for growth cone attachment mechanisms and a mechanism that counteractomyosin driven contractility.

FRAP Simulations and Computational Modeling show that F-Actin Meditated Focusing of Vesicles at the Cell Tip Is Essential for Polarized Growth. 
J.P. Bibeau¹, J.L. Kingsley², S.I. Mousavi², F. Furt¹, C. Unsai², Z. Chen³, X. Huang³, L. Vidali¹, E. Tuzel²; 
¹Department of Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA, 
²Department of Physics, Worcester Polytechnic Institute, Worcester, MA, ³Department of Electrical and Computer Engineering, Worcester Polytechnic Institute, Worcester, MA

Filamentous actin has been shown to be essential for tip growth in an array of plant models, including Physcomitrella patens. One hypothesis is that diffusion can transport secretory vesicles, while actin
plays a regulatory role during secretion. Alternatively, it is possible that actin-based transport is necessary to overcome vesicle transport limitations to sustain secretion. Therefore, a quantitative analysis of diffusion, secretion kinetics and cellular geometry is necessary to clarify the role of actin in polarized growth. Using FRAP analysis, we first show that secretory vesicles move toward and accumulate at the tip in an actin-dependent manner. We then depolymerized F-actin to decouple vesicle diffusion from actin-mediated transport, and measured the diffusion coefficient and concentration of vesicles. To measure vesicle diffusion and concentrations, we developed a three-dimensional computational model of the FRAP process that incorporates particle diffusion, cell boundary effects, and the optical properties of the scanning confocal microscope. Using the measured vesicle concentration and diffusion coefficient, and experimentally extrapolated vesicle fusion kinetics, we constructed another model this time for diffusion-mediated cell growth. This model predicts that diffusion-mediated growth is dependent on the size of the region of exocytosis at the tip, and that diffusion-based growth would be significantly slower than normal cell growth. To further explore the size of the secretion zone, we used a cell wall-degradation enzyme cocktail, and determined that the secretion zone is smaller than 6 μm in diameter at the tip. These results highlight the requirement for active transport in polarized growth and provide important insight into vesicle secretion during tip growth. Additionally, our computational FRAP model can easily be extended to other cellular geometries and other fluorescence dynamics assays, via the graphical Java-based application which we also provide—the Digital Confocal Microscopy Suite, DCMS.

Function of Dynamin-2 in Postsynaptic Neuromuscular Junction.  
S. Lin¹, Y. Liu¹;  
¹Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

A neuromuscular junction (NMJ) is a chemical synapse equipped with complex membrane and cytoskeleton structures designed for neurotransmission and recycling at presynaptic membrane, as well as neurotransmitter receptors clustering at postsynaptic membrane folds. Recently, an actin-rich adhesion and invasion structure, podosome, has been reported to be present in aneurally formed postsynaptic apparatus and participate in postsynaptic maturation. Moreover, the large GTPase dynamin, long known for catalyzing membrane fission during synaptic vesicle recycling, was found enriched at the synaptic podosomes. As yet, the function of dynamin in postsynaptic membrane remains to be investigated. Here we found that during the lifetime of podosomes, the ubiquitously expressed dynamin isoform, dynamin-2 (Dyn2), forms a ring-like structure around the actin core for a short period of time, and this structure strongly correlates with the maturation and turnover of podosomes in C2C12 myotubes. Defective or exaggerated podosome morphologies were found when we knocked-down Dyn2 or treated myotubes with a GTPase inhibitor dynasore. From in vitro analysis, we found that Dyn2 has promising bundling activity towards both filamentous and branched actin, and Dyn2 mutations with altered assembly ability have abnormal actin bundling efficiency. Overexpression of these mutants also lead to abnormal podosome morphologies in myotubes. Furthermore, we demonstrated that expression of the hyper-assembly Dyn2 resulted in disturbance to the postsynaptic NMJ cytoskeleton in Drosophila. Taken together, our findings suggest that Dyn2 plays a structural role in podosome maturation through actin bundling activity, and therefore affect the cytoskeleton organization in synaptic podosome-
regulated postsynaptic NMJ maturation. We are going to further examine our hypothesis in the mammalian NMJ with myotubes and primary neurons co-culture system.

Investigating cytoskeleton-mediated mechanotransduction using a stem cell model of oogenesis.
J.A. MacDonald¹, D.C. Woods¹, J.L. Tilly¹;
¹Biology Department, Northeastern University, Boston, MA

The cytoskeleton serves a crucial role at several stages of mammalian reproductive biology, such as meiotic maturation, fertilization, and the cleavage of early-stage embryos. However, the role of cytoskeletal dynamics in the differentiating mammalian female germ line is understudied. The isolation of oogonial stem cells (OSCs), and propagation of isolated OSC cultures in vitro, provides a new model to investigate the role played by the cytoskeleton during oogenesis. This work focuses on the organization and distribution of F-actin filaments throughout the differentiation of OSCs, starting with mitotically dividing progenitor cells, ending with the terminally differentiated oocyte-like cells (OLCs) that spontaneously differentiate in vitro.

OSCs maintained as pure germ cell cultures were stained with rhodamine phalloidin. Overall, OSCs exhibited fibrillar anisotropic actin filaments, as expected in adherent cultured cells. However, a small percentage of these cells, thought to be entering meiosis to form OLCs (thus differentiating from mitotically proliferating cell to OLC), showed a dramatic shift in cell morphology toward a large spherical OLC. With rounding, the actin network became highly radial, comprised of filaments flowing around the nucleus. After completing differentiation, OLCs were collected and found to have a dense cortical layer of actin, similar to the well-characterized cortical actin of mature oocytes. These three phases of actin organization: anisotropic, radial, and cortical, correlated with distinct patterns in the localization of YAP, a downstream mediator of the Hippo signaling network frequently associated with mechanotransduction. YAP was seen to be distributed between the both nucleus and cytoplasm in cells with randomly distributed F-actin, however, in cells with radial actin YAP was strongly localized within the nucleus, and distinctly cytoplasmic in OLCs, suggesting a previously unknown role for YAP during oogenesis. Treatment with the YAP inhibitor Verteporfin decreased basal rates of oogenesis (75 nM, -40%, n=3 P<0.01), with no negative impact on cell proliferation. Inhibiting F-actin stress fibers formation through treatment with the ROCK inhibitor Y-27632 did not impact basal differentiation of OSCs to OLCs, however treatment with Y-27632 prior to applying mechanical strain (10.5% elongation) inhibited both mechanical induction of oogenesis (Strain: 1.23-fold increase, Y-27632+Strain: 0.96, n=3; P<0.01) as well as strain-dependent decreases in phosphorylated YAP.

Taken together, these data indicate that OSCs are highly sensitive to cytoskeleton-mediated mechanotransduction mediated through the effector, YAP.

Src-mediated cortactin tyrosine phosphorylation regulates filopodia formation in neuronal growth cones.
Y. Ren¹, Y. He¹, D.M. Suter³;
¹Biological Sciences, Purdue University, West Lafayette, IN

Proper wiring of neurons is key to the functionality of nervous system. This is achieved by a highly motile structure referred to as the neuronal growth cone located at the tip of axons and dendrites during both development and regeneration. Sensing of extracellular cues and motility are main functions of filopodia and lamellipodia, two distinct actin-based structures in the peripheral domain of neuronal growth cones. Whereas the regulation of actin networks in lamellipodia has been extensively characterized, little is known about the signaling pathways that control the formation, dynamics, and stability of growth cone filopodia. Previously, we reported that cortactin mediates the effects of Src tyrosine kinase in regulating actin organization and dynamics in both lamellipodia and filopodia of Aplysia bag cell neuronal growth cones. Here, we identified a single cortactin tyrosine phosphorylation site (Y499) to be important for the formation of filopodia. By comparing mutants of the three putative Src tyrosine phosphorylation sites of Aplysia cortactin (Y499, Y505, Y509), we found that Y499 is the only phosphorylation site relevant for regulating filopodia formation. Overexpression of the 499F phospho-deficient cortactin mutant decreased filopodia length and density, whereas overexpression of the 499E phospho-mimetic mutant increased filopodia length, regardless of the phosphorylation state of Y505 or Y509. Using a custom-made antibody against cortactin phosphorylated at Y499, we showed that phosphorylated cortactin is enriched in the peripheral domain, specifically along the leading edge. We found that treatment with the Src inhibitor PP2 decreased cortactin phosphorylation, while overexpression of Src2 increased cortactin phosphorylation. In order to test the hypothesis that the Arp2/3 complex is a key effector of Src/cortactin-mediated filopodia formation, we expressed the cortactin NTA domain as dominant negative Arp2/3 inhibitor either alone or together with a cortactin triple tyrosine phosphorylation mutant FFF. Overexpression of the NTA domain together with the cortactin FFF mutant didn’t further decrease filopodia density or length when compared to neurons expressing either construct alone, suggesting that cortactin acts upstream of Arp2/3 complex in filopodia formation. In conclusion, we have identified a tyrosine phosphorylation site in Aplysia cortactin that plays a major role in the Src/cortactin/Arp2/3 signaling pathway controlling filopodia formation.

Actin crosslinking ACD toxin is a universal inhibitor of tandem-organized actin-regulatory proteins in living cells.
E. Kudryashova¹, D.B. Heisler¹, B. Williams¹, K. Shafer¹, A. Harker², D.R. Kovar², M. Quinlan³, D.S. Kudryashov³;
¹Chemistry and Biochemistry, The Ohio State University, Columbus, OH, ²Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, ³Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA

Delivery of bacterial toxins to host cells is efficiently hindered by a potency of the host protective barriers. This obstruction dictates remarkable efficiency of the toxins, a single copy of which can be sufficient to compromise a host cell. The efficiency of actin-targeting toxins is further hampered by an overwhelming abundance of the target: actin is one of the most abundant proteins in eukaryotic cells
 (>100 µM). To circumvent this barrier, toxins employ sophisticated mechanisms of toxicity amplification. One such mechanism is demonstrated by the actin crosslinking domain (ACD)-containing toxins of V. cholerae, V. vulnificus, and A. hydrophila, which catalyzes the formation of covalently crosslinked actin oligomers with actin subunits connected by side chain-amide bonds. Since these ACD-produced actin oligomers are non-polymerizable, crosslinking bulk amounts of actin eventually leads to failure of most of its functions and cell rounding, however, this mechanism requires high doses of the toxin to be effective. Conversely, our recent data imply that ACD-conferred cytotoxic effects are evidenced when only 2-6% of actin is crosslinked, suggesting that low doses of the actin oligomers are highly toxic. We recently reported a “gain-of-function” mechanism of toxicity amplification whereby the actin oligomers act as potent secondary toxins that directly inhibit the formin family of proteins with an abnormally high affinity, taking advantage of their unique geometry and tandem organization. Here we examined and verified a hypothesis that the toxicity of the oligomers extends towards WASP-homology motifs 2 (WH2) proteins involved in nucleation, elongation, severing, branching, and bundling of actin filaments. Many of these proteins contain G-actin-binding WH2-motifs in close proximity and may act as a multivalent platform for high-affinity interaction with the ACD-crosslinked actin oligomers. Using live-cell single-molecule speckle (SiMS) microscopy analysis, total internal reflection fluorescence (TIRF) microscopy, and bulk actin polymerization assays, we found that the actin oligomers potently inhibit Ena/VASP, Spire, and nucleation promoting factors (NPFs) of the Arp2/3 complex, albeit with different efficiencies. In live cells, SiMS microscopy confirmed potent inhibition of formins and Arp2/3 complex and halted dynamics of Ena/VASP and WAVE leading to a massive disarray of the host cytoskeleton. This study redefines ACD as an indirect, universal inhibitor of tandem-organized G-actin-binding proteins that overcomes the abundance of actin by redirecting the toxicity cascade towards less abundant targets whose inhibition by actin oligomers leads to disorganization of actin cytoskeleton and halts its dynamics disabling normal cellular functions.

Cryo electron tomography of the actomyosin cortex in isolated blebs.
D.A. Cassani1, B. Martins2, M. Smith1, E.K. Paluch1, O. Medalia2;
1MRC - LMCB, University College London, London, United Kingdom, 2Department of Biochemistry, University of Zurich, Zurich, Switzerland

Cell shape changes are key to cell physiology and underlie fundamental processes such as cell migration, cell division and tissue morphogenesis. Cell shape changes are precisely controlled by cell surface mechanics. Cell surface mechanics is primarily determined by the cellular cortex, a thin network of actin, myosin and associated proteins underlying the plasma membrane. Cortex mechanical properties are determined not only by the network composition but also by its nano-scale architecture. Yet, very little is known about cortical network organisation. This gap in understanding is mostly due to the small dimensions of the cortex, which thickness is close to the diffraction limit of light microscopy. To circumvent this issue, we have developed a method to image actin filaments in the cortex in three dimensions using cryo electron tomography. We use isolated blebs, which have been shown to repolymerise a cortex similar to that of intact cells (Biro et al., 2013) and which have dimensions compatible with cryo electron microscopy (Medalia et al., 2002). We first characterised isolated blebs using super resolution microscopy and observed that repolymerised cortices have dimensions, morphology and dynamics comparable to intact cells cortex. A first round of cryo electron tomography demonstrated the feasibility of our approach, allowing us to visualise actin filaments in isolated blebs. We have developed a protocol to automatically segment actin filaments and reconstruct the cortical network, focusing on crossings between filaments and branching points. These quantifications allow for
a quantitative description of cortical architecture. We are currently implementing this approach to investigate how cortex architecture changes during the cell cycle.

**Mechanisms regulating actin cortex architecture in embryonic stem cells.**

S. Xia¹, Y. Lim², Y. Wang³, Z. Zhang¹, C. Lim¹,², E. Yim¹,⁵, P. Kanchanawong¹,²;

¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ²Department of Biomedical Engineering, National University of Singapore, Singapore, Singapore, ³Department of Biology, Southern University of Science and Technology, Guangzhou, China, ⁴Materials Characterization and Preparation Center, Southern University of Science and Technology, Guangzhou, China, ⁵Department of Chemical Engineering, University of Waterloo, Waterloo, Canada

Embryonic stem cells (ESCs) are uniquely valuable cell types due to their pluripotency, the ability to differentiate into any specialized lineage. However, although their applications in regenerative medicine and tissue engineering have been intensively investigated, several fundamental aspects of their cell biology remain not well understood. For instance, recent studies suggest that the cytomechanical properties and mechanical cue responses of ESCs may differ significantly from differentiated cells. The actin cortex is an active network of actin cytoskeleton underlying the plasma membrane, and a major determinant of animal cell mechanics. We hypothesize that the cortical organization of ESCs may provide a structural basis accounting for their cytomechanical properties. Here, using super-resolution, live-cell, and atomic force microscopy to characterize mouse ESCs (mESCs), we observed that the mESC actin cortex comprises a low-density isotropic actin network of ~50-nm thickness, interspersed with high-density structures we termed “asters”. We found that the global architecture and the elasticity of the cortical networks are maintained by a fine balance between the activities of formin and Arp2/3 complex, with minimal contribution from Myosin II contractility. We identified the actin capping protein (CapZB) as a key regulator of both the network density and cortical elasticity, primarily via its activity in the transient asters. The asters also contain Arp2/3 complex and actin associated proteins such as a-actinin, and apparently serve as actin polymerization hotspots to regenerate the cortex upon local disruption. The isotropic nature of the mESC cortex largely excludes integrin-based adhesions, restring them to the cell periphery. However, these adhesions are compositionally mature, exhibit conserved multilayer nanoscale architecture, and are dependent on myosin contractility. Our results indicate that mESCs possess a distinctive and highly regulated cortical architecture which we suggest could represent a minimal undifferentiated state of the actin cortex that may be necessary for maintaining their nuclear softness and pluripotency. In addition, the mESC cortex is highly amenable to imaging and thus could serve as a useful model system for investigating the structure, dynamics, and mechanics of cellular actin networks.

**IRTKS elongates brush border microvilli using EPS8-dependent and -independent mechanisms.**

M.M. Postema¹, N.E. Grega Larson¹, A.C. Neininger¹, M.J. Tyska¹;

¹Dept. of Cell and Development Biology, Vanderbilt University, Nashville, TN

The intestinal brush border lines the apical surface of enterocytes and is composed of thousands of actin-supported protrusions called microvilli, which extend into the intestinal lumen. Microvilli function to increase intestinal surface area and a properly formed brush border is critical for maintaining
intestinal homeostasis. However, the mechanisms underlying the formation of microvillar protrusions remain unclear. Here we provide evidence that the I-BAR domain containing protein, insulin receptor tyrosine kinase substrate (IRTKS), is essential for normal microvillar growth and elongation. IRTKS targets to the tips of actively growing microvilli, elongates microvilli when overexpressed, and is required for microvilli to achieve their normal length during BB formation. Our experiments reveal that the SH3 domain of IRTKS binds to the actin capping and bundling protein epithelial growth factor receptor pathway substance 8 (EPS8), and the two proteins colocalize at the distal tips of microvilli. Similar to IRTKS, knockdown of EPS8 impairs microvillar elongation. Interestingly, when IRTKS is knocked down, EPS8 levels at microvillar tips are reduced. This latter finding suggests that IRTKS promotes tip enrichment of EPS8 and provides at least one explanation for the short microvillar phenotype upon IRTKS knockdown. We also found that an IRTKS construct lacking its C-terminal WH2 domain generates microvilli that are significantly shorter; however the length of these protrusions can be rescued to WT levels when EPS8 is simultaneously overexpressed. Together these results suggest that IRTKS elongates microvilli in two ways: directly using its WH2 domain, and indirectly using its SH3 domain to promote the tip localization of EPS8, which in turn promotes microvillar elongation using a separate mechanism. Thus, an IRTKS/EPS8 complex targets to the tips of microvilli where it controls the length of these protrusions during brush border formation.

\textsuperscript{1}Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN, \textsuperscript{2}Department of Biological Sciences, The University of Toledo, Toledo, OH

During intestinal epithelial differentiation, apical microvillar packing and organization are driven by adhesion complexes formed between two protocadherins, CDHR2 and CDHR5, that localize to the distal tips of microvilli, where they drive physical interactions between neighboring protrusions. CDHR2 is also capable of weak homophilic interactions. We recently reported that the actin-based motor myosin-7b (Myo7b) promotes the accumulation of the intermicrovillar adhesion complex (IMAC) components at microvillar tips, which is essential for the proper function of the complex. Additionally, two scaffolding proteins, USH1C and ANKS4B, play critical roles in complex formation and function. However, many questions still remain about how Myo7b, a monomeric motor, is capable of localizing these proteins and why there are so many seemingly redundant interactions. To address these questions, we developed an in-cell reconstitution assay using filopodial protrusions and their myosin transporter, myosin-10 (Myo10). The use of filopodia provides better spatial and temporal resolution, and heterologous expression allows us to control which IMAC components are present and able to interact. To allow us to take advantage of filopodia, we generated a chimera containing the motor domain of Myo10 and the cargo-binding tail domain of Myo7b, which localizes to the distal tips of filopodia. IMAC components that can interact with Myo7b will become enriched at filopodial tips when coexpressed with the chimeric motor. Using this assay, we found that the chimeric motor alone can target CDHR2 and CDHR5 to the distal tips of filopodia. Tip enrichment of CDHR2 results in increased filopodial number and stability. Additionally, CDHR2 forms homophilic interactions between adjacent filopodia, resulting in interfilopodial adhesion and tipi-like clusters of dorsal filopodia which resemble the clusters of microvilli found on differentiating epithelial cells. The chimeric motor can also transport both USH1C and ANKS4B individually to filopodial tips. Future studies will focus on determining how the adaptors promote the transport efficiency, stability, and lifetime of the IMAC.

During cytokinesis in fungi, amoeba, and animals, cells divide physically into two using the tension generated by a contractile actomyosin ring. Ring tension is generated by myosin-II that pulls on actin filaments, but how these forces are marshalled to generate tension is unclear. Recently the ultrastructure of fission yeast constricting rings was probed by super-resolution microscopy (FPALM), showing that myosin-II and formin-capped barbed-ends of actin filaments colocalize in membrane-anchored protein complexes called nodes (Laplante et al., 2016). Using this information, a mathematical model showed there exists two contra-rotating families of nodes. Actomyosin forces operate both within and between families, and we show both contribute equally to ring tension. Anchoring ensures that nodes aggregate slowly such that turnover can protect the ring from these instabilities.
We incorporated this nodes ultrastructure in a mathematical model of the fission yeast ring that uses a coarse-grained, continuous representation of the nodes, and is severely constrained by the ample experimental data about the fission yeast ring. We find there are two classes of node, stochastically determined by the polarity of the actin filaments associated with the node: nodes that move clockwise, or nodes that move counterclockwise around the ring, due to myosin-II pulling forces. Thus, two node families contra-rotate with respect to one another. This agrees with the bidirectional motion measured in FPALM.
We find that nodes of opposite polarity are pulled towards one another, and this sliding filament mechanism generates 50% of ring tension due to the resistance provided by anchor drag that resists motion. Pulling forces between nodes of the same polarity contributes another 50% and involves no relative motion. The predicted ring tension agrees with experiment (390 pN), with a best-fit force per Myo2 head of ~1 pN, close to previous measurements.
To test for the effects of turnover, we ran the simulation with turnover switched off. Without turnover, an intrinsic contractile instability of catastrophic proportions sets in. Small density fluctuations are amplified and fracture the ring. Restoring turnover reduced instabilities as turnover time is smaller than the aggregation time.
In conclusion, long ago a sliding filament mechanism of ring tension similar to striated muscle was proposed (Schroeder 1968). Our model shows that a sliding filament mechanism is at work, of a highly stochastic and transient nature due to turnover. In addition to the mutual sliding of apposing filaments originating in the contra-rotating families, we find an equal contribution from a fixed filament mechanism, arising from interactions between nodes of the same family that rotate in the same sense.
Two isoforms of myosin-II cooperate to organize the fission yeast cytokinetic ring for maximal tension production.

S. Wang¹, H.F. Chin², S. Thiyagarajan¹, E. Karatekin³, T.D. Pollard⁴, B. O'Shaughnessy⁵;
¹Department of Physics, Columbia University, New York, NY, ²Department of Chemical Engineering, Columbia University, New York, NY, ³Department of Cellular and Molecular Physiology, Yale University, New Haven, CT, ⁴Department of Molecular Cellular and Developmental Biology, Yale University, New Haven, CT

Cytokinesis of animal, fungal and amoeboid cells is driven by an actomyosin contractile ring that generates tension. How ring components organize to generate tension, and how the organization is maintained are unanswered questions. Here we show that the two isoforms of myosin-II in the fission yeast ring not only exert force, but have equally important roles as crosslinking agents that bundle actin filaments and organize the ring, cooperating to boost ring tension while avoiding fracture. Recent FPALM super-resolution fluorescence microscopy measurements of the fission yeast ring showed that protein complexes (“nodes”) from which the ring is assembled persist into constricting rings (Laplanche et al., 2016). Nodes, anchored to the plasma membrane, contain several components including myosin-II Myo2. A second myosin-II isoform, Myp2, may be unanchored: fluorescence images show a Myp2 ring of smaller radius than the Myo2 ring (Laplanche et al., 2015), and Myp2 vanishes from the ring following Latrunculin A-mediated disassembly (Takaine et al., 2015). Here we measured ring tension in fission yeast protoplasts. We found ~650 pN tension in wild type cells, ~65% the normal tension in mpy2 deletion mutants and ~40% normal tension in myo2-E1 mutant cells with negligible ATPase activity and reduced actin binding.

To understand the relation between organization and tension, we developed a molecularly explicit simulation of the fission yeast ring with the above organization. Our simulations revealed a clear division of labor between the 2 myosin-II isoforms, which maintains organization and maximal tension. (1) Myo2 anchors the ring to the plasma membrane, and transmits ring tension to the membrane. (2) Myo2, extending ~100 nm away from the membrane, bundles half (~25) of the actin filaments in the cross-section due to filament packing constraints, as only ~25 filaments are within reach. (3) To increase tension requires that the ring be thickened, as tensions in the ~25 membrane-proximal filaments are close to fracture. (4) Unanchored Myp2 indeed enables thickening, by bundling an additional ~25 filaments and doubling tension. Anchoring of these filaments to the membrane is indirect, via filaments shared with the anchored Myo2.

In simulated myo2-E1 rings ~20% of the actin filaments peeled away from the ring and formed Myp2-dressed bridges, as observed experimentally in myo2-E1 cells. The organization in simulated Δmyp2 rings was highly disrupted, with ~50% of the actin filaments unbundled.

In summary, beyond their widely recognized job to pull actin and generate tension, myosin-II isoforms are vital crosslinking organizational elements of the ring. Two isoforms in the ring cooperate to organize the ring for maximal actomyosin interaction and tension.

Self organization in liquid droplets of cross-linked actin filaments.
K.L. Weirich, K. Dasbiswas, S. Banerjee, T.A. Witten, S. Vaikuntanathan, M.L. Gardel; 1James Franck Institute, University of Chicago, Chicago, IL, 2Department of Physics and Astronomy, University College London, London, United Kingdom, 3Department of Physics, University of Chicago, Chicago, IL, 4Department of Chemistry, University of Chicago, Chicago, IL, 5Institute for Biophysical Dynamics, University of Chicago, Chicago, IL

Soft materials constructed from biomolecules self-assemble into a myriad of structures that work in concert to support cell physiology. One critical soft material is the actin cytoskeleton, a viscoelastic gel composed of cross-linked actin filaments. Although actin networks are primarily known for their elastic properties, which are crucial to regulating cell mechanics, the viscous behavior has been theorized to enable shape changes and flows. We experimentally demonstrate a liquid phase of cross-linked actin using a model system where cross-linker condenses dilute short actin filaments into spindle-shaped droplets, called tactoids. By theoretically describing the tactoid shape dynamics with a liquid crystal continuum model, we find that the cross-linker provides a tunable parameter to modulate the liquid interfacial tension and viscosity. In cells, the molecular motor myosin II binds to and translocates actin filaments, creating contractile actomyosin structures. In liquid actin tactoids, we find that myosin II filaments self-organize at the equator, reminiscent of organization observed in mitotic spindles. The motors also cluster, eventually creating distortions in the actin liquid crystal resulting in tactoid deformation. Our results demonstrate self-organization in cytoskeletal assemblies and provide insight to how anisotropy influences structures formed from macromolecular liquid phases.

A-Band Assembly in Vertebrate Cardiac and Skeletal Muscles Observed with Super-resolution Microscopy.
J. Wang, M. Welchons, Y. Fan, J.M. Sanger, J.W. Sanger; 1Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Myofibrils in vertebrate cardiac and skeletal muscle are organized in aligned arrays of filaments formed from multiple protein components. Despite considerable functional information on individual proteins, determining how they assemble de novo into mature myofibrils is still an imposing challenge. Studies of sarcomeric protein localization during myofibril assembly in our lab has led us to propose that assembly proceeds in a three-step progression from premyofibrils to nascent myofibrils, culminating in the formation of mature myofibrils. This is accompanied by transitions in myosin isoforms and maturation in structure (reviewed in Sanger et al., 2017). Premyofibrils, forming initially at the spreading edges of muscle cells, are composed of minisarcomeres that contain small bands of non-muscle myosin II filaments alternating with muscle-specific alpha-actinin-enriched Z-Bodies attached to thin actin filaments. Titin and muscle myosin molecules first appear in nascent myofibrils, and the Z-Bodies in adjacent fibrils align to form beaded Z-Bands. In addition to non-muscle myosin II, muscle-specific myosin filaments in nascent myofibrils localize in an overlapping arrangement when viewed in widefield and confocal microscopes. In the mature myofibrils, non-muscle myosin II is absent and M-Band proteins localize to the muscle-specific myosin filaments, presumably aiding their alignment by cross-linking them into A-Bands. Super-resolution microscopes (SIM and STED) were used in this study to uncover details of the arrangement of the two different types of myosins in nascent myofibrils. With
this technology, filaments of non-muscle myosin II in nascent myofibrils appear to be flanked by mini-A-bands of muscle-specific myosin. Furthermore, in contrast to decades-old statements that vertebrate muscle myosin thick filaments form at their final 1.6 micron lengths, mini-A-bands are first detected at a length of about 0.4 microns. The bands gradually increase four-fold in length to 1.6 microns in elongating myotubes and spreading cardiomyocytes. These new discoveries in vertebrate muscle cells share a common characteristic with nonvertebrate muscles where some A-Bands can grow to lengths reaching 25 microns.

Actin rod formation and cytoskeletal dysregulation in the neurodegenerative motoneuron disease Spinal Muscular Atrophy (SMA).
S. Rademacher¹, N. Hensel¹, L. Walter¹, I. Wefel¹, G. Brandes¹, P. Claus¹;¹²;¹
¹Institute of Neuroanatomy and Cell Biology, Hannover Medical School, Hannover, Germany, ²Center for Systems Neuroscience (ZSN), Hannover, Germany

Cytoskeletal dysregulation and impaired maintenance of neuromuscular junctions (NMJs) partially lead to muscle denervation followed by muscle atrophy in SMA. We and others showed that the RhoA/ROCK pathway, a key pathway in the control of the actin cytoskeleton, is hyperactive in SMA. Nonetheless, responsible receptor-ligand interactions upstream of RhoA/ROCK are poorly understood. Based on transcriptome analysis in SMN-depleted NSC34 cells, we identified the guidance receptor PlexinD1 (PLXND1) as a potential upstream effector. Due to its role in axonal guidance, NMJ maintenance, control of monosynaptic specificity of reflex arcs, and vascularization, we analyzed the role of PlexinD1 in different in vitro and in vivo SMA models with regard to SMA pathology. PLXND1 was differentially expressed in SMN-depleted NSC34 cells, but the protein level was unchanged compared to control cells. Interestingly, PLXND1 formed predominantly intranuclear aggregates in about 50% of the cells upon SMN knockdown and in 10% of the control cells. Those structures were also detected in lumbar spinal cord sections of SMA model mice starting pre-symptomatically at P3. Density gradient enrichment of the structures from NSC34 cells revealed them as actin rods (actin-containing, aggregate-like pathologic structures known from other neurodegenerative diseases and congenital myopathies) which were here decorated with an intracellular PLXND1 cleavage product. Additionally, we found that PLXND1 is processed by a metalloprotease (MP) and that its cleavage altered the cellular response to PLXND1’s specific ligand Semaphorin3E (SEMA3E) as assessed by quantification of growth cone collapse. Actin rods are initially protective to prevent ATP decline upon oxidative stress. When the stress persists, rods become permanent and develop pathologic features. Since we detected rods prior to onset of symptoms in SMA mice, our data suggest that actin rods contribute to SMA pathogenesis even upon ASO-mediated SMN increase. Additionally, a PLXND1 fragment binds to rods and its cleavage as well as signal transduction were restored by knockdown or inhibition of MPs. Therefore, the responsible MP displays a putative novel target for a combinatorial treatment of SMA. Whether MP inhibition in vivo prevents rod formation and PLXND1 cleavage as a molecular link to vascularization defects, altered NMJ maturation and malformed monosynaptic reflex arcs as seen in SMA, will be part of future investigations.
Dynamic interplay between filopodia, focal adhesions and stress fibers.

Actin mediates migration both by providing a protrusive or “pushing” force against the plasma membrane, as well as a contractile or “pulling” force in combination with myosin II. Filopodia are protrusive structures at the leading edge, whereas stress fibers (SF) are contractile structures. Here, we use dynamic Airyscan microscopy to examine the coordination of these two structures at focal adhesions (FA) in U2OS cells, and find an interesting reciprocal relationship in both actively spreading and stably spread cells. In spreading cells, the majority of new FAs (72%) are assembled directly at the sites of filopodial protrusion, with two main locations of new adhesion: at the filopodial base, and within the filopodial shaft. These nascent FA not homogenous, but are composed of parallel linear units of 0.3 micron width. As the cell spreads, the FA and their associated SF undergo a progressive series of longitudinal “splitting” events, resulting in mature FA of single linear units. These structures further differentiate to the three SF classes previously identified in stably spread cells: ventral SF, dorsal SF and transverse arcs. A different relationship between filopodia and SF exists in stably spread cells, whereby a disproportionate percentage of filopodia (84%) arise directly from FA. We have quantitatively analyzed the roles of four actin-regulators (Arp2/3 complex, FMNL3, mDia1, and VASP) in the assembly and dynamics of filopodia, FA, and the three SF sub-types, with each regulator having distinct effects. From these studies, we propose that FAs can assemble either filopodia or SF, depending on the complement of assembly factors. Arp2/3 complex, mDia1 and VASP are necessary for FA-based actin assembly in general, whereas FMNL3 is crucial for coordinating filopodia assembly. VASP’s role in FA-mediated filopodial assembly is at the FA itself, not at the filopodial tip. Little detectable VASP is present at filopodia in U2OS cells, in contrast to past studies showing abundant VASP at filopodia tips in neuronal growth cones. Together, our findings highlight a striking coordination between filopodia and SF assembly in migrating cells.

Filamentation in *Schizosaccharomyces japonicus* in response to natural stimuli.

*Schizosaccharomyces japonicus* is a dimorphic fungus related to the well-established fission yeast *Schizosaccharomyces pombe*. It is the only fission yeast able to undergo hyphal growth, which it does in response to nutritional, nitrogen and DNA damage stresses. We identified a new inducer of vegetative hyphal formation that is independent of nutrient stress: grape extract. The unique ability of *S. japonicus* to undergo such fast cell shape modification provides an ideal and fascinating model to study dimorphism in this distant ascomycete clade. A first part of the project aims to describe and characterize *S. japonicus* morphological transition from yeast to filamentous growth. Interestingly, we found that it does not assemble a classical Spitzenkörper, a well-described spherical structure guiding hyphal growth observed in other filamentous organisms such as *Neurospora crassa* or *Candida albicans*. We also observed that *S. japonicus* does not form multi-septated filaments and appears to stay mononuclear during its life cycle therefore underlining again its distinctness from other well studied filamentous fungi. We also described cytoskeleton behavior and vesicular transport associated with the change in
type of growth. Interestingly, we noticed that actin and microtubule cables were partially colocalizing in both the yeast form and the hyphal form suggesting cooperation in delivery of cargo to the tips. A second part of the project aims to identify the genes involved in the transition. To do so, we used RNA sequencing to study gene expression changes, over time, upon addition of the hyphal inducer. This work will help us understand what genes and metabolic pathways are involved in filamentation and shed light on how S. japonicus can achieve such a dramatic change in growth.

Intranuclear and cytoplasmic actin rod assembly in Dictyostelium discoideum.
H.C. Ishikawa-Ankerhold1, A. Müller-Taubenberger2;
1Cardiology, Walter Brendel Centre of Experimental Medicine, LMU Munich, Munich, Germany, 2Cell Biology (Anatomy III), Biomedical Center, LMU Munich, Planegg-Martinsried, Germany

Intranuclear and cytoplasmic rods are aggregates consisting of actin and coflin that are formed in consequence of chemical or mechanical stress. The formation of actin rods is associated with a variety of pathological conditions in humans such as Nemaline myopathy and certain neurological disorders. It is still not well understood what exactly triggers the formation of rods, and what the underlying mechanisms of rod assembly or disassembly are. Furthermore, it is unclear whether other proteins contribute to the formation of rods. We have used Dictyostelium discoideum as a model to study appearance, stages of assembly, composition, stability, and dismantling of intranuclear rods. We have employed in-vivo microscopy of cells expressing fluorescently labeled proteins as well as immunolabeling, and have analyzed wild-type or mutant cells lacking specific actin-binding proteins under different conditions that provoke the formation of actin rods. Our data show that intranuclear rods, in addition to actin and coflin, are composed of a distinct set of other proteins comprising actin-interacting protein 1 (Aip1), coronin (CorA), filactin (Fia), and the 34 kDa actin-bundling protein B (AbpB). A finely tuned spatio-temporal pattern of protein recruitment was found during formation of rods. Aip1 is important for the final state of rod compaction indicating that Aip1 plays a major role in shaping the intranuclear rods. In the absence of both Aip1 and CorA, rods are not formed in the nucleus, suggesting that a sufficient supply of monomeric actin is a prerequisite for rod formation. Furthermore, we have explored the conditions that lead to the induction of cytoplasmic actin-cofilin rods, and show that rods formed in the cytoplasm are characterized by a greater variability in appearance and shape.

Identifying actin cytoskeletal components required for actin-based motility in the frog-killing chytrid fungus: Batrachochytrium dendrobatidis (Bd).
M.R. Kakley1, L. Fritz-Laylin3;
1Department of Biology, University of Massachusetts Amherst, Amherst, MA

Chytrids are a polyphyletic clade of fungi categorized by their flagellated zoospores. They represent an ancient lineage diverging over 800 million years ago from their most recent common ancestor. The chytrid species Batrachochytrium dendrobatidis (Bd) has a 2-stage life cycle; a flagellated non-substrate
dependent zoospore, and a substrate-dependent zoosporangium. The swimming zoospore attaches to the substrate and forms a cell wall, transitioning to a zoosporangium. Immediately after release from the zoosporangium, we have observed zoospores swimming with flagella but also creating dynamic actin-filled structures used to crawl. The Bd cytoskeleton includes polymerized branched actin networks and activated Arp 2/3 complexes, creating pseudopods within the first 6-10 hours. We are identifying the components that differentiate branched actin networks used for motility, rather than other cellular functions (i.e. cytokinesis, endocytosis, etc.), by identifying gene orthologs of components and regulators of the actin cytoskeleton in Bd and other chyrid species, some of which appear to crawl, and others that do not. We expect motility-specific genes to be conserved exclusively in crawling chyrid species.

Anti-Inflammatory effects of annonacin in vascular endothelium in response to TNF-α-induced cell stress.

G.D. VanNorden\(^1\), E. Chambers\(^1\), E. Charamut\(^1\), C. Kovaleski\(^1\), F. Mayville\(^1\), J.B. Slee\(^1\);

\(^1\)Department of Natural Science, DeSales University, Center Valley, PA

Annonacin, an acetogenic compound present in certain tropical fruits, like the pawpaw fruit, has been noted to have anti-inflammatory properties; however, the mechanisms underlying these anti-inflammatory properties are still being characterized. The actin cytoskeleton has been shown to reorganize into stress fibers following treatment with various forms of mechanical and chemical cell stress. An established model of cell stress in vascular endothelial cells uses TNFα to induce an accumulation of actin stress fibers. We hypothesize that pretreatment with annonacin prior to TNF-α will prevent cell stress in vascular endothelial cells. Annonacin was extracted from the North American pawpaw fruit using Soxhlet Extraction, and verified using IR, NMR, and UV spectroscopy. Pretreatment of vascular endothelial cells with annonacin prior to TNF-α treatment resulted in a marked decrease in actin stress fiber number and intensity. These data suggest that annonacin may be involved in preventing inflammation at the cellular level.

Anti-Inflammatory effects of resveratrol in vascular endothelium in response to TNF-α-induced cell stress.

B. Evert\(^1\), T. Judge\(^1\), C. McGlocklin\(^1\), F. Mayville\(^1\), J.B. Slee\(^1\);

\(^1\)Department of Natural Science, DeSales University, Center Valley, PA

Resveratrol, an antioxidant found in high concentrations in red grapes and wine, is thought to have beneficial effects on cardiovascular disease and incisional wound healing. Studies of resveratrol have shown that it possesses anti-inflammatory properties, which may help reduce the TNF-α-induced inflammation upregulated in cardiovascular disease. The actin cytoskeleton has been shown to reorganize into stress fibers following treatment with various forms of mechanical and chemical cell stress. An established model of cell stress in vascular endothelial cells uses TNFα to induce an accumulation of actin stress fibers. We hypothesize that pretreatment with resveratrol prior to TNF-α will reduce cell stress in vascular endothelial cells. Resveratrol was extracted from red wine (Merlot) using liquid-liquid extraction, and verified using IR, NMR, and UV spectroscopy. Preliminary data suggest that pretreatment of vascular endothelial cells with resveratrol prior to TNF-α treatment resulted in an
apparent increase in actin stress fiber number and intensity. These data suggest that resveratrol in higher concentrations may be involved in promoting inflammation at the cellular level.

Evolution and interplay of axonal actin assemblies.
P. Dubey\(^1\), K. Ladt\(^2\), J. Loi\(^3\), S. Roy\(^4\);
\(^1\)Department of Pathology, University of Wisconsin-Madison, Madison, WI, \(^2\)Department of Neurosciences, University of California, San Diego, WI, \(^3\)Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison, Madison, WI

Actin dynamics are fundamental to neuronal survival, growth, and differentiation. Most studies on neuronal actin have focused on terminal growth cones and synapses, and actin along axon shafts has been relatively unexplored. More recent experiments have revealed three distinct types of cytoskeletal structures in axons: actin waves, actin rings, and actin trails. While actin waves are growth cone-like structures that originate near the cell body and move towards the neurite tips; actin rings are stable, circumferential, and periodic cytoskeletal structures that are separated by spectrin tetramers. Actin trails are dynamic filaments that elongate bidirectionally, originating from discrete actin foci inside the axon shaft. Though all three assemblies organize into very different structures, they are fundamentally composed of the same cytoskeletal protein, and may have underlying commonalities that can lead to new biological insight. Working on this premise, we examined various axonal actin assemblies in cultured hippocampal neurons as they mature. We found that the actin rings are visible in the putative axon as early as two days after plating, predominantly as nascent patches of loosely organized “ring-like” structures. As the axon develops, the discrete patches become continuous, probably by coalescing. Interestingly, although the frequency of actin waves diminishes over time, actin rings and trails become more numerous and prominent as the neurons develop. While perturbation of actin rings – by knockdown of βII-spectrin – had no effect on actin waves, there was a striking attenuation of actin trails; suggesting mechanistic links between the actin rings and trails. Current experiments in the lab are focused on investigating the nature of this relationship, and underlying mechanisms.

Autonomous structure formation and contraction of actomyosin regulated by contractile ring related cross-linking proteins (CRCPs).
K. Matsuda\(^5\), M. Sugawa\(^5\), J. Yajima\(^5\);
\(^1\)Dept. of Life Sciences, Univ. of Tokyo, Tokyo, Japan

While actin makes various structures, which play important roles in eukaryotic cells such as morphogenesis and cytokinesis, it is not that these functions are achieved both by only actin dynamics. A variety of ordered structures are formed and changed by both ATP-hydrolyzing motor, myosin that drives F-actin and crosslinking proteins that connect F-actin to each other in an ATP independent manner. Currently, collaborative structure formation and contraction by these three kinds of proteins are attracting attention. However detailed mechanisms are not yet understood. In this study, we reconstruct actin network using actin, myosin and contractile ring related cross-linking protein (CRCP) to characterize CRCP function in autonomous structure formation and contraction. In the solution of G-actin and myosin, the minimum clusters, which F-actin were contracted by myosins in minimum-scale, were formed immediately after the start of the assay in the presence of ATP. When CRCP was added to
the solution, the F-actin networks were first formed and shrunk locally. The size of this network and contraction expanded as the concentration of CRCP (CCRCP) increased. We also found that the contraction initiation time (CIT) was constant with a range of ATP 1 – 6 mM (CATP) when CRCP was absent or low concentration. Conversely, when the CCRCP was high, CIT was delayed as the CATP increased. It was also found that myosin was able to cleave F-actin crosslinked by CRCP at low CATP.

These results suggested that (i) the actin network formed by crosslinking of CRCP is not able to contract owing to the balance of forces across the network, (ii) a trigger element, which is considered to be dissociation of CRCP from F-actin in the case of low CCRCP and severing of F-actin in the case of high CCRCP, is necessary to contract the network.

Shootin1-Mediated Dendritic Spine Formation in Hippocampal Neurons.
R.F. Kastian¹, H. Katsuno¹, N. Inagaki¹;
¹Biological Sciences, Nara Institute of Science and Technology, Ikoma, Japan

Dendritic spines are actin-enriched protrusions emanating from dendritic shafts and provide contact sites for axons to form synapses. They are thought to play key roles in learning and memory. Dynamic filopodia-like spines are precursors of dendritic spines, which are thin and long, and commonly observed in the early developmental stages of neurons. As neurons mature, filopodia-like spines change into mushroom-shaped spines and form stable synapses. The morphological changes of dendritic spines require a dynamic network of actin. It has been demonstrated that actin filament (F-actin) polymerizes at the tip of filopodia-like spines and undergoes retrograde movement (Tatavarty et al., Mol. Biol. Cell, 2012). Here we analyzed a possibility that the spine formation is regulated by a mechanical linkage between F-actin retrograde flow and cell adhesion through molecular clutch. Shootin1a is a brain-specific clutch molecule involved in the axon outgrowth and neuronal polarity formation (Toriyama et al., J. Cell. Biol., 2006; Shimada et al., J. Cell. Biol., 2008). Shootin1a mechanically couples F-actin and cell adhesion molecule, L1-CAM, through actin-binding protein, cortactin, in order to generate traction force for axon outgrowth (Kubo et al., J. Cell. Biol., 2015). In this study, we show that shootin1a was detected not only in early stage (DIV 3) but also in the later stages (DIV 7, DIV14 and DIV 28) of cultured hippocampal neurons. Our immunocytochemistry assay showed that shootin1a is co-localized with PSD-95, a postsynaptic marker protein. Additionally, shootin1a is also co-localized with F-actin, cortactin and L1-CAM in dendritic spines and highly accumulated at the tip of filopodia-like spines. Suppression of shootin1a by RNAi led to a significant decrease in number of postsynapses and presynapses, which are stained with PSD-95 and synaptophysin, respectively. Similar data were obtained with hippocampal neurons cultured from shootin1 knockout mice. Furthermore, our in vivo data showed that hippocampal neurons in shootin1-KO mice brain exhibited a low number of dendritic spines compared to those in wildtype. The numbers of mushroom-shaped spines were also lower in the shootin1-KO mice brain. Taken together, these data suggest that shootin1a is involved in the dendritic spine formation, probably mediating the linkage between F-actin retrograde flow and L1-CAM as a clutch molecule.
The Sharpin interactome reveals a role for Sharpin in lamellipodium formation via the Arp2/3 complex.

Sharpin, a multifunctional adaptor protein, regulates several signalling pathways. For example, Sharpin enhances signal-induced NF-kB signalling as part of the linear ubiquitin assembly complex (LUBAC) and inhibits integrins, the T cell receptor, caspase1 and PTEN. However, despite recent insights into Sharpin and LUBAC function, a systematic approach to identify signalling pathways regulated by Sharpin has not been reported. Here, we present the first ‘Sharpin interactome’, which identifies a large amount of novel potential Sharpin interactors in addition to several known ones. These data suggest that Sharpin and LUBAC might regulate a larger number of biological processes than previously identified, such as endosomal trafficking, RNA processing, metabolism and cytoskeleton regulation. Importantly, using the Sharpin interactome we have identified a novel role for Sharpin in lamellipodium formation. We demonstrate that Sharpin interacts with Arp2/3, a protein complex that catalyses actin filament branching. We identified the Arp2/3-binding site in Sharpin and demonstrate using a specific Arp2/3-binding deficient mutant that the Sharpin-Arp2/3 interaction promotes lamellipodium formation in a LUBAC-independent fashion.

Three-dimensional simulation of remodeling lamellipodial actin filament network.

D. Holz¹, A. Hall¹, D. Vavylonis¹;
¹Physics, Lehigh University, 18015, PA, ²Physics, University of Wisconsin-Milwaukee, 53211, WI

The dense actin network of branched filaments provides the driving force for lamellipodial protrusions. Within this network, filaments undergo structural network changes such as polymerization, depolymerization, branching, capping, and severing. Electron microscopy of the lamellipodia has revealed that the structure of filaments vary with distance to the leading edge. Near the leading edge filaments are short within a dense brushwork. Density decreases with distance from the leading edge and filaments in the rear are longer and appear more linear. The mechanisms behind this remodeling have yet to be determined. We created a three-dimensional stochastic model at the filament level to understand how size and structural properties are regulated within lamellipodia. We found the size of the lamellipodia depends on polymerization, depolymerization, branching, capping, and severing. Larger severing rates resulted in lamellipodia with smaller depths. Lamellipodia with branching throughout caused an increase in the depth. Our simulation also reproduces orientation patterns similar to the two-dimensional simulations. These mechanisms are being studied to better understand the process of lamellipodial remodeling.

Mutations in Non-muscle Myosin 2A Disrupt Actomyosin-Microtubule Dynamics Resulting in Male Infertility.
D.C. Sung1, C.B. Lerma Cervantes1, Y. Zhang1, X. Ma1, R.S. Adelstein1;
1Genetics and Developmental Biology Center, National Heart, Lung, and Blood Institute, Bethesda, MD

Mutations in non-muscle myosin 2A (NM2A) encompass a wide spectrum of anomalies collectively known as MYH9-Related Disease (MYH9-RD) that can include cataracts, glomerulosclerosis, macrothrombocytopenia, and deafness. We previously created mouse models of the three mutations most frequently found in humans: R702C, D1424N, and E1841K. While homozygous R702C and D1424N mutations are embryonic lethal, we found homozygous mutant E1841K mice to be viable, but male, and not female, mice were infertile. Here, we report that E1841K homozygous males have reduced testes size with defects in Sertoli-Sertoli and Sertoli-germ cell junctions, resulting in loss of blood-testis barrier integrity and premature germ cell loss. Furthermore, excessive acetylation of tubulin in mutant testes and Sertoli cells are correlated with actin disorganization indicating potential disruptions in actomyosin-microtubule dynamics. Analysis of NM2A and tubulin expression in primary Sertoli cells in culture shows that mutant cells have abnormal NM2A distribution, form thicker filaments, and fail to coordinate spatial localization of NM2A and tubulin. Together, these results identify a previously unreported characteristic of NM2A mutations in MYH9-RD mouse models and provide further insight into the role of NM2A in regulating actomyosin-microtubule dynamics in Sertoli cells to support germ cell maturation during postnatal testes development.

Nonmuscle Myosin 2 Is Important for Atrioventricular Endocardial Cushion Remodeling.
X. Ma1, D.C. Sung1, R.S. Adelstein1;
1LMC/GDBC, NHLBI/NIH, Bethesda, MD

Anomalies in endocardial cushion formation lead to the most common congenital cardiac defects including septal defects (atria, ventricular and atrioventricular septal defects) and cardiac valve disease. We have previously shown that mice globally ablated for nonmuscle myosin 2B (NM 2B) developed cardiac structural defects such as double outlet of the right ventricle (DORV) and ventricular septal defects (VSD). Moreover, global introduction of the NM 2B motor-impairing mutation (R709C) into mice resulted in an additional cardiac defect, the abnormal enlargement of atrioventricular (AV) endocardial cushions. This study is designed to understand the role of NM 2 in regulating cardiac cushion development by conditional ablation of NM 2A and/or 2B from endocardial cells in mice using Nfatc1-cre. Ablation of either NM 2A (A\(^{f\text{natc}1}/A^{\text{f\text{natc}1}}\)) or 2B (B\(^{f\text{natc}1}/B^{\text{f\text{natc}1}}\)) alone in endocardial cells does not affect AV cushion remodeling. However compound ablation of NM 2B together with one allele of NM 2A (A\(^{f\text{natc}1}/A^{\text{f\text{natc}1}}\); B\(^{\text{f\text{natc}1}}/B^{\text{f\text{natc}1}}\)) results in markedly increasing the thickness of AV cushions at E14.5 and E17.5. A\(^{+/f\text{natc}1}\); B\(^{f\text{natc}1}/B^{\text{f\text{natc}1}}\) AV cushions are less compact with a reduced cell density compared to control cushions. A\(^{+/f\text{natc}1}\); B\(^{f\text{natc}1}/B^{\text{f\text{natc}1}}\) cushions also show reduced mesenchymal cell apoptotic activity, but no changes in their proliferative activity compared to controls. Compound A\(^{f\text{natc}1}/A^{\text{f\text{natc}1}}\); B\(^{f\text{natc}1}/B^{\text{f\text{natc}1}}\) cushions show a moderate increase in cushion thickness, but not as severe as A\(^{+/f\text{natc}1}\); B\(^{f\text{natc}1}/B^{\text{f\text{natc}1}}\) cushions, compared to control cushions. The data demonstrate that NM 2 (2A and 2B) is required for AV cushion
remodeling to form thin and elongated normal cardiac AV valves. Since mice expressing motor-impaired R709C-NM 2B showed similar defects in cushion remodeling compared to compound endocardial NM 2A/2B ablated mice, these results provide further direct evidence that mutant NM 2B interferes with NM 2A in cardiac cushion remodeling.

The term of contact guidance describes a phenomena of microenvironment geometry dependent orientation and motility of cells. In vivo contact guidance is responsible for both proper positioning and migration of cells inside the growing embryo and during maintenance of adult tissues. As non-muscle myosin 2A and 2B proteins were shown to be crucial for embryonic development and cell migration we addressed their functions in contact guidance using a micropatterning technique to allow precise control over the topography of microenvironment in order to dissect out possible non-redundant functions of these isoforms. We found that absence of NM 2B altered contact guidance of fibroblasts manifesting in substantial loss of cellular projections and uniaxial directional polarization, increased contractility and elasticity of cells. Using cytoskeleton targeting compounds and series of genetic transformations we verified a possible role of 2B isoform in contact guidance and proposed a model in which roles of NM 2A and 2B isoforms diverge in control over structure of actin cytoskeleton and its crosstalk with microtubules.

Nonmuscle Myosin 2 (NM2) is an actin associated motor protein that is essential for cellular processes like adhesion, migration, polarity, and division. The NM2 family is composed of three isoforms, NM2A, NM2B, and NM2C. Each of these isoform has unique and redundant functions in cells due to differences in their affinity for actin and ATPase activity. Our previous work demonstrated that NM2 function (isoforms NM2A and NM2B) is critical for both compensatory and constitutive clathrin mediated endocytosis. Previous studies have shown that point mutations in the NM2A gene, MYH9, are associated with human diseases involving blood, eye, ear and kidney disorders. We hypothesized that
the underlying mechanism in NM2 related kidney disorders is compromised renal tubular endocytosis resulting in decreased protein reabsorption. Consistent with this hypothesis all three isoforms are expressed in the renal tubules with NM2B and NM2C being the predominant isoforms expressed in the renal tubules. Although NM2A is expressed to a similar degree as the other isoforms in whole kidney lysates, its distribution in the renal tubules is limited to a single segment, the loop of Henle. The distinct localization of the NM2 isoforms within the epithelial cells of the renal tubules suggests that each isoform has a unique function and loss of each isoform may lead to specific pathophysiology. Inducible conditional inactivation of NM2A, NM2B, and both NM2A/NM2B within the renal tubules of adult mice using the doxycycline inducible Pax8-rtTA; Tet-O-Cre system revealed critical roles of NM2A and NM2B in the renal tubules. Histological evaluation showed that both NM2A and NM2B single knockout mice have mild tubular dilation by 20 weeks of age with infiltrating cells that progressed over time especially in the NM2A knockout mice. The NM2A/NM2B double knockout mice show decreased urine pH and increased blood urea nitrogen and serum creatinine levels by 9 weeks of age. Histological analysis revealed major tubular dilation as well as glomerular sclerosis by 12 weeks of age and mice were moribund by 13 weeks of age. Our data demonstrates the critical role of NM2 in maintaining normal renal tubular function in the adult mouse kidney. In addition, these inducible conditional knockout models will be excellent models to study the progression of kidney disease.

The role of nonmuscle myosin 2A in early embryonic development.
T. Wei1, X. Ma1, R.S. Adelstein1;
1Laboratory of Molecular Cardiology, NHLBI/NIH, Bethesda, MD

Nonmuscle myosin 2A (NM 2A) not only plays numerous and diverse roles in vertebrate development, but also functions as a negative regulator for the formation of squamous cell carcinoma (SSC). Our previous research reported that ablation of NM 2A in mice (A-/A-) led to abnormal formation of the visceral endoderm and embryonic lethality by E7.5. However, the molecular mechanisms responsible for A-/A- embryonic lethality were not fully characterized. Since in vitro differentiation of embryonic stem cells (ESCs) has been shown to faithfully mimic in vivo early embryonic development, we first established mouse ESC differentiation systems, including a spontaneous differentiation system and a hematopoietic differentiation system. The morphology of A-/A- ESCs was less organized and the surface cells were frequently scattered, in contrast to the tightly clustered A+/A+ ESCs. A-/A- ESCs significantly increased Sox2 and Nanog expression by almost 30 percent. Moreover, spontaneous differentiation of NM 2A deleted ESCs inhibited endoderm expression of genes, such as Sox17, Foxa2, and HNF4a. Analysis of the cell cycle with propidium iodide revealed that the peaks of G1 and G2/M shifted to the right in A-/A- embryonic body (EB) cells, indicating the increased binding of the propidium iodide to the DNA in the A-/A- cells compared to controls, by day 6 of EB formation. These data suggest that NM 2A deletion could affect chromatin structures. Using a nucleosomal DNA prep kit, it was determined that the genomic DNA of A-/A- ESCs or EBs was more easily digested into nucleosomes than control counterparts. Moreover, the levels of tri-methylation of K9 and K27 on histone H3 (H3K27me3 and H3K9me3, markers for repressive signals controlling development regulators), were significantly decreased in A-/A- EBs. These data indicate that there is a difference in chromatin structures between the wild-type and the A-/A- EBs. Because chromatin change has been demonstrated to be critical in early embryonic development, we hypothesize that ablation of NM 2A induces chromatin changes which consequently affect early embryonic development. Hematopoietic differentiation of ESCs in vitro is a useful method for investigating the molecular mechanisms controlling hematopoietic fate decisions. The ESC hematopoietic differentiation system has been widely used to study primitive hematopoiesis,
including hematopoietic progenitors, primitive erythropoiesis, and primitive macrophage development. Flow cytometry analyses showed that A-/A- EBs yielded a 50 percent reduction in hematopoietic progenitors by day 6. Since primitive hematopoiesis occurs in mouse embryogenesis about E7.5, these data suggest that abnormal primitive hematopoiesis might be one cause of embryonic lethality of NM 2A knockout mice.

Intestinal enteroids: A 3D model system to study the role of cytoskeletal dynamics and motor proteins in epithelial cell extrusion.
K. Remmert1, J.A. Hammer III1;
1NHLBI, CBPC, NIH, Bethesda, MD

Epithelia are a composed of highly-specialized cells that come together to form barriers between different compartments within an organism. Importantly, epithelia perform their barrier function while at the same time being highly regulated and dynamic. This way, epithelial cells regulate the transport of solutes, fluids, macromolecules, and immune cells/pathogens through the space between them, while preserving epithelial integrity. Epithelia also maintain their integrity in the face of a constant removal of damaged cells and addition of fresh cells. This process is very pronounced in mammalian gut, where the shedding of cells at the villus tip in a process known as apical cell extrusion is counterbalanced by recurring cell divisions in the stem cell population located in the villus crypt. Cell extrusion is essential for epithelial homeostasis because cells are constantly being damaged by exposure to toxins and infectious agents. Two striking features of apical cell extrusion are that both tight and adherens junctions remain functional during extrusion events, and that these junctions are intimately coupled to an underlying actomyosin cytoskeleton. Until now, most studies that looked at cytoskeletal dynamics during epithelial cell extrusion have focused on model epithelia (e.g. MDCK cells) growing on porous substrates. In this study, we adapted the 3D intestinal enteroid culture model to study the involvement of nonmuscle myosin 2 isoforms and their close relative myosin 18 in apical cell extrusion in a setting more closely reflecting the environment in the gut. To this end, we prepared enteroids from GFP myosin 2 A/B/C knock-in mice, as well as from mice expressing fluorescent reporter proteins. In addition, we introduced genes into epithelial stem cells using lenti virus. Immunostaining and live cell imaging revealed an interesting glimpse into how the different myosin 2 isoforms contribute to epithelial cell extrusion in the gut. First, the expression level and steady state localization of the three myosin 2 isoforms in intestinal enteroids is rather different. Myosin 2A is expressed at high levels and consistently localizes to cell:cell contacts, the apical domain and more diffusely in the cytoplasm. 2B, on the other hand, is expressed at very low levels without any striking localization pattern. Expression level of myosin 2C falls in between that of 2A and 2B and it is predominantly localized to the apical domain. Secondly both, myosin 2A and 2C dynamically change their localization pattern during extrusion events. Interestingly, myosin 2A is strongly enriched at the basal domain within the cell that is about to exit the epithelial layer, whereas myosin 2C seems to redistribute along the entire cell:cell contact area of the neighboring cells.

Identification and characterization of a putative myosin-mediated contractile activity in sponges.
E. Chang¹, C. Cotter¹, M.S. Hill¹, O.A. Quintero¹;
¹Department of Biology, University of Richmond, Richmond, VA

A relatively uncharted field of study concerns the evolution of muscles and muscle-like cells in the earliest animals (e.g., Porifera, Cnidaria). Freshwater and marine sponges display coordinated contractile ability in response to the presence of particular environmental cues. These simple animals offer the opportunity to explore the cellular origins of contraction in models absent of neurons or true muscle cells. Little is known about the cellular characteristics of contraction in sponges as traditional muscle-like tissues have not been identified or described. We have shown in field studies that sponges living in the Florida Keys (Cliona varians) contract in response to exposure to the neurotransmitter GABA. We measured contraction by analyzing the size of the oscular opening through quantitative video analysis. Laboratory-cultured Ephydatia fluviatilis, a fresh-water sponge, also contracted in response to GABA exposure. To determine if this contraction was acto-myosin mediated, we treated the E. fluviatilis sponges with blebbistatin prior to GABA exposure. Contraction was measured via quantitative analysis of time-lapse microscopy. We observed that blebbistatin pretreatment resulted in a delay in the onset of GABA-induced contraction. With the increase in availability of sequence databases, we also approached the question of contractility in sponges using an informatics. We took to the task of uncovering the muscle-like components by searching sponge databases for genes within the myosin superfamily. We searched within the genome of the Pacific Ocean sponge, Amphimedon queenslandica and within the transcriptome of Cliona varians. We found evidence for multiple myosin classes within both datasets, including multiple class II myosins in each species. We then compared the motor domains of the class II myosins to known striated muscle, smooth muscle, and non-muscle myosins from other species. Sequence alignment and phylogenetic analysis revealed that the majority of the C. varians myosin II like sequences grouped with the striated muscle myosin sequences. We then searched the A. queenslandica genome for other components present in the minimal muscle-like contractile unit, the sarcomere. Many of the sarcomere components were present in the sponge genome except for Troponin T. We also searched for evidence of the dystrophin complex, and the G-protein regulatory machinery. Few dystrophin complex components could be easily identified and strong evidence exists for G-protein mediated regulation. We would next like to understand the structure of contractile tissues as well as the mechanisms that lead to regulated tissue contraction. In doing so, we hope to further our understanding of the evolution of muscle and of contractility in general.

Myosin II A controls red blood cell membrane morphology and mechanical properties.
A.S. Smith¹, R.B. Nowak¹, S. Zhou², J. Wan², I.C. Ghiran³, V.M. Fowler⁴;
¹Molecular Medicine, The Scripps Research Institute, La Jolla, CA, ²Microsystems Engineering, Rochester Institute of Technology, Rochester, NY, ³Medicine, Beth Israel Deaconess Medical Center, Boston, MA

Nonmuscle myosin II (NMII) is an F-actin-activated Mg++ATPase that assembles into bipolar filaments and binds a variety of F-actin cytoskeletal structures to generate force to mediate diverse cellular processes such as migration, division, and shape changes. In mammalian red blood cells (RBCs) and other differentiated cell types, F-actin forms a network of short, membrane-associated filaments cross-
linked by spectrin tetramers. Previous studies have identified NMII in mature human RBCs, but whether and how NMII interacts with F-actin in the RBC spectrin-actin network, or if NMII controls RBC membrane properties and function, remain completely unknown. Here, we show that NMIIA is the NMII isoform present in RBCs and that it associates with the spectrin-actin network in an ATP-dependent manner, suggesting that this interaction involves NMIIA motor domains and the short F-actins in the network. Indeed, results from epifluorescence and TIRF microscopy reveal NMIIA puncta, identified as bipolar filaments by super-resolution microscopy, localized near the RBC membrane. The NMIIA heavy and light chains are both phosphorylated in vivo in RBCs, indicating that NMIIA motor activity and filament assembly are actively regulated. To test the function of NMIIA in RBC membrane morphology and mechanical properties, we treated RBCs with blebbistatin, an inhibitor of NMII motor activity. The results show that treatment with the active enantiomer of blebbistatin resulted in an altered distribution of NMIIA and F-actin at the RBC membrane, suggesting rearrangements in the long-range organization of the spectrin-actin network. In addition, RBCs treated with active blebbistatin exhibit elongated cell shapes and reduced biconcavity, as well as changes in membrane oscillations and increased membrane deformability in microfluidic assays. Together, this data characterizes a novel function for NMII in regulating cell membrane morphology and mechanical properties through interactions with the spectrin-actin network.

A Novel Role for Nonmuscle Myosin II Monomers in Regulation of Focal Adhesion Dynamics.
M. Shutova¹, T.M. Svitkina¹;
¹Biology, University of Pennsylvania, Philadelphia, PA

The role for nonmuscle myosin II (NMII) in positive regulation of actin stress fiber contraction, cell cortex tension and focal adhesion (FA) maturation is well established. In order to perform these functions, NMII must be activated by myosin light chain (MLC) phosphorylation and, according to the classic model, be polymerized into bipolar filaments. However, bipolar filament assembly and disassembly is regulated separately from NMII activation through MLC. A combination of these regulatory mechanisms, in principle, can produce motor-active but unpolymerized NMII molecules (monomers), which can represent a physiologically relevant functional NMII species in cells. Using methods of molecular cloning, biochemistry, and light and electron microscopy, we provide evidence that NMII monomers can regulate FA dynamics in cells. We show that endogenous MLC-activated NMII monomers exist in the cell and often associate with FAs through their tail domain. To explore their function, we created monomeric mutants of NMIIA and NMIIIB isoforms by deleting both Assembly Competence Domains (ACD1 and ACD2) from the respective heavy chains. The monomeric NMIIA and NMIIIB mutants neither formed bipolar filaments nor incorporated into stress fibers; however, TIRF microscopy revealed their increased accumulation in active cell protrusions and at the front and sides of the mature FAs. When expressed in cells, monomeric NMIIIB mutant produced a strong phenotype on cell adhesion. Specifically, cells overexpressing monomeric NMIIIB exhibited more dynamic protrusions, smaller FAs, thinner stress fibers, decreased spreading area, and eventually detached. Quantitative analysis of FA dynamics showed that overexpression of monomeric NMIIIB increased rates of both FA assembly and disassembly, but with greater enhancement of the disassembly rate. Time-lapse imaging revealed a correlation between the accumulation of monomeric NMIIIB at the front of a FA and subsequent FA disassembly. Monomeric NMIIIB mutant lacking the actin-binding motor domain also localized to the vicinity of FAs, whereas the isolated short C-terminal nonhelical tailpiece did not. We propose a model in which MLC-activated monomeric NMII is targeted to FAs through its tail domain and enhances FA dynamics. The mechanisms of FA regulation by monomeric NMII and NMII tail interaction partners are currently under investigation.

Myosin IIB mechanoresponsive accumulation is determined by relative assembly into bipolar filaments.
E.S. Schiffhauer¹, D.N. Robinson¹²;
¹Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Pharmacology and Molecular Science, Johns Hopkins University School of Medicine, Baltimore, MD

Mechanoresponse, the ability of cells to sense and respond to mechanical stimuli, drives essential processes such as cell division, tissue morphogenesis, cell migration, and metastasis. However, the direct mechanism by which the components of the cortical cytoskeleton assemble and interact to exert force and change cell shape in response to mechanical perturbations remains unclear. To quantify and characterize the contributions of the non-muscle myosin II paralogs to a responsive shape-change process, we perturbed cells by aspiration and defined the kinetics of fluorescent myosin IIA, IIB, or IIC accumulation to a region of high strain. We discovered that in a number mammalian of cell types, myosin IIA and IIC display similar kinetics and magnitudes of accumulation. However, myosin IIB displayed different magnitudes of accumulation in different cells types and in different phases of the cell cycle, indicating a unique regulatory system for myosin IIB mechanoresponse. In fact, the relative assembly of myosin IIB into bipolar thick filaments in these different situations, i.e. the ratio of assembled to unassembled myosin, reveals an optimal zone where myosin IIB mechanoresponse is highest. This is found where ~18% of the total myosin IIB is in the filament state, very similar to historical observations in Dictyostelium. Myosin IIB mechanoresponse can be perturbed by altering the assembly of myosin IIB by mimicking a phosphorylation event at S1935 in the heavy chain tail. Additionally, myosin IIA can influence the assembly state of myosin IIB and alter IIB mechanoresponse. Therefore, the cell can respond to network strain by accumulating myosin II to contract in opposition, and can regulate its response to this strain by tuning the relative assembly state of myosin IIB.

The role of cAMP and protein kinase A (PKA) in regulation of myosin II-dependent pigment granule aggregation in RPE of sunfish, Lepomis spp.
C. King-Smith¹, J.G. Quinlan¹, N.E. Fischer¹, E.A. Del Rio¹, M.L. Quinlan¹, M.T. Messalti¹;
¹Department of Biology, Saint Joseph's University, Philadelphia, PA

Retinomotor movements in eyes of fish and other lower invertebrate include long-distance migration of RPE pigment granules in response to light or dark. While it has been established that actin filaments and myosin motors, including myosin II and other unidentified plus-end myosins, are involved in pigment granule motility, the mechanisms and regulation of motility remain elusive. The benefits using fish RPE as a model system is that pigment granule movement can be chemically triggered, manipulated, and observed in isolated cells using relatively simple techniques, making this an extremely useful system for the study of organelle transport. In dissociated, cultured RPE cells, centripetal movement of pigment granules, which has been shown to be dependent on myosin II and ROCK activation, can be triggered by application of underivatized cAMP. We sought to confirm that cAMP stimulation of aggregation occurs through a canonical pathway involving activation of protein kinase A (PKA), and characterized targets of PKA phosphorylation in RPE to better understand the myosin II dependence and regulation of pigment granule motility. Isolated RPE cells from sunfish (Lepomis spp.) were microinjected with PKA catalytic subunit and the position of pigment granules (aggregated vs. dispersed) was compared that of un-
injected cells. PKA catalytic subunit stimulated pigment granule aggregation (N=6 cells) while pigment granules in uninjected cells remained dispersed. Previous results have demonstrated that pigment granules in sham-injected cells punctured with a microneedle similarly remain dispersed. Thus, cAMP-dependent activation of aggregation occurs via PKA phosphorylation. To identify PKA targets, RPE tissue was treated with phosphatase inhibitors and cAMP (stimulates pigment granule aggregation) or dopamine (stimulates pigment granule dispersion). PKA-phosphorylated proteins were identified by immunoblotting and immunoprecipitation using an anti-Ser/Thr PKA phosphorylated PKA substrate antibody. PKA-phosphorylated proteins in cAMP-treated samples were identified as 112, 82, and 42-48 kD proteins. Potential candidates for PKA-phosphorylated targets include proteins associated with the activation of myosin II.

**Differential actomyosin contractility in tumorigenecity.**

S.K. Dey¹, R.K. Singh¹, S.S. Jana¹;
¹Biological Chemistry, Indian Association for the Cultivation of Science, Kolkata, India

Bleb formation has been correlated with nonmuscle myosin II (NM-II) activity. Whether three isoforms of NM-II (NM-IIA, -IIB and -IIC) have the same or differential roles in bleb formation is not well understood. Here we report that ectopically expressed, GFP-tagged NM-II isoforms exhibit different types of membrane protrusions, such as NM-IIA induces multiple bleb protrusion and NM-IIC1 induces lamellipodia, whereas multiple blebs or lamellipodia formation was not affected by over expression of NM–IIB in tumor MCF-7 cells (Dey and Singh et al., MBoC 2017, 28:1034-1042). Of interest, NM-IIB has an almost 50% lower rate of dissociation from actin filament than NM-IIA and –IIC1 as determined by FRET analysis both at cell and bleb cortices. Interestingly, when cortex was ablated in metastasis tumor MDA MB 231 cells, we find majority of cells (88%) show multiple blebs formation whereas only 42% of normal MCF-10A cells shows multiple blebs formation upon cortex ablation, suggesting the presence of differential actomyosin contractility in the different degree of tumor cells. We correlate that differential actomyosin contractility is dependent on the type of NM II isoform present in the actomyosin complex. This study also suggests tumorigenecity can be evolved by changing the actomyosin contractility.

**Characterization of MYO19 knockdown phenotype in a cultured neuron-like cell line.**

J.L. Bocanegra¹, J.L. Hawthorne¹, B.M. Fujita¹, A. Li¹, O.A. Quintero¹;
¹Department of Biology, University of Richmond, Richmond, VA

Myosin-XIX (MYO19) is an actin-based motor protein implicated in normal mitochondrial dynamics and distribution. Mitochondrial movement and positioning is thought to be essential in order for energy intensive processes (such as cell division, cell motility, and morphogenesis) to occur efficiently. We hypothesized that MYO19 aids in mitochondrial dynamics and positioning during neuronal differentiation, a complex and energy intensive process resulting in long cellular extensions protruding from the cell body. During this cellular event MYO19 may be involved in supporting cell motility (growth cone or cell body motility) as well as overall morphogenesis (neurite establishment). In order to test this hypothesis, we used the murine, neuron-like CAD cell line and lentiviral infection to generate new lines stably-expressing short-hairpin RNA (shRNA) that target the MYO19 message. We generated multiple non-clonal CAD lines that each expressed a different shRNA, and verified knockdown via western
Surprisingly, quantitative Morris, and consisting actin localize motor lines R.T. plasmids. We made a delay may differentiation-IQ1-IQ2 domain, actin, and mitochondria. We observed actin filaments were destabilized, thereby interfering with the linkage between actin and mitochondria. These results suggest that decreased levels of MYO19 may be influencing CAD cell differentiation by altering the cell's ability to move and position mitochondria via the actin network.

**Contributions of Myo1 motor and tail domains to Myo1 localization and function at the endocytic sites in fission yeast.**

R.T. Carroll¹, E. Oakes¹, M.L. James¹, V. Sirotkin¹;

¹Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Myo1, the only class-1 myosin in Schizosaccharomyces pombe, is recruited to sites of endocytosis called actin patches just before a burst of branched actin assembly. Myo1 plays a role in endocytic internalization since without Myo1, internalization is reduced. Yet, how Myo1 is recruited to and functions at actin patches is not fully understood. Myo1 has an N-terminal motor domain which binds F-actin, a lever arm with two light-chain-binding motifs (IQ1 and IQ2), and a C-terminal cargo-binding tail consisting of a phospholipid-binding TH1 domain, a proline-rich TH2 domain, an SH3 domain and an Arp2/3 complex-binding CA domain. To dissect the contribution of each domain to Myo1 localization, we made a nested series of deletions starting from either the N- or C- terminus of Myo1. Loss of the motor domain or its activity resulted in re-localization of Myo1 from actin patches to the plasma membrane (PM) and eisosomes. However, disruption of F-actin with Lat A was not sufficient to re-localize Myo1 to eisosomes, resulting in Myo1 at stable cortical puncta with other endocytic proteins. Surprisingly, while Myo1 tail (TH1-TH2-SH3-CA) alone localized to the cytoplasm, deletion of SH3-CA, TH2-SH3-CA and internal deletion of TH2 reduced Myo1 accumulation in actin patches and upon treatment with Lat A resulted in complete cytoplasmic localization of these mutants. To further understand how the tail regulates localization, we expressed GFP-tagged tail domain constructs from plasmids. We found that TH2-SH3-CA but not full Myo1 tail could weakly localize to patches suggesting TH1 may inhibit TH2- and SH3- mediated interactions. We propose that while the motor-IQ1-IQ2 and TH1 function in Myo1 recruitment, TH2 and SH3 domains help retain Myo1 at patches. We tested the functional impacts of Myo1 truncation mutations by tracking the internalization of actin patches. We found that the motor-IQ1-IQ2-TH1 portion of Myo1 is minimally sufficient to support endocytic internalization. We then tested whether attaching motor-IQ1-IQ2 tagged with a GFP binding protein to GFP-tagged tail, which alone is cytoplasmic, or IQ2-tail, which alone is in eisosomes, would rescue Myo1 patch localization. Surprisingly, while heterodimerization of the motor–IQ1-IQ2 and tail restored Myo1
actin patch localization and rescued internalization, heterodimerization of the motor-IQ1-IQ2 and IQ2-tail failed to restore patch localization as both fragments co-localized in eisosomes. This suggests that the state of the tail dominates Myo1 localization and we propose that the functional motor portion of Myo1 is able to suppress the state of IQ2-tail that drives eisosome localization in the context of the full length Myo1 but not when the two halves are heterodimerized.

The dynein activator Hook1 is required for long-distance trafficking of BDNF-signaling endosomes in neurons.

M. Olenick1, E.L. Holzbaur2;

1Biochemistry and Molecular Biophysics Graduate Group, University of Pennsylvania, Philadelphia, PA, 2Physiology, University of Pennsylvania, Philadelphia, PA

In neurons, neurotrophic signals are transported long distances along the polarized microtubules of the axon via signaling endosomes, which promotes neuronal development and survival. The retrograde transport of signaling endosomes is driven by the molecular motor cytoplasmic dynein, yet it remains unclear how dynein is spatially and temporally regulated in this context. We hypothesize that adaptor proteins mediate precise cargo transport by differentially regulating dynein motors associated with distinct cargos. To assess this model, we focused on coiled-coil proteins in the human Hook family, Hook1 and Hook3. Using single molecule TIRF assays and inducible dimerization assays, we found that Hook proteins act as dynein adaptors that induce superprocessive motility. Hook proteins induced both longer run lengths and higher velocities than the previously characterized dynein activator, bicaudal D2 (BICD2). These results indicate that dynein adaptors can differentially regulate dynein to allow for organelle-specific tuning of the motor. Next, we used live cell imaging to investigate the role of Hook proteins in endosomal transport in primary hippocampal neurons. We found that Hook1 co-migrates with a subpopulation of Rab5-positive endosomal vesicles, which display more retrograde-directed motility and faster velocities than Hook1-negative early endosomes. While Hook1 was also associated with a subpopulation of Rab7-positive endosomes, Hook1 did not appear to enhance the motility of this subpopulation. Knockdown of Hook1 produced modest effects on the overall motility of Rab5- and Rab7-positive endosomes, but significantly reduced the motility of BDNF-positive signaling endosomes. This inhibition of signaling endosome motility was specific to depletion of Hook1 but not Hook3, and was rescued by expression of siRNA-resistant Hook1. To specifically model signaling endosome transport from the axon terminal to the nucleus, we used microfluidic chambers to control addition of BDNF-bound Quantum dots to axonal tips only. Hook1 knockdown resulted in a significant decrease in the frequency of BDNF-Qdot motility along the mid-axon suggesting that Hook1 may affect both the generation and motility of signaling endosomes. Together, this work suggests that Hook1 acts as a specific dynein adaptor for BDNF uptake and signaling endosome transport from the distal axon back to the soma, and supports the model that differential association with cargo-specific adaptors efficiently regulates dynein function in neurons.

Distribution of Cortical Dynein Attachment Molecule Regulates Dynein-Mediated Spindle Pulling Mechanism in Budding Yeast.

S. Omer1, W. Lee2;

1Biology department, University of Massachusetts, amherst, Amherst, MA, 2Department of Biological Sciences, Dartmouth College, Hanover, NH

In budding yeast, dynein-dependent microtubule sliding along the bud cortex mediates spindle movement into the mother-bud neck. Here we show that spatial distribution of the dynein-anchoring protein, Num1, plays a role in regulating dynein-dependent cortical pulling mechanisms. We found that Num1 accumulated at the bud tip in cells lacking cortical ER attachment molecules Scs2 and Scs22. Three-dimensional time-lapse imaging of astral microtubule behavior revealed that bud tip-localized Num1 mediated capture-shrinkage of astral microtubule plus ends, pulling the mitotic spindle into the mother-bud neck. Disrupting dynein anchorage or dynein motor activity at the bud tip, but not deleting Kar9, Kar3 or Kip3 (the canonical components mediating capture-shrinkage pathway), abolished the observed end-on capture-shrinkage of microtubule plus ends. Intriguingly, a NUM1-CAAX allele restored Num1 distribution throughout the cell cortex, rescuing dynein-dependent cortical pulling via microtubule sliding. Our findings revealed a novel mechanism of dynein-dependent spindle pulling in budding yeast that is regulated by the distribution of the cortical attachment molecule Num1.

Investigating the mechanism by which the dynein cortical receptor Num1 activates dynein motility.

L.G. Lammers1, D. Garno1, S.M. Markus1;

1Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Cytoplasmic dynein is the major minus-end directed microtubule motor in cells. To regulate its myriad functions, dynein requires numerous regulatory proteins including LIS1 (Pac1 in yeast), NudE/NudEL (Nd1 in yeast), and the growing family of adaptor proteins (e.g., BicD2, Spindly, Hook) that link dynein to dynactin. The potential interplay between these various regulatory proteins has been difficult to parse out, and may depend on the specific dynein function (e.g., cargo transport vs. spindle positioning). For instance, LIS1 reduces dynein velocity while dynactin promotes its processivity and it is unclear whether their activities are mutually exclusive. We are utilizing budding yeast as a model to dissect the various roles of several such regulators, and to understand how these molecules individually and in concert contribute to dynein regulation. Specifically, we have previously shown that dynein motility is activated in cells by Num1, the dynein cortical receptor. Our in vivo data supported a model in which Num1 activates dynein motility by relieving inhibition by Pac1/LIS1. To further examine the mechanism by which Num1 activates dynein, we have reconstituted Num1-dynein-dynactin motility in vitro, and are examining the effects of Pac1 and Nd1 on this motility. Despite Num1 exhibiting structural similarity with adaptor proteins, we find that it has no appreciable effect on the processivity of single molecules of dynein-dynactin. Our data also demonstrate that Pac1/LIS1 can reduce the velocity of dynein-dynactin to an extent similar to that of dynein alone, indicating that Pac1/LIS1 and dynactin binding to dynein is not mutually exclusive. We find that Pac1/LIS1 has a similar effect on the motility of single Num1-dynein-dynactin complexes, indicating that Num1 is not sufficient to disengage Pac1 from dynein. Given that human NudE has been shown to compete with dynactin for a binding site on the dynein tail, we are
currently investigating what role, if any, Ndl1 has in affecting the motility of Pac1-Num1-dynein-dynactin complexes. Our work will provide an unambiguous dissection of many of the effector proteins involved in the regulation of cellular dynein activity.

**Cell cycle regulation of dynein activity prevents DNA damage.**

C.E. Estrem$^1$, J.K. Moore$^1$;

$^1$Cell and Development, University of Colorado Anschutz Medical Campus, Aurora, CO

How do cells balance active, motor driven, transport to position the mitotic spindle while retaining genome integrity? Dynein is a molecular motor responsible for positioning the mitotic spindle, which is critical for proper cell division and cell fate determination. Understanding how dynein activity is controlled during the cell cycle is an important step of regulation. In budding yeast, dynein activity is restricted to positioning the spindle during anaphase onset by using astral microtubules to pull the nucleus into the daughter cell. We hypothesize dynein activity is tightly controlled during cell division to limit mechanical damage exerted on the genome. We are testing this hypothesis in two ways: 1) investigating whether hyper-activating dynein is sufficient to cause DNA damage, and 2) identifying cell cycle regulators that are mechanistically linked to dynein regulation. We have shown several mutations that increase dynein-dependent spindle movement also increase DNA damage. Using confocal imaging of living budding yeast cells, we measured the accumulation of DNA double stranded breaks by tracking fluorescently labeled Rad52 foci and we measured a 10-fold increase in Rad52 foci accumulation through anaphase in the mutants that hyper-activate dynein, compared to wild type control cells. We are now testing other mutants that increase or decrease dynein activity to investigate how DNA damage is generated, and elucidate the mechanism that normally restricts dynein to specific phases of the cell cycle. These results will give insights into the mechanisms that regulate dynein during the cell cycle and why dynein regulation is important for the integrity of DNA.

**Mechanism for G2 phase-specific nuclear export of the kinetochore protein CENP-F.**

$^1$Department of Chemistry, State University of New York at Binghamton, Binghamton, NY, $^2$Laboratory of Cell Biology, The Rockefeller University, New York, NY, $^3$Mass Spectrometry Laboratory, Howard Hughes Medical Institute at University of California, Berkeley, Berkeley, NY

Centromere protein F (CENP-F) is a component of the kinetochore and a regulator of cell cycle progression. CENP-F recruits the dynein transport machinery and orchestrates several cell cycle-specific transport events, including transport of the nucleus, mitochondria and chromosomes. A key regulatory step for several of these functions is likely the G2 phase-specific export of CENP-F from the nucleus to the cytosol, where the cytoplasmic dynein transport machinery resides; however, the molecular mechanism of this process is elusive. Here, we have identified 3 phosphorylation sites within the bipartite classical nuclear localization signal (cNLS) of CENP-F. These sites are specific for cyclin-dependent kinase 1 (Cdk1), which is active in G2 phase. Phosphomimetic mutations of these residues strongly diminish the interaction of the CENP-F cNLS with its nuclear transport receptor karyopherin α. These mutations also diminish nuclear localization of the CENP-F cNLS in cells. Notably, the cNLS is phosphorylated in the −1 position, which is important to orient the adjacent major motif for binding into
its pocket on karyopherin α. We propose that localization of CENP-F is regulated by a cNLS, and a nuclear export pathway, resulting in nuclear localization during most of interphase. In G2 phase, the cNLS is weakened by phosphorylation through Cdk1, likely resulting in nuclear export of CENP-F via the still active nuclear export pathway. Once CENP-F resides in the cytosol, it can engage in pathways that are important for cell cycle progression, kinetochore assembly and the faithful segregation of chromosomes into daughter cells.

The contribution of electrostatic interactions to the processivity of inner-arm dynein c.
M. Kikumoto¹, R. Nakamori¹, H. Kojima¹, H. Sakakibara²;
¹Structural Biology Research Center, Nagoya University, Nagoya, Japan, ²Advanced ICT Research Institute, National Institute of Information and Communications Technology, Kobe, Japan

Dynein c, one of the axonemal inner-arm dyneins of Chlamydomonas flagella, shows a high processivity although it functions as a single-headed molecule in vitro and has a low duty ratio. In this study, we evaluated the effects of electrostatic interactions on the processivity of dynein c using a high ionic strength solution and deletion of the negative-charge rich region of tubulin. Continuous movement assays revealed that the contribution of electrostatic interactions between dynein c and microtubules to maintain gliding movements was small. The number of dynein c molecules required to maintain microtubule movement was estimated to be one for intact microtubules. Under high ionic strength conditions, that number increased to two, but was not changed when the negative-charge rich region of tubulin was deleted. On the other hand, electrostatic interactions between dynein c and microtubules significantly contributed to the capture of diffusing microtubules and to the start of their translocation. Landing Rate assays revealed that the number of dynein c molecules required to start microtubule translocation was two. That number was increased to five under high ionic strength conditions and by deleting the negative-charge rich region from tubulin. These results suggest that dynein c has at least two different microtubule binding states: one is at the moment of capturing the microtubule before the beginning of movement and the other is during the translocation of the microtubule. Electrostatic interactions significantly contribute to the process of microtubule capture before movement, but are less essential to microtubule movement.

The 3.5Å cryoEM structure of a fast dynein/dynein complex.
L. Urnavicius¹, C.K. Lau¹, M.M. Elshenawy², E. Morales³, A. Yildiz², A.P. Carter¹;
¹MRC LMB, Cambridge, United Kingdom, ²UC Berkeley, Berkeley, CA

Dynein and its cofactor dynactin form a highly processive microtubule motor in the presence of a coiled coil adaptor, such as BICD2. Different adaptors link dynein/dynactin to distinct cargos. Here we use electron microscopy (EM) and single molecule studies to show that adaptors can recruit a second dynein to each dynactin. Whereas BICD2 is biased towards recruiting a single dynein, the adaptors Hook3 and BICDR-1 predominantly recruit two. Shifting the equilibrium towards a double-dynein complex increases both force and speed by almost two-fold. A 3.5 Å cryo-EM reconstruction of the dynein tail/dynactin/BICDR-1 complex explains how the second dynein is recruited. Our work provides a
structural basis for how diverse adaptors recruit different numbers of dyneins and suggests the mechanism by which adaptors can tune the properties of the dynein/dynactin machine.

**A Conserved Interaction of the Light Intermediate Chain with Dynein-Dynactin Effectors.**  
I. Lee, M.A. Olenick, M. Boczkowska, C. Franzini-Armstrong, E.L. Holzbaur, R. Dominguez;  
1Physiology, University of Pennsylvania, Philadelphia, PA, 2Cell Developmental Biology, University of Pennsylvania, Philadelphia, PA

Cytoplasmic dynein 1 (dynein) is the major minor-end–directed microtubule-based motor in eukaryotic cells. Dynein cargo selectivity is achieved through interactions with cargo-specific effector proteins that mediate the formation of dynein-dynactin-effector (DDE) ternary complexes. While these effectors are generally unrelated, they share the ability to interact with both dynein and dynactin and to activate dynein processivity. How this is achieved is poorly understood. Here, we describe the identification and characterization of a region of the dynein Light Intermediate Chain 1 (LIC1) that mediates the interaction with unrelated effector proteins. Binding studies with purified proteins and using isothermal titration calorimetry allowed us to map the interaction to a conserved helix within LIC1 and to N-terminal fragments of BICD2, Hook1 and Hook3. A crystal structure of the LIC1 helix bound to an N-terminal fragment of Hook3 reveals a major conformational change of the extended C-terminal helix of the conserved Hook domain to form a hydrophobic cleft where the LIC1 helix binds. Mutating the interacting interface of the LIC1 helix identified in the crystal structure impaired lysosomal positioning in cells. Addition of a peptide corresponding to the LIC1 helix competitively inhibits processive, dynein-driven motility in single-molecule assays using total internal reflection fluorescence (TIRF) microscopy of cell extracts. Together, the results demonstrate the existence of a conserved mechanism of interaction between the dynein LIC1 and dynein-dynactin effectors.

**Dynein Light Intermediate Chains participate differently in fundamental aspects of neocortex development.**  
J.C. Gonçalves, R.B. Vallee;  
1Department of Pathology and Cell Biology, Columbia University Medical Center, New York City, NY, 2Life and Health Sciences Research Institute (ICVS), School of Medicine, University of Minho, Braga, Portugal, 3ICVS/3B's - PT Government Associate Laboratory, Braga/Guimarães, Portugal

Cytoplasmic dynein is the major retrograde microtubule motor and participates in several aspects of neocortex development. These include Radial Glial Progenitor (RGP) cell cycle-dependent interkinetic nuclear migration (INM) and division, the multipolar-to-bipolar transition of newborn neurons, axon extension, and neuronal migration to the cortical plate (CP). The dynein light intermediate chains (LICs) are cargo-binding subunits, but the relative roles of the two LIC genes, LIC1 and LIC2, are not well understood. To test whether they play overlapping or distinct roles in vivo we used in utero electroporation in E16 rat embryos injected intracerebrally with LIC1 and/or LIC2 shRNAs. We analyzed the brain tissue subsequently by fixed and live imaging. LIC1 RNAi led to a marked inhibition of apical INM and a decrease in mitotic index in RGPs. In contrast, LIC2 RNAi had little-to-no effect at this stage. BICD2 expression, which can rescue defects in other apical INM genes and is a known LIC interactor, failed to rescue LIC1 knockdown, suggesting a role for the LIC1-BICD2 interaction in INM. LIC1 RNAi also
blocked further steps of brain development, with an accumulation of cells at the incompletely differentiated multipolar stage and a decrease in the number of cells in CP, their final destination. Expression of truncated LIC1, lacking the cargo binding domain, also caused a decreased number of cells in this region, highlighting the importance of cargo binding function of LIC1 for the progression of the newborn neurons to the CP. In contrast, there was little apparent effect of LIC2 depletion in the number of bipolar neurons in the CP, though the number of neurons reaching the upper regions was reduced. Co-expression of RNAi-insensitive LIC1 or LIC2 each rescued the LIC1 knockdown phenotype, though incompletely. Despite the greater severity of the LIC1 vs. LIC2 knockdown effect, the ratio of LIC1:LIC2 protein levels was unaltered in during the late embryonic period (E16-E20), and even in the adult rat. Nonetheless, pull-down experiments showed a greater affinity of BICD2 for LIC1. Over-all, we find that LIC1 and LIC2 are associated with distinct phenotypic effects during brain development, with a particularly important role for LIC1 in apical nuclear migration in RGP cells and for the steps of neuronal differentiation and migration. In view of the constant ratio of LIC1 to LIC2 during brain development, these results may reflect the stronger interaction of LIC1 with at least one dynein cargo-binding protein. Model for RILP mediated Autophagosome Assembly and Transport.
N.V. Khobrekar1,2, T.J. Dantas2, R.B. Vallee2;
1Department of Biological Sciences, Columbia University, New York, NY; 2Department of Pathology and Cell biology, Columbia University Medical Center, New York, NY

Autophagy is a highly conserved cellular process used to degrade damaged and misfolded proteins and organelles, to recycle amino acids and to destroy pathogens. Defects in neuronal autophagy lead to toxic protein aggregates, resulting in degeneration and neuronal death, a hallmark of Alzheimer’s, Parkinson’s and Huntington’s Disease. Autophagy is regulated by mTOR kinase, which when inactivated under conditions of cellular stress, leads to formation of autophagosomes (APs), which are retrogradely transported towards the lysosomal compartment by cytoplasmic dynein.

We have identified a novel role for the dynein adaptor RILP (Rab interacting lysosomal protein) in neuronal autophagy. RILP recruits dynein to Rab7-GTP-positive late endosomes (LEs) in nonneuronal cells, but its neuronal function has not been explored. With high resolution live cell imaging, we have found that RILP is associated with and required for retrograde transport of autophagosomes (APs) in neuronal and nonneuronal cells (ASCB 2016). We found that, in addition to a Rab7-binding site, RILP contains three LC3 Interacting Regions (LIRs) and can bind independently to either nascent and mature APs or LEs in neurons. We found, furthermore, that expression of LIR-mutant RILP results in substantially lower numbers of APs, suggesting a novel role for RILP in AP formation as well as transport. To test for a role in AP formation, we have further examined RILP localization to DFCP1-positive AP nucleation sites and ATG5-positive isolation membranes. We find that RILP and its N-terminal motor binding domain bind to ATG5-positive structures in neurons. Further immunofluorescence analysis suggests mutually exclusive ATG5 vs. dynein colocalization with RILP, suggesting competition for RILP binding. This arrangement might serve to ensure that incomplete isolation membranes remain immotile, and that only more mature structures can be transported.

Finally, we now find that small molecule-mediated inhibition of mTOR results in upregulation of RILP mRNA levels in neurons as judged by qRT-PCR, and this increase correlates with induction of autophagy. These results suggest that RILP plays an important role in mTOR-sensitive neuronal autophagosome assembly and transport.
Based on these results, we propose a model for RILP mediated neuronal AP assembly and transport: mTOR inhibition in neurons may upregulate RILP, which in turn stimulates AP assembly by associating with growing isolation membranes. RILP may further transport newly formed APs through their fusion with LEs and lysosomes. This mechanism may be involved in mTOR-sensitive autophagy in neurons to respond to diverse forms of cellular stress.

Membrane-associated septins promote dynein-driven transport by scaffolding dynein light and intermediate chain interactions.
I. Kesisova¹, E.T. Spiliotis³;
¹Biology, Drexel University, Philadelphia, PA

Septins are GTPases that assemble into non-polar hetero-oligomers and self-organize into higher order polymers such as filaments, rings and gauzes. Septins associate with cell membranes and the cytoskeleton, functioning as molecular scaffolds for protein-protein interactions or as diffusion barriers for the spatial compartmentalization of membrane proteins. Here we show that membrane-associated septins promote dynein dependent transport by recruiting cytoplasmic dynein through direct interactions with the dynein light chain Tctex-1 and dynein intermediate chain (DIC). Using the ActA protein of *Listeria monocytogenes* and the TagRFP fluorescent protein, we targeted various septins to mitochondria and we found that SEPT9-tethered mitochondria accumulate at the perinuclear region of COS7 cells. This accumulation was dependent on dynein, because overexpression of dynamitin p50 disperses mitochondria throughout the cell. Staining for the dynein light chain Tctex-1 and intermediate chain DIC showed that they accumulate on SEPT9-tethered mitochondria. *In vitro* GST pull downs using recombinant proteins show that SEPT9 interacts directly with Tctex-1. We identify two Tctex-1 binding motifs on SEPT9 matching the consensus sequence [R/K]-[R/K]-X-[R/K] found in various Tctex-1 targets. Tctex-1 binding null mutants of SEPT9 fail to cause perinuclear clustering of mitochondria or accumulate Tctex-1. Interestingly, Tctex-1, DIC and SEPT9 form a tripartite complex *in vitro* and the presence of SEPT9 increases the DIC-Tctex-1 interaction. Taken together, our findings suggest that SEPT9 promotes dynein-mediated transport by scaffolding the interactions of the Tctex-1 cargo adaptor with the dynein motor complex. On-going studies aim at determining if through this interaction, septins affect the positioning and trafficking of membrane organelles such as the Golgi complex and endolysosomes.

Dynein force production and its regulation.
D.E. Chapman¹, B. Narayanareddy¹, M.J. Bovyn¹, H. Han¹, B. Huy¹, W. Wang¹, S.P. Gross¹;
¹Developmental and Cell Biology, University of California Irvine, Irvine, CA

The molecular motor dynein is responsible for most microtubule-driven cargo traveling towards the microtubule minus-ends, near the cell nucleus. Though biophysically, mechanisms of many dynein function are well characterized, its regulation in the cell is less understood. Recently, our lab reported that dynein-driven lipid droplet cargos are able to adapt their force production to improve transport when facing opposition to motion, a dynein function that was previously unknown. While we have
identified two important factors involved in this function, NudEL and Lis1, the work presented here will discuss other proteins involved in control of this adaptation pathway.

Molecular basis for dynein dysfunction in a spectrum of motor neuron diseases.
M.G. Marzo1, S.M. Markus1;
1Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Proper intracellular transport along axons is crucial for maintaining the health of motor neurons. In these cells, dynein is the primary method by which cargos from distal ends of axons are transported to the soma. As such, dysfunctions in the dynein motor due to genetic mutations are the primary underlying cause in a spectrum of neurodegenerative disorders. This spectrum of dyneinopathies encompasses a variety of muscular dystrophy and neurological diseases. These diseases are typified by missense mutations to the dynein heavy chain with dominant negative phenotypes, cellular degeneration, and are typically childhood onset. However, studying dynein in mammalian tissues remains challenging and limited data is available about the effect of these mutations on the motor. Using the power of budding yeast dynein as a high-throughput platform to study how missense mutations influence motor behavior, we may investigate the molecular basis for dysfunction in mutant dynein isoforms and attempt to reverse the dysfunction.

The Drosophila MAST Kinase Drop out controls Dynein-mediated transport and is required for phosphorylation of cytoplasmic Dynein.
H.C. Sonnenberg1, A. Langlands1, D. Hain1, A.J. Müller1,2;
1School of Life Sciences, University of Dundee, Dundee, United Kingdom, 2Developmental Genetics, University of Kassel, Kassel, Germany

A family of four Microtubule-associated Ser/Thr (MAST) protein kinases have been implicated in several human diseases including breast cancer, neurodegenerative diseases and inflammatory bowel disease, but the cellular biological function of this kinase family is poorly understood. We identified a single Drosophila MAST kinase homolog encoded by the drop out (dop) gene. Mutations in dop affect several processes depending on Dynein-dependent transport in early embryos including transport of polarity proteins, Golgi-derived vesicles, lipid droplets and rab11-dependent endosomal transport. By creating the first null mutants of Dop, we present evidence that Dop is a key upstream regulator of membrane growth during cell formation in early embryos. We used a SILAC based proteomic approach in embryos to identify substrates of Dop and found a 4.8-fold reduction in phosphorylation of the conserved Ser401 residue of Dynein-light-intermediate chain (Dlic) in dop mutants. We demonstrate that a phospho-mutant form mimicking Ser401 phosphorylation is able to suppress the phenotypes of dop mutant embryos. These results indicate that Dop is a regulator of Dynein-dependent transport during key events in the initiation of plasma membrane growth and may shed light on the mechanisms of MAST kinases in human diseases.

The actin capping protein is involved in dynein function but non-essential for Arp1 filament assembly.

J. Zhang1, R. Qiu1, X. Xiang1;
1Biochemistry and Molecular Biology, Uniformed Services University - F. Edward Hébert School of Medicine, Bethesda, MD

Cytoplasmic dynein, a minus-end-directed microtubule motor, requires the dynactin complex for a variety of in vivo functions. The backbone of the vertebrate dynactin complex is the Arp1 (actin-related protein 1) mini-filament whose barbed end binds to the heterodimeric actin capping protein (Schafer et al., 1994 J Cell Biol). However, it has been unclear whether the actin capping protein is a dynactin component in lower eukaryotic organisms, especially because there is no evidence that it binds to the budding yeast dynactin complex (Moore et al., 2008 Traffic). Here our biochemical data show that the actin capping protein is a component of the dynactin complex in the filamentous fungus Aspergillus nidulans. Moreover, deletion of the gene encoding capping protein alpha (capA) results in a partial defect in both nuclear distribution and early endosome transport, two dynein-mediated processes. A recently published study using RNAi to knockdown capping protein beta in mammalian cells revealed a critical role of the capping protein in dynein-mediated spindle orientation (di Pietro et al., 2017 Curr Biol). While our conclusion on the involvement of capping protein in dynein function is consistent with this study, capping protein in fungi seems less critical for dynein function than that in mammalian cells. In the ΔcapA mutant, the defect in nuclear distribution is obviously less severe than that exhibited by a dynein heavy chain mutant. The defect in early endosome transport exhibited by the ΔcapA mutant only becomes obvious when an abnormally bigger early endosome is formed via endosomal fusion, but the defect is still less severe than that exhibited by the deletion mutant of p25, an Arp1 pointed end protein (Zhang et al., 2011 JCB, Schroer 2004 Annu Rev Cell Dev Biol). Moreover, although capping protein blocks the elongation or shortening of conventional actin filaments (Cooper and Sept, 2008 Int. Rev. Cell Mol Biol), our biochemical analysis suggests that its loss does not affect the dynactin Arp1 filament in an obvious way. Recently, cryo-EM structural studies found that one dynactin complex binds two dimeric dyneins and one of them binds at the barbed end of the Arp1 filament close to the capping protein (Urnavicius et al., 2017 bioRxiv; Grotjahn et al., 2017 bioRxiv). Based on all these results, we suggest that the capping protein may enhance dynein function not by affecting significantly the assembly of the Arp1 filament but by modulating dynein binding or positioning on dynactin and consequently its activity.

NEEP21 Family Member Calcyon Regulates Biogenesis and Axonal Transport of Late Endosome/Lysosome Related Organelles.

L. Shi1, T.J. Hines2, D. Smith2, C. Bergson1;
1Department of Pharmacology and Toxicology, Medical College of Georgia at Augusta University, Augusta, GA, 2Department of Biological Sciences, University of South Carolina, Columbia, SC

The findings reported here identify a possible novel mechanism regulating axonal transport and biogenesis of late endosomes and lysosome related organelles (LE/LROs) based on the coordinated coupling of microtubule motor and vesicular coat proteins by the neuron-enriched, transmembrane protein Calcyon (Caly). The C terminus of Caly pulled down proteins involved in microtubule transport (DIC, KIF5A, p150Glued and Lis1) and organelle biogenesis (AP-1 and AP-3) from mouse brain...
homogenates. Removing 10 amino acids from the juxtamembrane domain of Caly abolished motor protein binding, but not AP-3 interaction. A Caly mutant that does not bind AP-3 (ATEA) was unable to pull down motor proteins from brain homogenates, suggesting that adaptor protein and motor protein binding are coupled in vivo. While shRNA mediated knockdown of Caly reduced the motility of LE/LROs labeled by LysoTracker in dorsal root ganglion neuron axons, upregulation of Caly stimulated movement of LE/LROs. Caly upregulation also increased the motility of organelles labeled by the AP-3 cargo GFP-PI4KI\(\alpha\), but not GFP-Rab5 labeled early endosome/sorting endosomes. Whereas Caly upregulation produced equivalent increases in anterograde and retrograde speeds and run lengths, knockdown resulted in longer anterograde but shorter retrograde motile events. Further, the raw number of LE/LROs, as well as the percent of LE/LROs co-localizing with dynein intermediate chain also correlated with Caly upregulation and knockdown. These results suggest that Caly also impacts organelle biogenesis and motor protein recruitment. In contrast to wild type Caly, expression of the ATEA mutant failed to alter either LE/LRO flux or levels of associated dynein, but abolished effects on organelle biogenesis. Taken together, these data support the hypothesis that Caly is a multifunctional scaffolding protein that promotes AP-3 dependent organelle biogenesis and transport in axons.

She1 affects dynein by interactions with the microtubule and the dynein microtubule-binding domain.

K. Ecklund\(^1\), T. Morisaki\(^1\), L.G. Lammers\(^1\), M.G. Marzo\(^1\), T.J. Stasevich\(^1\), S.M. Markus\(^1\);

\(^1\)Biochemistry Molecular Biology, Colorado State University, Fort Collins, CO

Cytoplasmic dynein is an enormous \(\sim 1.2\) MDa molecular motor that transports myriad cargoes toward the minus ends of microtubule tracks. Rather than existing as bare tracks, microtubules are bound by numerous microtubule-associated proteins (MAPs) that have the capacity to affect various microtubule-based cellular functions, including motor-mediated transport. One such MAP is She1, a potent effector of dynein motility that plays a role in polarizing dynein-mediated spindle movements in budding yeast. Here we characterize the molecular basis by which She1 affects dynein motility, providing the first such insight into which a MAP can directly modulate motor motility. We find that She1 reduces the rate by which dynein hydrolyzes ATP, likely due to the enhanced microtubule-binding affinity and consequent reduced stepping frequency imparted on dynein by She1. Microtubule binding by She1 is required for it to affect dynein motility. Moreover, we find that She1 and dynein directly interact and that this interaction is sensitive to dynein’s nucleotide-bound state. We narrowed down the She1 binding region to the microtubule-binding domain (MTBD) of dynein. Accordingly, a dynein motor with a mutated MTBD displays reduced sensitivity to She1 in vitro and in vivo. Taken together, our data support a model in which simultaneous interactions between the microtubule and the dynein MTBD provides She1 with the ability to reduce dynein velocity and prolong its microtubule encounters.

Upregulation of the beta-tubulin isoform tubb6 (beta 6, class V) in regenerating skeletal muscles of the mdx mouse model of Duchenne muscular dystrophy: too much of a good thing?

1Light Imaging Section, Office of Science and Technology, National Institute of Arthritis and Musculoskeletal and Skin Diseases, National Institutes of Health, Bethesda, MD; 2Department of Biochemistry, Molecular Biology, and Biophysics, and Program in Molecular, Cellular, Developmental Biology, and Genetics, University of Minnesota-Twin Cities, Minneapolis, MN; 3Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

Many essential cellular functions depend on microtubules. It is therefore not surprising that microtubule defects are found in many diseases. The cause of the defects and their link with the pathology are not easy to pinpoint. Our work focuses on the muscle microtubules of the mdx mouse model of Duchenne muscular dystrophy (DMD). Microtubules in mdx are abnormal and lack the regular grid organization typical of fast rodent muscle fibers. It has been proposed that these altered microtubules contribute to the dystrophic pathology. We now have evidence that an aberrantly high level of the beta-tubulin tubb6 (beta 6, class V) may be involved in the mdx microtubule defects. Tubb6, a ubiquitous minor beta-tubulin isoform, is essential for cell division but disturbs microtubules when overexpressed. We have previously reported that overexpressing a GFP-tagged tubb6 but not tubb5 (beta V, class I tubulin), in the WT flexor digitorum brevis (FDB) muscle causes microtubule changes resembling those of mdx. In contrast, knocking down tubb6 (but not tubb5) from the mdx FDB normalizes microtubules. We also find that the long-term overexpression of GFP-tubb6 in WT FDB causes morphological changes suggesting regeneration of damaged fibers. Why is there a large increase in tubb6 mRNA and protein in mdx and (at least of tubb6 mRNA) in DMD muscles? We have observed that tubb6 is also upregulated during differentiation of the C2 mouse muscle cell line, while tubb5 is decreased. In undifferentiated C2 myoblasts, tubb6 is mostly present in mitotic spindles. In C2 myotubes, which need microtubules for elongation, all microtubules show high tubb6 immunofluorescence. WT adult muscle fibers however show a low level of tubb6 by immunostaining or immunoblotting. It is therefore plausible that tubb6 is elevated in mdx because regenerating (i.e. differentiating) muscle fibers need it for elongation. This idea is supported by our recent observation that tubb6-rich myotubes cluster in IgG-positive areas of inflammation and regeneration in mdx muscle sections. No tubb6 accumulation can be detected in matching WT sections. From these results emerges a model: in WT mice, tubb6 is elevated in elongating myotubes but decreases when myotubes mature into fibers; in mdx, tubb6 increases during the initial wave of muscle regeneration (at 3-4 weeks of age) but fails to subsequently come down because inflammation or other stimuli for regeneration persist. A permanently high tubb6 level in mature fibers could cause microtubule defects and further muscle damage. Thus, mdx microtubule defects may result from a normal reaction to muscle damage gone awry. It will be important to further investigate this model and identify the stimuli causing tubb6 upregulation.

Effect of TPX2 extreme C-terminal domain on microtubule dynamics.
D. Fahy1, A. Kostyukova2, A. Smertenko1;
1Institute of Biological Chemistry, Washington State University, Pullman, WA, 2The Gene and Linda Voiland School of Chemical Engineering and Bioengineering, Washington State University, Pullman, WA

Organization and dynamics of the metaphase spindle critically depend on the microtubule-nucleating activity of TPX2. It has been shown that TPX2 C-terminal half is sufficient to promote microtubule nucleation in vitro1. This half contains two evolutionarily conserved domains: (1) the importin-binding domain located close to the center of TPX2 is essential for the microtubule-nucleating activity1 and (2) the extreme C-terminal domain binds kinesins and controls their activity2,3. The role of the latter domain in regulation of microtubule dynamics remains poorly understood. Here we address this knowledge gap using a small protein, TPX2-CT, from Brachypodium distachyon with a high degree of homology to the extreme C-terminal domain of TPX2 but lacking the N-terminal region and the importin-binding domain. We demonstrate that in vitro at high concentrations TPX-CT can: (1) induces formation of microtubule asters; (2) inhibit catastrophe; (3) restrict microtubule elongation; (4) nucleate microtubules; and (5) bundle microtubules. At lower concentrations TPX2-CT exhibits weak microtubule polymerase and bundling activity. In vivo, the TPX2-CT suppresses microtubule catastrophe resulting in the formation of arrays. The geometry of these arrays can undergo global re-orientation even though microtubule dynamic instability is dramatically reduced. Our modeling experiments demonstrate that inhibition of catastrophe is sufficient to alter the microtubule organization through progressive microtubule elongation and simulates the in vivo reorganization. Inhibition of catastrophe by TPX-CT requires highly evolutionarily conserved residues within a putative coiled-coil domain. These residues confer higher affinity of TPX2-CT to microtubules and increase oligomerization of TPX2-CT. We conclude that the suppression of catastrophe by TPX2-CT in vivo depends on its oligomerization capacity. Our findings advance understanding of TPX2-dependent microtubule dynamics and demonstrate a novel mechanism responsible for generation of acentrosomal microtubule arrays.

Investigating the role of lateral interactions in microtubule dynamics.
G.A. Li1, J.K. Moore1;
1Department of Cell and Developmental Biology, University of Colorado Anschutz Medical Campus, Aurora, CO

Microtubules are an essential component of the cytoskeleton, and cells regulate their functions by controlling microtubule dynamics. How the dynamics of microtubules are intrinsically regulated remains unknown. Several observations, including drugs that stabilize microtubules and electron micrographs of disassembling microtubules, suggest that lateral interactions are the weak point of a microtubule. Based
on these observations, we hypothesize that lateral interactions are the key site for regulating microtubule dynamics. We focus on the M-loop of β-tubulin and its interaction with H1-S2 and H2-S3 of the neighboring β-tubulin subunit predicting that more flexible loops promote microtubule polymerization while strengthening and structuring these interactions will stabilize microtubules. At low temperatures, yeast microtubules depolymerize but Antarctic animal species have dynamic microtubules. The lateral loops of β-tubulin from several Antarctic animal species are hot spots for sequence differences. We make mutations in the yeast β-tubulin gene, TUB2, mimicking the lateral loops of Antarctic species or treat with microtubule stabilizing drugs and determine the affect on microtubule dynamics. Studying TUB2 mutations located in the lateral loops, we hope to define the role the lateral interactions play in regulating microtubule dynamics.

Phosphatases participate in the control of microtubule organization through CDK regulation. J. Magescas¹, J.L. Feldman¹;

¹Department of Biology, Stanford, Satnford, CA

The cytoskeleton is a critical regulator of internal cell organization. Among it, microtubules are organized from specific structures called microtubule organizing centers (MTOCs). The vast majority of research has historically focused on the centrosome, however, in non-cycling cells MTOC function can be reassigned to non-centrosomal structures such as the plasma membrane. However, how the cell inactivates MTOC function at the centrosome and maintains it inactive while other sites assume the MTOC function is unknown Activation of MTOC activity at the centrosome is catalyzed by cell cycle regulated kinases (e.g. CDK-1, PLK-1, and Aurora-A/AIR-1), and so one hypothesis is that inactivation of MTOC activity at the centrosome involves phosphatases that could directly or indirectly regulate the function of those kinases. We are using C. elegans as a model to characterize MTOC inactivation at the centrosome, particularly how it is maintained inactive, and test the implication of PPPs in this process. We are using the C. elegans adult germ line as an in vivo model to study the maintenance of centrosome inactivation. The hermaphrodite germline is distributed over two gonad arms, each composed of a thousand germ cells. In the majority of these cells, MTOC function has been reassigned to the plasma membrane and the centrosomes are maintained in an inactive state. For example, the microtubule nucleating complex γ-TuRC associates with the membrane and the centrosome lacks PCM and associated microtubules. We tested a role for phosphatases in the maintenance of centrosome inactivation using pharmacological inhibitors. Inhibition of PPPs in the gonad resulted in a loss of γ-TuRC from the membranes and in the reactivation of the centrosome as an MTOC. Indeed, microtubules and Aurora-A/AIR-1 relocalized to the centrosome following phosphatase inhibition. Using a combination of different inhibitors, we conclude that a PP1 phosphatase is required to maintain the membrane MTOC state and centrosome inactivation in the germline. Additionally, inhibition of PPPs and CDK resulted in only a small reduction of γ-TuRC at the membrane and the centrosome remained inactivate, suggesting that PPPs control CDK activity in the gonad and thus centrosome MTOC activity. Based on these observations we propose that a single or a combination of PPPs control the organization of the microtubule in differentiated germ cells. This happens partially through the control of CDKs activity although not entirely. We are further characterizing this process by identifying the PPPs involved as well as their targets.

Microtubule glycylation regulates cortical microtubule assembly and ciliary array organization.
A.D. Junker¹, J. Gaertig², C.G. Pearson¹;
¹Cell, stem cell, and developmental biology, University of Colorado Denver, Aurora, CO, ², Department of Cell Biology, University of Georgia, Athens, GA

Motile ciliary arrays generate directed fluid flow that is essential for respiratory airway mucus clearance, cerebral spinal fluid movement and cell motility. To optimize directed fluid flow, motile cilia within the array are organized and polarized. This is achieved by cortically anchoring the basal bodies that nucleate and organize motile cilia. Basal body associated cortical microtubules are a conserved population of microtubules that position basal bodies within the ciliary array. Using the ciliate model organism, Tetrahymena thermophila, we studied the timing and dynamics of basal body associated microtubule assembly during new basal body assembly, maturation and incorporation into the ciliary array. Tetrahymena possess two major classes of basal body associated microtubules, post-ciliary microtubules and transverse microtubules. Post-ciliary microtubules assemble immediately following new basal body assembly whereas transverse microtubules slowly assemble and elongate. We propose that microtubule elongation promotes basal body attachment to the cell cortex. Both basal body associated microtubule structures are prominently marked with the microtubule post translational modification, glycylation. When glycylation is disrupted in Tetrahymena, transverse microtubules promiscuously elongate during early basal body maturation and fail to reach their complete lengths. Consistent with the importance of basal body associated microtubules in basal body positioning, loss of microtubule glycylation causes basal body disorganization. These data reveal the importance of basal body associated cortical microtubules, and their glycylation, in organizing ciliary arrays.

Fodrin as a regulator of microtubule nucleation.
J.S. Sreeja¹, R.K. Nellika¹, S. Sengupta¹;
¹Cancer Research Program - 3, Rajiv Gandhi Center for Biotechnology, Trivandrum, India

Fodrin is a non-erythroid homologue of spectrin, underlying the plasma membrane found in most eukaryotic cells. The functions delegated to this protein include structural integrity of the cell upon interaction with other cytoskeletal components, signal transduction and apoptotic pathways. Reports published from our lab detail the presence of fodrin as a component of the γ-TuRC (gamma tubulin ring complex) derived from neuronal tissue and neuronal lineage cells. The major objective of this study is to understand the functional contribution of fodrin in γ-TuRC mediated mechanisms in the cells. γ-TuRC is a complex association of proteins, utilised in the cells as a major tool for microtubule formation and organisation. Centrosome, being the major hub of microtubule nucleation in mammalian cells, is rich in γ-TuRCs.
Towards understanding the aforementioned objective, we employed both in vitro and in vivo approaches. We chose U251 MG, a glioblastoma cell line as our working system. Fodrin was downregulated by targeted shRNA treatment and centrosomal microtubule nucleation was judged by analysing the astral microtubule intensity around the centrosomes in these cells. It was found that the fodrin downregulated cells show significant reduction in astral microtubule intensity in comparison to the control. We also found that fodrin downregulated cells showed delayed microtubule nucleation as compared to control cells upon microtubule regrowth after cold depolymerisation. Concurrent studies
from our lab show reduced gamma tubulin presence at the centrosome of fodrin downregulated cells. This implies that fodrin might contribute towards efficient recruitment of gamma tubulin, and in fodrin downregulated cells this could result in impaired centrosome functions. For understanding the significance of the direct association of fodrin with γ-TuRC, in vitro assays were designed. Microtubule polymerization was monitored turbidometrically using purified neuronal γ-TuRC. The functional efficiency of this complex was compared with a typical, nucleation competent γ-TuRC devoid of fodrin, purified from HEK 293 cells. The nucleation time analysis revealed a significant reduction in the nucleation potential of fodrin containing γ-TuRC as opposed to fodrin negative γ-TuRC. The overall polymerization was also considerably reduced. Moreover incubation of purified fodrin with canonical γ-TuRC from HEK 293 cells reduced its nucleation potential. Electron microscopic analysis also showed a reduction in the number of microtubules formed by neuronal γ-TuRC when compared to HEK 293 derived γ-TuRC. This shows that even though fodrin is incapable of inducing microtubule nucleation, its association makes gamma-tubulin less competent in affecting nucleation in neuronal cells.

Cytoplasmic Ran regulates acentrosomal microtubule nucleation in neurons.
C. Hsu1, H. Chiu1, W. Chen2, Y. Chen1, Y. Huang3, B. Hsieh1, E. Hwang1,2,3;
1Institute of Molecular Medicine and Bioengineering, National Chiao Tung University, Hsinchu, Taiwan,
2Institute of Bioinformatics and Systems Biology, National Chiao Tung University, Hsinchu, Taiwan,
3Department of Biological Science and Technology, National Chiao Tung University, Hsinchu, Taiwan

The proper formation of microtubules (MT) is essential for neuronal developmental processes, such as differentiation, polarization, and migration. The generation of MTs in post-mitotic neurons highly depends on nucleation by acentrosomal MT-organizing centers (MTOCs). While Golgi outposts have been shown to promote acentrosomal MT formation in dendrites, the acentrosomal MTOCs in axon remain elusive. We have previously shown that TPX2 is an important component of the acentrosomal MTOC in neurons. TPX2 distributes along the neurite shaft and binds to the MTs. In addition, TPX2 depletion in neurons impairs MT formation at the tip and the base of the neurite. Because it has been shown that the small GTPase Ran regulates TPX2 activity and MT nucleation around the chromosomes during mitosis, we set out to examine whether Ran also regulates MT nucleation in neurons. Here we show that the active GTP-bound Ran concentrates in regions similar to TPX2 (i.e. at the tip of the neurite and in the soma). Overexpressing the TPX2 inhibiting protein importin-alpha results in the decrease of acentrosomal MT formation in neurons. Additionally, acentrosomal MT formation decreases when importazole, a Ran signaling interrupting molecule, is applied. Furthermore, both of the neurite length and the microtubule intensity increase when a constitutively active Ran mutant (RanQ69L) is overexpressed in neurons. These data suggest that cytoplasmic Ran regulates TPX2 activity and promotes MT nucleation in neurons. Finally, we will provide data using the optogenetic tool to support this hypothesis.

Regulation of mitotic spindle assembly factor, NuMA, by Importin-β.
C. CHANG1;
1 Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan

ABSTRACT Ran-GTPase orchestrates mitotic spindle assembly by modulation of the interaction between Importin-α/-β and spindle assembly factors (SAFs). The inhibition of SAFs carried out by importins needs to be done without much sequestration from abundant nuclear localization signal (NLS)-containing proteins. However, the molecular mechanisms that determine NLS-binding selectivity and that inhibit the activity of Importin-β-regulated SAFs (e.g. Nuclear Mitotic Apparatus protein (NuMA)) remain undefined. Here, we present a crystal structure of the Importin-α•NuMA C-terminus complex showing a novel-binding pattern that accounts for selective NLS recognition. We demonstrate that, in the presence of Importin-α, Importin-β inhibits the microtubule-binding function of NuMA. Further, we have identified an uncharacterized high-affinity microtubule-binding region that lies carboxyl-terminal to the NLS, which is sterically masked by Importin-β on being bound by Importin-α. Our study provides mechanistic evidence of how Importin-α/-β regulates the NuMA functioning required for assembly of higher-order microtubule structures, further illuminating how Ran-governed transport factors regulate diverse SAFs and accommodate various cell demands.

XMAP215 functions synergistically with gamma-TuRC to promote microtubule nucleation.
R.S. Kadzik1, A. Thawani2, S. Petry1;
1Molecular Biology, Princeton University, Princeton, NJ, 2Chemical and Biological Engineering, Princeton University, Princeton, NJ

How microtubules are generated in the cell is a major open question in understanding how the microtubule cytoskeleton is assembled. For several decades, gamma-TuRC has been accepted as the universal microtubule nucleator in the cell. Although there is evidence gamma-TuRC might not be the sole nucleator, identification of other factors has proven difficult. We have developed an assay that resolves individual microtubule nucleation events in Xenopus egg extract. This allows the direct and simultaneous measurement of microtubule nucleation kinetics and microtubule plus-end polymerization in a physiological environment. Using this assay, we have been able to identify factors that are required for microtubule nucleation. Here, we report that XMAP215, the well-characterized microtubule polymerase of the cell, is essential for microtubule nucleation in meiotic Xenopus egg extracts and promotes microtubule nucleation in a concentration-dependent manner. XMAP215 functions synergistically along with gamma-TuRC to promote microtubule nucleation in physiological conditions as well as in vitro.

The role of TPX2 in branching microtubule nucleation.
R. Alfaro-Aco1, A. Thawani2, S. Petry1;
1Department of Molecular Biology, Princeton University, Princeton, NJ, 2Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ

The mitotic spindle is a bipolar array of microtubules, which orchestrates the accurate segregation of chromosomes during cell division. Microtubules in the spindle are nucleated by the gamma-tubulin ring complex (γ-TuRC). How γ-TuRC gets activated at the right time and location remains elusive. Recently, it was uncovered that microtubules nucleate from pre-existing microtubules within the mitotic spindle. This process, termed branching microtubule nucleation, is stimulated by the protein TPX2. However, the exact mechanism of TPX2 in this pathway remains unknown. We established the domain organization of Xenopus laevis TPX2 and define the minimal TPX2 version still capable of stimulating branching microtubule nucleation, which we find is unrelated to TPX2’s ability to nucleate microtubules in vitro. Several domains of TPX2 contribute to its microtubule binding and bundling activities. However, the property necessary for TPX2 to induce branching microtubule nucleation is contained within newly identified γ-TuRC nucleation activator motifs. Separation-of-function mutations leave the binding of TPX2 to γ-TuRC intact, while branching microtubule nucleation is abolished, suggesting that TPX2 may activate γ-TuRC to promote microtubule nucleation.

Microtubules are filamentous tubes that are required for organizing the internal structure of cells, maintaining cell shape, and facilitating cell division. In cells, some microtubules remain highly dynamic and undergo multiple cycles of growth and collapse, while others are stabilized and do not exhibit stochastic length changes. Microtubules are also subject to several post-translational modifications. The post-translational modification acetylation has been widely reported to mark stable microtubules, such as those that are particularly abundant in some cellular structures such as neuronal axons. However, the enzyme responsible for α-tubulin lysine 40 acetylation, α-tubulin acetyltransferase 1 (αTAT1), has been reported to increase microtubule dynamics in cells, instead of stabilizing them. How an enzyme that increases microtubule dynamics could also be associated with generating a mark associated with stable microtubules in cells remains a puzzle. In this work, we used in vitro reconstitution experiments and found that αTAT1 is able to acetylate both stable and dynamic microtubules at similar rates without a strong preference for either group. However, αTAT1 itself strongly destabilizes dynamic microtubules while not significantly increasing the basal depolymerization rate of stabilized microtubules. Thus, αTAT1 may enrich the cellular population of stable microtubules by selectively destabilizing dynamic microtubules. We tested this model in cells by analyzing specialized nerve endings called boutons at the Drosophila neuromuscular junction. Boutons have core stable microtubules and peripheral dynamic microtubules, which are associated with the formation of new boutons. We found that the loss of αTAT1 led to an increase in the overall number of boutons as well as the formation of ectopic satellite boutons.
suggestive of increased dynamic microtubules. Although bouton number increased, Futsch, a marker of stable microtubules, was unaffected by the loss of αTAT1. Our results are consistent with the model that αTAT1 acts to shift the balance between stable and dynamic microtubules in cells.

1The Francis Crick Institute, London, United Kingdom, 2European Molecular Biology Laboratory, Heidelberg, Germany

Different cell states and cell types are characterised by distinct microtubule cytoskeleton architectures which contribute to cell function. Although most of the involved molecular activities have been identified, the design principles for cytoskeleton self-organization are still poorly understood. Biomimetic systems with a limited set of purified motors and stable microtubules have provided some important mechanistic insight into the properties of minimal active filament networks that roughly fall into two classes: (1) contracting networks that often lead to the formation of asters; or (2) percolating networks consisting of extensible microtubule bundles. However, the rules determining the topological outcome of self-organization are still poorly understood. Here we examine the morphogenetic potential for microtubule organization of mitotic human motor proteins kinesin-5 and kinesin-14, two motors with well-established roles in intracellular microtubule cytoskeleton organization during cell division. Using an assay with dynamic microtubules displaying distinctly asymmetric growth properties, we show that different motors with opposing directionality can both form a range of morphologically different structures, including contracting networks or asters with focussed poles, or extensible microtubule networks, albeit at different microtubule nucleation efficiencies, growth properties, or motor and microtubule densities. Morphogenetic phase space is characterised by a broad transition zone between the two extreme network topologies. Numerical computer simulations of active network formation using Cytosim can effectively recapitulate the experimentally observed regimes, allowing us to reveal simple rules explaining the choice of network topology by the system based on biochemical and kinetic characteristics of the motors and the asymmetrically growing microtubules.

Using smFRET to Understand the Structural Changes that Underlie Tau’s Behavior on the Microtubule Surface.
J.L. Stern12, R. Ali1, A. Cario12, C. Berger123;
1Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, 2Cellular, Molecular and Biomedical Sciences Program, University of Vermont, Burlington, VT, 3Neuroscience Graduate Program, University of Vermont, Burlington, VT

The microtubule associated protein Tau is involved in multiple aspects of axonal transport in neurons, regulating microtubule dynamics, kinesin motility, and cargo delivery. Misregulation of Tau function results in a number neurodegenerative diseases, including Alzheimer’s, collectively known as “Tauopathies”. Recent in vitro studies have shown that Tau binds microtubules in an equilibrium
between static and diffusive states. Furthermore, Tau’s dynamic binding equilibrium differs with Tau isoform and correlates with the isoform’s ability to directly inhibit kinesin-1 motility. However, the mechanisms that control Tau’s static-dynamic state equilibrium and define Tau’s different functions have yet to be determined. We recently demonstrated that phosphorylation at tyrosine 18, the last residue in Tau’s phosphatase activating domain, shifts Tau towards the diffusive state on the microtubule surface, both in vitro and ex vivo. These results suggest that long-range structural changes in Tau are responsible for shifts between static and diffusive binding on the microtubule surface, given the large distance between the N-terminal position of Y18 and the C-terminal microtubule-binding region of Tau. However, the structure of Tau on the microtubule surface is not known. To better define the structural states of Tau that underlie its functional behavior, we have developed a novel single molecule fluorescence resonance energy transfer (smFRET) system to image conformational changes of Tau interacting dynamically with the microtubule surface. Using total internal reflection fluorescence (TIRF) microscopy and alternating laser excitation (ALEX), we have observed N- and C-termini dual labeled Tau bound to both paclitaxel and Guanosine-5’-[(α,β)-methylene]triphosphate (GMPCPP) stabilized microtubules in the static and dynamic states. Our results suggest N-C termini interactions occur while Tau is bound statically to the microtubule surface but are lost while in the diffusive state. This work is the first direct evidence of dynamic structural change affecting Tau’s behavior and therefore it’s function on the microtubule surface.

1Physiology Department, Perelman School of Medicine , University of Pennsylvania, Philadelphia, PA,  
2ICFO The Institute of Photonic Sciences, Barcelona, Spain

The Tubulin-Code hypothesis proposes that Post Translational Modifications (PTMs) of tubulin can mediate unique interactions with motor proteins and has been assessed by in-vitro studies. Here, we investigate the regulation of motor driven cargo transport by Acetylation and Detyrosination in living cells using correlative single particle tracking (SPT) and super resolution microscopy (STORM). By mapping the vesicular trajectories on to the distinct microtubule populations, we elucidate the differential cargo dynamics on post-translationally modified microtubules with high spatiotemporal resolution. Our results show that about 30% of microtubules in epithelial cells are both acetylated and detyrosinated. Stationary lysosomes are preferentially anchored on this microtubule sub-population. Further, motile lysosomes on the detyrosinated-acetylated MTs have shorter run-lengths and higher pause frequencies with respect to lysosome on unmodified MTs. The differences in lysosome motility was due to the detyrosination and not the acetylation state of this MT sub-population. We observed similar results for autophagosomes, suggesting that the impact on motility is likely a general phenomenon affecting diverse sets of organelles and vesicles. Our results suggest that the PTMs are recognized by microtubule motors differentially and modified motility could be cue for organelle interactions such as lysosome-autophagosome fusion.

1Laboratory of Chemistry and Cell Biology, The Rockefeller University, New York, NY, 2Department of Biological Sciences, Rensselaer Polytechnic Institute, Troy, NY, 3Howard Hughes Medical Institute, Janelia Research Campus, Ashburn, VA

Accurate chromosome segregation must be maintained over multiple cell division cycles to stably propagate genetic information. At anaphase onset, microtubules with opposite polarity interdigitate to form the spindle midzone, a specialized array that functions to keep chromosomes apart and position the cell division plane. The proper assembly of this structure depends on PRC1 (protein regulator of cytokinesis 1), a nonmotor microtubule-associated protein that selectively crosslinks antiparallel microtubules, and Kinesin-4, a plus-end directed motor protein. Prior studies have shown that these proteins form a stable complex in vitro and are thought to “measure” features of microtubule arrays. For example, PRC1/Kinesin-4 complex in vitro can both autonomously regulate the length of antiparallel microtubule overlap in dynamic filament networks and also can form micron-scale “end tags” of different lengths on stable microtubules depending on the size of the filament. However, we do not know how the length-dependent regulation of individual filaments or overlap regions between filaments contributes to spindle midzone assembly in human cells. Here, we use lattice light sheet microscopy to image whole cell volumes of dividing cells at rates varying from 1.8 to 4.4 seconds per volume. We quantitatively investigate the association of fluorescently-labeled PRC1 on microtubule bundles during the metaphase to anaphase transition in hTERT-RPE1 cells. In metaphase, approximately 40 PRC1 bundles are established that span the cell equator and measure 4.6 +/- 1.2 microns in length. Immediately after anaphase onset, PRC1 bundles shrink five-fold to 0.9 +/- 0.3 microns in between the separating chromosomes. We are designing PRC1 mutant constructs that have reduced binding to microtubules which we hypothesize may alter the number of bundles established in metaphase or the length of PRC1 bundles in metaphase and anaphase.

An optogenetic approach to control microtubule acetylation in living cells.  
N. Kaul1, H. Wang1, O. Dagliyan2, K.M. Hahn1;  
1Pharmacology, University of North Carolina, Chapel Hill, NC, 2Neurobiology, Harvard Medical School, Boston, MA

Dynamics of microtubules are regulated by post-translational modifications, the extent and variety of which depend on the cell type and environmental conditions. Acetylation of specific microtubules regulates cargo selection and trafficking to specific regions of the cell edge. Cell stress causes hyper-acetylation of microtubules, and increased microtubule acetylation correlates with metastasis, indicating that microtubule post-translational modification is important in cancer cell biology. To study the role of microtubule acetylation in live cells, we designed an analog of alpha tubulin acetyl transferase1 (αTAT1) that can be controlled with light. Unlike other tubulin modification enzymes, αTAT1 is highly specific for tubulin in its polymerized form. αTAT1 binds and transfers an acetyl moiety from acetyl coA to lysine 40 on alpha tubulin. A fragment of αTAT1 was sandwiched between the photo-responsive LOV2 domain from Avena Sativa phototropin and a peptide that we had engineered to bind
selectively to the dark state of LOV2 (Wang et al. Nature Methods 13 755-758, 2016). Only in the dark, the LOV2 and Zdk bound to each other, occluding the microtubule binding interface. Peptide linkers at the attachment sites of LOV2 and Zdk were optimized for the most effective caging. Photoactivatable αTAT1 (PA αTAT) could be fully activated in less than a second, and the half-life for return to the off state could be adjusted between 1.7 and 496 seconds by mutating residues around the LOV2 flavin. We observed extensive acetylation of microtubules in living cells upon irradiation of cells expressing PA αTAT1. Use of the analog to elucidate the role of microtubule acetylation in directed motility will be described.

Illuminating the role of Microtubule-Actin Crosslinking via Optogenetics.
R.C. Adikes¹, R.A. Hallett², B.F. Saway¹, B. Kuhlman², K.C. Slep³;
¹Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, ²Department of Biochemistry Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC

The dynamic cytoskeletal network is composed of microtubules (MTs), actin and intermediate filaments (IFs). How the physical coupling of the cytoskeletal filaments dictates downstream cellular morphological changes remains poorly understood. We developed a novel optogenetic tool (based on iLID light induced dimerization (Guntas et al., PNAS 2015)), SxIP-iLID, to facilitate the reversible recruitment of factors to MT plus ends in an End Binding (EB) protein-dependent manner using blue light. SxIP-iLID constitutively tracks MT plus ends and when activated with blue light (405-500 nm) an SspB-tagged protein is recruited to SxIP-iLID. This system is highly reversible: post activation, SxIP-iLID returns to the dark-state and releases SspB-tagged proteins from MT plus ends. We show that SxIP-iLID tracks MT plus ends and recruits tgRFP-SspB upon blue light activation without altering MT comet velocities. We used this system to investigate the effects of temporally cross-linking MT plus ends and F-actin in Drosophila S2 cells to gain insight into spectraplakin function and mechanism. Spectraplakins are the primary class of proteins that cross-link and integrate the different cytoskeletal filaments, aiding in the dynamic remodeling of the cytoskeleton. The spectraplakin family plays a fundamental role in cellular processes including polarity, morphogenesis, migration and intracellular trafficking. We show that blue light-mediated MT-F-actin cross-linking decreases MT growth velocities and generates a MT exclusion zone in the lamella. We are now positioned to test photo-induced MT-F-actin crosslinking in vivo. Currently, we are introducing this modular system into Drosophila to probe how MT-F-actin cross-linking regulates the establishment of cell polarity and cell migration. SxIP-iLID facilitates the general recruitment of specific factors to MT plus ends with temporal control enabling researchers to systematically regulate MT plus end dynamics and probe MT plus end function in many biological processes.

¹Department of Cell and Tissue Biology, UCSF, San Francisco, CA, ²Institute of Epigenetics and Stem Cells, Helmholtz Center Munich, Munich, Germany, ³Department of Pharmacology, UNC Chapel Hill, Chapel Hill, NC

Throughout the cell cycle and during differentiation, the highly dynamic microtubule (MT) cytoskeleton self-organizes to form polarized intracellular tracks that enable directional transport, facilitate chromosome segregation and help to establish cell polarity. MT remodeling through stochastic switching between phases of growth and shortening is critical for all MT functions in cells, but it is unclear how MT dynamics are spatially and temporally coordinated. Amongst the regulators of MT growth dynamics and interactions are a heterogeneous family of >30 plus end tracking proteins (+TIPs) that associate with growing MT ends. End Binding proteins (EBs) associate autonomously with MT ends and are considered core +TIPs, as they recruit most other +TIPs to the MT end. Interestingly, while all growing MT plus ends are decorated with EBs, MT functions vary in different parts of the cell, suggesting that the activity of the +TIP complex is spatially controlled. Because no tools existed to manipulate subpopulations of MTs with high spatiotemporal resolution, we sought to develop a novel optogenetics approach to spatially control the activity of the EB recruited +TIP complex and investigate the functions of different MT populations during cell migration and mitosis. We developed a photo-inactivated (pi) EB1 molecule by utilizing a phototropin LOV2 domain-based protein interaction pair that rapidly dissociates upon blue light exposure. The resulting pi-EB1 replaced endogenous EB function in EB1/EB3 double CRISPR/Cas9 knockout cells and was rapidly inactivated by blue light in a highly reversible manner. Inactivation of pi-EB1 efficiently disrupted the +TIP network at growing MT ends, induced depolymerization of a population of cell edge associated MTs and reduced persistent growth of MTs in the cell body, without affecting the recruitment of the MT polymerase ch-TOG. Patterned illumination allowed inactivation of pi-EB1 with micrometer precision, and enabled spatial control of MT polymerization in migrating and dividing cells. While the MT network is polarized toward the leading edge of migrating cells, it has remained unclear if this is a cause or consequence of directional cell movement. Our results show that local pi-EB1 inactivation results in an immediate aversive turning response, indicating that EB1-mediated +TIP interactions are essential to maintain migration direction. pi-EB1 also allowed us to investigate how subsets of dynamic MTs contribute to various aspects of mitotic spindle organization and positioning, and found that the EB recruited +TIP complex is required for spindle size homeostasis.

A two-step mechanism for inactivation of MTOC function at the centrosome.
J. Magescas¹, J.C. Zonka¹, J.L. Feldman¹;
¹Department of Biology, Stanford, Stanford, CA

During mitosis, the centrosome acts as a microtubule organizing center (MTOC), creating a radial array of microtubules to separate chromosomes between daughter cells. Microtubules are organized by complexes within the centrosome’s pericentriolar material (PCM), which is steadily recruited to the centrosome, culminating in a peak in MTOC activity in metaphase. After metaphase, PCM is removed from the centrosome thereby attenuating MTOC function. This inactivation of MTOC function at the
centrosome is likely required for the timely exit from mitosis and for subsequent cell cycle events such as centriole duplication and the reassignment of MTOC function to other structures. While a large body of work has revealed the phosphorylation-dependent steps required for MTOC assembly at the centrosome, little is known about the mechanisms reversing this process at the end of mitosis. We are using C. elegans as a model to characterize MTOC inactivation at the centrosome. In C. elegans, the PCM is comprised of two main proteins, SPD-2/CEP192 and SPD-5, which localize the microtubule nucleating complex γ-TuRC to the centrosome. Pairwise analysis of SPD-2, SPD-5, and γ-TuRC components revealed that the PCM proteins decrease at different rates: SPD-2 decreases at a faster rate than SPD-5 and γ-TuRC, leaving a “cage” of SPD-5/γ-TuRC around the centrosome. Following the gradual removal of SPD-2, the SPD-5/γ-TuRC cage fragments into smaller “packets” that are still associated with microtubules. The packets move towards the cell cortex and first lose their association with γ-TuRC and microtubules, leaving only SPD-5 foci in the cytoplasm that eventually disappear. These data strongly suggest that PCM disassembly is a two-step process, beginning with the initial removal of SPD-2 from the centrosome, followed by the fragmentation of the remaining PCM. We used pharmacological and genetic manipulations to determine the mechanisms underlying either step in disassembly. Using inhibitors of serine/threonine phosphatases, we observed a stabilization of the PCM during anaphase, implicating this phosphatase family in the process of disassembly. Because of the cortical directionality of the packets and their association with microtubules, we hypothesized that packet formation relies on cortical microtubule pulling forces. Using RNAi to perturb these cortical forces we observed a loss of the packets and PCM disassembly was instead accomplished through a much slower, steady removal of components. Based on these observations we propose that PCM disassembly is initiated in anaphase through a phosphatase-dependent removal of SPD-2. SPD-2 removal weakens the PCM that is then torn apart by cortical pulling forces, ultimately inactivating MTOC function at the centrosome.

Stimulation of microtubule-based transport by nucleation of microtubules on membrane organelles.
I.V. Semenova1, D. Gupta2, T. Usui3, I. Hayakawa3, A.E. Cowan4, V. Rodionov5;  
1R.D.Berlin Center for Cell Analysis and Modeling, and Department of Cell Biology, UConn Health, Farmington, CT, 2Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan, 3Division of Applied Chemistry, Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan

Microtubule (MT)-based transport can be regulated through changes in organization of MT transport tracks, but the mechanisms that regulate these changes are poorly understood. In Xenopus melanophores, aggregation of pigment granules in the cell center involves their capture by the tips of MTs growing toward the cell periphery, and granule aggregation signals facilitate capture by increasing the number of growing MT tips. This increase could be explained by stimulation of MT nucleation either on the centrosome or on the aggregate of pigment granules that gradually forms in the cell center. To discriminate between these possibilities, we prevented aggregation of pigment granules and compared nucleation activity of the centrosome between the signaling states. Pigment granule aggregation was prevented by injecting melanophores with antibodies specific for a major granule protein, tyrosinase-related protein 1. The injected antibodies crosslinked pigment granules with each other and created granule clusters too large to be effectively transported to the cell center. Quantification of EGFP-EB1-labeled MT plus-ends that emerged from the centrosome in the same cells treated to aggregate or disperse pigment granules indicated that granule aggregation signals did not increase nucleation activity
of the centrosome. However, inspection of time-lapse sequences of fluorescence images of cells indicated MTs often originated within pigment granule clusters produced by the injected antibodies, which suggested that pigment granules nucleated MTs. To directly test MT nucleation activity of pigment granules, we isolated them from melanophores and incubated in the presence of chromatographically purified fluorescently labeled brain tubulin. Fluorescence microscopy revealed short MTs that were often connected to pigment granules, and showed that the amount of assembled MTs was significantly increased if granules were isolated from cells exposed to granule aggregation than dispersion stimuli. This increase in MT amount correlated with recruitment of gamma-tubulin, a major component of MT nucleation templates, to pigment granules, and was suppressed by the gamma-tubulin inhibitor gatastatin or function-blocking gamma-tubulin antibodies. We conclude that pigment granule aggregation signals stimulate recruitment of gamma-tubulin to pigment granules thus increasing their MT nucleation activity. We suggest that generation of new MT transport tracks by nucleation of MTs on leading pigment granules accumulating in the cell center provides a positive feedback loop that enhances capture of trailing pigment granules by MT tips at the cell periphery.

**Measuring and modeling polymer gradients argues that spindle microtubules regulate their own nucleation.**
S. Fürthauer1, B. Kaye2, P. Foster2, M. Shelley1,3, D.J. Needleman2;
1CCB, Flatiron Institute, New York, NY, 2J. A. Paulson School of Engimeering, Harvard University, Cambridge, MA, 3Courant Institute, NYU, New York, NY

Spindle microtubules are nucleated by accessory proteins whose activity is spatially regulated. It was shown that many spindle assembly factors bind microtubules. Here, we investigate whether binding microtubules changes the activity of nucleators. To study this issue, we use novel FLIM-FRET measurements to map the concentration of microtubules and monomeric tubulin in and around the spindle. We find that oligomeric tubulin is constrained to the spindle, with no detectable gradient around it. This argues that microtubule nucleation is restricted to the spindle. Using mathematical modelling we demonstrate that this is indicative of a feedback from microtubule binding to nucleator activity. Our results strongly suggest that nucleators binding to microtubules stimulates their activity.

**Regulation of centrosomal proteins by Zika virus-encoded proteins.**
C.M. Cabrera1, E.R. Weiland1, R.A. Buchwalter1, T.L. Megraw1;
1Biomedical Sciences, Florida State University, Tallahassee, FL

Over the past two years, the world has become increasingly concerned with the spread of Zika virus (ZIKV) throughout Latin America and now parts of the United States due to its devastating neurological effects in developing fetuses. According to the World Health Organization, congenital microcephaly via Zika virus infection will affect about 2500 babies this year in Brazil alone (WHO 2016). Although much research has been focused on drug targeting to stop infection of ZIKV, not much is known about the mechanism behind fetal microcephaly secondary to maternal ZIKV infection. Inherited genetic diseases that cause fetal microcephaly most often affect centrosome protein-encoding genes (Buchwalter et al, eLS 2016). Recent studies in our lab have turned to centrosomal activity in SNB19 glioblastoma cells to decipher this phenomenon (unpublished data), concluding that ZIKV activates the microtubule-
organizing center (MTOC) of the centrosome. However, not enough is known about the individual proteins in the ZIKV genome or their effects on SNB19 cells individually. In one study, we transfected SNB19 cells with each of the twelve individual proteins encoded by the ZIKV genome to observe their effects independently with the goal of identifying which protein(s) are sufficient to activate the MTOC activity of the centrosome. We found that some specific proteins in the ZIKV genome have observed changes in the phenotype of SNB19 glioblastoma cells. In this study, we will be investigating further into the specific mechanism of activation of the MTOC and other phenotypic changes attributed to those genomic proteins.

Rescuing Microtubules with Human CLASP2.
E.J. Lawrence¹, I. Kaverina¹, M. Zanic¹;
¹Cell Developmental Biology, Vanderbilt University, Nashville, TN

Cytoplasmic Linker-Associated Proteins (CLASPs) belong to a conserved family of microtubule-associated proteins that regulate microtubule dynamics in various cellular contexts including cell migration, axonal growth and cell division. In cells, CLASPs localize to microtubule tips and stabilize dynamically growing microtubules, however, the molecular mechanisms underlying human CLASP activity are not understood. Here, we use in vitro reconstitution with purified protein components and Total Internal Reflection Fluorescence (TIRF) microscopy to investigate the molecular mechanisms employed by human CLASP2 to regulate microtubule dynamics. We demonstrate that CLASP2 suppresses microtubule catastrophe and promotes rescue but does not affect the rates of microtubule growth or shrinkage. Strikingly, when CLASP2 is combined with EB1, a known binding partner of CLASP2, microtubules become hyper-stabilized and display an increased frequency of rescue compared to microtubules grown with CLASP2 alone. We show that the synergy between CLASP2 and EB1 is dependent on a direct interaction, since a truncated EB1 protein that cannot bind CLASP2 does not enhance CLASP activity. Further, we find that EB1 targets CLASP2 to microtubule tips and increases the dwell time of CLASP2. In summary, our data show that human CLASP2 is a microtubule anti-catastrophe factor and rescue factor whose activity is enhanced by EB1-mediated enrichment at growing microtubule tips.

Developing a non-invasive intravitral imaging strategy for analysis of pre-synaptic microtubule dynamics at the Drosophila neuromuscular junction.
V.T. Chou¹, H. Lai², J.B. Long¹, M. Arnes¹, K. Obbad¹, L.A. Lucas², S.V. Alworth³, J.S. Lee³, D. Van Vactor¹;¹Department of Cell Biology and Program in Neuroscience, Harvard Medical School, Boston, MA, ²DRVision Technologies LLC, Bellevue, WA, ³AcuraStem Inc., Los Angeles, CA

Microtubules (MTs) play critical roles in the development of synapses, but their regulation and precise functions are only beginning to be understood at the molecular level. In particular, little is understood about how the dynamic growth and shrinkage of MTs contribute to pre-synaptic growth and morphogenesis. MT dynamics have been analyzed in Drosophila tissue culture and sensory dendrites. However, due to the less favorable signal/noise ratio and higher background inherent to many in vivo and ex vivo tissue preparations, studies of pre-synaptic MT dynamics at the fly neuromuscular junction (NMJ) have been comparatively limited. To address this, we have optimized a novel software platform,
Aivia (formerly SVCell), for automated and unbiased in vivo 3D particle detection and tracking that effectively addresses the challenges of the Drosophila NMJ. We performed non-invasive intravital imaging of EB1-GFP labeled MTs both in sensory dendrites and at the NMJ. We quantified multiple MT dynamics parameters in both cell types, finding striking differences in MT behaviors between sensory dendrites and at the NMJ. We furthermore analyzed sensory dendrite MT dynamics using multiple drivers of EB1-GFP expression and identified significant differences in distinct driver backgrounds. Thus, we demonstrate a novel strategy for intravital imaging and multiparametric analysis of pre-synaptic MT dynamics at the NMJ of intact animals, which we have used to identify distinct MT behaviors in different cell types and driver backgrounds. Our future studies will combine our imaging and software platform with traditional Drosophila genetics to dissect signaling networks and cytoskeletal effectors that orchestrate MT dynamics in the development of the synapse.

Microtubule assembly and disassembly dynamics (MADDY) model: exploring dynamic remodeling of microtubule tip by using tubulin polymerization-depolymerization in silico.
V.A. Barsegov¹;
¹Chemistry, University of Massachusetts, Lowell, MA

Microtubules (MT), the primary components of the chromosome segregation machinery, can switch stochastically from growth to shortening, but the mechanisms of these processes at the molecular level are poorly understood. We developed a bead-per-monomer coarse-grained model of the αβ-tubulin heterodimers: an MT lattice is stabilized by the longitudinal and lateral interactions between the tubulin subunits; the protofilaments have a bending rigidity and the GTP or GDP-bound state-dependent equilibrium bending angles. The model is parametrized against the experimental rates of MT assembly and disassembly and biomechanics of MT polymers. We carried out Molecular Dynamics simulations implemented on a GPU of entire MT polymers in the experimentally relevant second timescale, in order to explore the mechanisms of MT growth. A growing MT tip reaching 50-nm in length forms thin sheets curving outward. These gradually straighten with an increasing number of protofilaments as the lateral interactions gradually incorporate them into an MT cylinder. The growth is accompanied by formation of erroneous attachments and/or accumulation of “lattice defects” lacking tubulin dimers. These defects tend to self-correct over time, but a critical number of erroneous attachments might result in a transient catastrophe, after which a normal growth resumes. These findings offer a quantitative platform to link the molecular tubulin characteristics with the physiological behavior of MT on biological scales of length and time. The model can be used to probe the onset of dynamic instability and to explore the mechanism of catastrophe and rescue of MT polymers.

IDA3 associates with IFT in growing cilia to selectively mediate transport and assembly of axonemal I1 dynein.

1Department of Cell Biology, Emory University, Atlanta, GA, 2Department of Cell Biology and Biophysics, UT Southwestern Medical Center, Dallas, TX, 3Department of Biology, Oglethorpe University, Atlanta, GA, 4Department of Biological Sciences, Osaka University, Osaka, Japan, 5Department of Biological Sciences, Chuo University, Tokyo, Japan, 6Department of Genetics, Washington University School of Medicine, St. Louis, MO, 7Department of Biochemistry, University of Mississippi Medical Center, Jackson, MS, 8Department of Cellular Biology, University of Georgia, Athens, GA

Many ciliary substructures such as dynein arms assemble in the cell body before IFT-mediated transport in the ciliary compartment and docking to the axoneme. How these axonemal cargoes interact with IFT remains largely unknown. Here, we analyze the transport of the conserved inner dynein arm I1/f, a 1.5 MDa dynein complex that preassembles in the cytoplasm and is transported by IFT (Viswanadha et al., 2014). The Chlamydomonas ida3 mutant (Kamiya et al., 1991) preassembles I1 dynein in the cytoplasm but I1 dynein fails to enter the cilium for assembly on the axoneme, resulting in a slow-swimming phenotype. Cryo-ET confirms that I1 dynein is the sole structural defect in ida3 axonemes. Using whole genome resequencing, we identified a premature stop codon (W22X) in the ida3 mutant and loss of a 115 kDa coiled-coil protein with an intrinsically disordered region in the C-terminal half. This mutation co-segregates with the loss of I1 assembly on the axoneme. Several independent intragenic revertants restore I1 dynein assembly and subsequent motility defect. Expression of HA or NeonGreen (NG)-tagged IDA3 also rescues the motility and I1 dynein assembly phenotypes in ida3. Immuno-blotting demonstrates that IDA3 is restricted to the cell body in cells with full-length cilia, but IDA3 enters the ciliary matrix in growing cilia. Live-cell TIRF microscopy of cells transformed with IDA3::NG confirms the selective entry of IDA3::NG during ciliary assembly and indicates IDA3 entry is regulated in a cilium-autonomous manner (Craft et al., 2016). IDA3::NG moves by anterograde IFT into elongating cilia and largely exits the cilia by diffusion. Immunoprecipitation of IDA3::HA from the matrix fraction of regenerating cilia reveals an association of IDA3 with the I1 dynein intermediate chain IC140. GFP-tagged IC140 also moves by anterograde IFT. We propose that IDA3 interacts with IC140 and acts as an adapter selectively linking the I1 dynein complex to IFT to ensure transport into and within the growing cilium.

The CEP19-RABL2 GTPase complex binds IFT-B to initiate intraflagellar transport at the ciliary base.

T. Kanie1,2, P.K. Jackson1,2;
1Microbiology and Immunology, Stanford University, Stanford, CA, 2Baxter Laboratory, Stanford University, Stanford, CA

Highly conserved intraflagellar transport (IFT) protein complexes direct both the assembly of primary cilia and the trafficking of signaling molecules. Despite its initial purification from isolated...
Chlamydomonas flagella, immunofluorescence indicates the predominant localization of IFT components and motor proteins is at the ciliary base. Given that IFT trains periodically enter into the cilia from this large pool of IFT particles located at the base, it has been long hypothesized that regulatory components accumulate at the ciliary base to initiate anterograde IFT. To date, no critical regulator for the initiation of IFT has been identified. Here, by tandem affinity purification and mass spectrometry (AP-MS) of the human obesity gene CEP19, we discover two interlinked protein complexes that organize and trigger the entry of IFT-B into the cilia: the FOP-CEP350 and the CEP19 complex with the highly conserved RABL2B GTPase. CEP19 is localized specifically to the distal end of the mother centriole, and patients carrying the nonsense mutation of this gene (R82X) causes morbid obesity, male infertility, and intellectual disability. We discover that CEP19 specifically binds to and is tethered at the base of cilia by the FOP-CEP350 complex. We further find that CEP19 makes a stoichiometric complex with the highly conserved RABL2B GTPase. In vitro assay using fluorescent MANT guanine nucleotides revealed that RABL2 is an example of the class of GEF-independent GTPases, which bind to GTP via its intrinsic nucleotide exchange. Interestingly, CEP19 captures GTP-bound RABL2B specifically, thus allowing only activated RABL2 to accumulate at the ciliary base. Furthermore, AP-MS of GTP-locked, but not of wild-type and GDP-locked, RABL2 revealed that all 17 known components of the IFT-B complex were the top and almost exclusive hits in the purification. The overall very high efficiency of copurification of RABL2 GTP with IFT-B suggests that IFT-B complex is a single effector of RABL2B.

What is the role of RABL2B in the regulation of IFT-B complex? CEP19-RABL2B complex did not affect stability, complex formation, or pre-recruitment of IFT-B, but was critical for triggering the entry of IFT into the cilium. IFT particles visualized by structured illumination microscopy were reduced in CEP19/RABL2 knockout cells. The frequency of IFT-B determined by live-cell imaging of GFP-IFT80 was strongly decreased in CEP19/RABL2 knockout cells, while the velocity of IFT was unchanged, suggesting that CEP19/RABL2 trigger the ciliary entry of intraflagellar transport. The CEP19-RABL2B-IFT pathway thus provides a new molecular mechanism directing ciliary trafficking and important for the formation of the cilium.

Diffusion as a ruler: Modeling kinesin diffusion as a length sensor for intraflagellar transport.
N.L. Hendel1, M. Thomson2, W.F. Marshall1;  
1Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, 2Biology and Biological Engineering, California Institute of Technology, Pasadena, CA

An important question in cell biology is whether cells are able to measure size, either whole cell size or organelle size. Perhaps cells have an internal chemical representation of size that can be used to precisely regulate growth, or perhaps size is just an accident that emerges due to constraint of nutrients. The eukaryotic flagellum is an ideal model for studying size sensing and control because its linear geometry makes it essentially one-dimensional, greatly simplifying mathematical modeling. The assembly of flagella is regulated by intraflagellar transport (IFT), in which kinesin motors carry cargo adaptors for flagellar proteins along the flagellum and then deposit them at the tip, lengthening the flagellum. The rate at which IFT motors are recruited to begin transport into the flagellum is anticorrelated with the flagellar length, implying some kind of communication between the base and the tip and possibly indicating that cells contain some mechanism for measuring flagellar length. Although it is possible to imagine many complex scenarios in which additional signaling molecules sense length and carry feedback signals to the cell body to control IFT, might the already-known components of the IFT system be sufficient to allow length dependence of IFT? Here, we investigate a model in which the
anterograde kinesin motors unbind after cargo delivery, diffuse back to the base, and are subsequently reused to power entry of new IFT trains into the flagellum. By modeling such a system at three different levels of abstraction we are able to show that the diffusion time of the motors can in principle be sufficient to serve as a proxy for length measurement. In all three implementations, we found that the diffusion model can not only achieve a stable steady-state length without the addition of any other signaling molecules or pathways, but also is able to produce the anticorrelation between length and IFT recruitment rate that has been observed in quantitative imaging studies.

Axonemal Lumen Dominates Cytosolic Protein Diffusion inside the Primary Cilium.

W. Luo1, A. Ruba1, D. Takao2, L.P. Zweifel3, R.Y. Lim3, K.J. Verhey3, W. Yang1;

1Biology, Temple University, Philadelphia, PA, 2Department of Cell and Developmental Biology, University of Michigan Medical School, Ann Arbor, MI, 3Biozentrum and the Swiss Nanoscience Institute, University of Basel, Basel, Switzerland

Transport of membrane and cytosolic proteins in primary cilia is thought to depend on intraflagellar transport (IFT) and diffusion. However, the relative contribution and spatial routes of each transport mechanism are largely unknown. Although challenging to decipher, the details of these routes are essential for our understanding of protein transport in primary cilia, a critically affected process in many genetic diseases. By using high-speed super-resolution microscopy, we have mapped the 3D transport routes for various cytosolic proteins in the 250-nm-wide shaft of live primary cilia with an unprecedented spatiotemporal resolution of 2 ms and < 16 nm. Our data reveal two spatially distinguishable transport routes for cytosolic proteins: an IFT-dependent path along the axoneme, and a passive-diffusion route in the axonemal lumen that escaped previous studies. While all cytosolic proteins tested primarily utilize the IFT path in the anterograde direction, differences are observed in the retrograde direction where IFT20 only utilizes IFT, and approximately half of KIF17 and one third of α-tubulin utilizes diffusion besides IFT.

Ran-mediated ciliary entry of the heterotrimeric kinesin-2 motor complex.

S. Huang1, P. Avasthi1, 2;

1Ophthalmology, University of Kansas Medical Center, Kansas City, KS, 2Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS

In eukaryotic cells, cilia and flagella are microtubule based protrusive organelles. Their structure and function are remarkably conserved throughout the tree of life. Precise control of protein trafficking into cilia is essential for its structure and function. Two kinesin-2 motor complexes, heterotrimeric KIF3A-KIF3B-KAP3 and homodimeric KIF17, exist in vertebrate cells and regulate the intraflagellar transport (IFT) mechanism responsible for anterograde (base to tip) trafficking in cilia. Previous work demonstrated that RanGTP and importin-β2 regulate KIF17 trafficking to the cilia. But its role in generalized trafficking of other ciliary motors is unknown. The unicellular green alga Chlamydomonas reinhardtii is an excellent model system to identify the conserved mechanisms of ciliary protein entry due to the ease of quantifying flagellar protein/assembly dynamics and biochemically isolating flagella in this system. Here we show that in Chlamydomonas, flagellar entry of KAP (ortholog of human KAP3) is regulated by the small GTPase Ran1. Immunofluorescent staining indicates Flag-Ran1 is mainly localized
to the nucleus and flagella. Chemical disruption of Ran1-importin β-mediated import blocks KAP3 transport to flagella. Moreover, inhibition of Ran1-importin β-mediated import, but not CRM1-mediated export, can shorten flagellar length. Finally, in mammalian cells, we have mapped a potential nuclear localization signal to the C-terminus of KAP3, which may be required for ciliary/flagellar targeting as well. Our results suggest Ran1-mediated protein transport regulates entry of the heterotrimeric KIF3A-KIF3B-KAP3 complex into Chlamydomonas flagella, which may provide new insights into conserved molecular mechanisms regulating ciliary protein gating.

Local regulation of IFT train assembly and injection at eight distinct flagellar pores in the multiciliate, Giardia lamblia.
S.G. McInally¹, S.C. Dawson²;
¹Microbiology and Molecular Genetics, University of California, Davis, Davis, CA

Many protists have duplicated organelles that vary in cellular function, such as the oral and locomotory cilia in ciliated protozoa. For instance, Giardia lamblia is a multiciliated parasitic diplomonad protist with four distinct flagellar pairs. Each pair has a unique interphase length and unique associated ancillary structures, suggesting that Giardia has different ways of building, sensing and/or regulating the length and composition of the different flagella in the same cell. Giardia also has extensive non-membrane bound regions of each axoneme in the cytoplasm. In this way, Giardia is an ideal model to evaluate how cells can precisely control the production and distribution of a common pool of precursor subunits to build duplicated cellular structures. To evaluate how Giardia may differentially assemble and regulate more than one of the same kind of flagellum, we tracked fluorescently tagged intraflagellar transport (IFT) particles required for assembly and maintenance of the length of flagella. IFT particles localize along the entire flagellar axoneme with distinct accumulations at the flagellar pore, the site that marks the transition from the cytoplasm to the membrane bound axoneme. IFT particles are dynamic, but not actively transported along the cytoplasmic regions of the flagellar axoneme, while distinct IFT trains traverse the membrane bound regions of the flagellar pairs. We suggest that the membrane bound axonemal regions are assembled and maintained by IFT, while cytoplasmic regions are assembled via an IFT independent mechanism. We also used quantitative live cell imaging to compare IFT dynamics between flagellar pairs in the same cell. While IFT train speed is consistent between all flagellar pairs, longer flagella have more frequent injections of larger IFT trains than shorter flagella. The size and number of IFT trains also scale linearly with the equilibrium length of the flagellum. Perturbation of flagellar length using the microtubule stabilizing drug Taxol promotes the remodeling of IFT trains to scale to the new equilibrium flagellar length. This works suggests that Giardia differentially regulates IFT train assembly and injection at each of the eight flagellar pores to generate four flagellar pairs with unique equilibrium lengths. We are also exploring how the composition of IFT trains is remodeled during injection from cytoplasmic to membrane bound regions of flagella and identifying the components that regulate this remodeling.

Novel IFT-A gene, Thm2, interacts with its paralog, Thm1, in ciliary protein transport and in adipogenesis.
W. Wang1,2, B.A. Allard1,2, L.M. Silva1,2, D.T. Jacobs1,2, P.V. Tran1,2;
1Department of Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS, 2Kidney Institute, University of Kansas Medical Center, Kansas City, KS.

Primary cilia are antenna-like sensory organelles that project from the apical surface of most vertebrate cells. Primary cilia are built and maintained by intraflagellar transport (IFT) protein complexes, IFT-B and IFT-A, which mediate bidirectional trafficking of proteins along the ciliary axoneme. Here we characterize the ciliary phenotype of IFT-A mutants, Thm1 (also known as Ttc21b) and its paralog, Thm2. Thm1 and Thm2 are orthologous to Chlamydomonas FAP60, which encodes IFT139. Mouse embryonic fibroblasts (MEF) from E12-E14 Thm1-null, Thm2-null and Thm1; Thm2 double-knockout (dko) mice were generated. Using immunofluorescence, Thm1+/− MEF showed shortened primary cilia with more intense staining of IFT-B components (IFT52, IFT81) and of anterograde motor subunit, KIF3A, at bulbous distal tips. BBSome subunits (BBS2, BBS5) also stained more prominently in Thm1-null cilia, indicating that loss of Thm1 results in defective retrograde transport of these IFT-B and BBS proteins. In contrast, less ciliary staining of IFT-A component, IFT140, was observed in Thm1+/− MEF, suggesting a partial disruption in ciliary entry. Yet in instances when IFT140 was present in Thm1+/− cilia, staining was more intense at bulbous distal tips, indicating a retrograde defect. Thm2+/− cilia showed normal length and staining of IFT and BBS proteins, suggesting Thm2 alone is dispensable for ciliogenesis. However, Thm1; Thm2 dko MEF showed even greater accumulation of IFT81 at ciliary bulbous distal tips than Thm1+/− MEF, suggesting that Thm2 works with Thm1 to regulate retrograde transport of IFT81. Ciliary localization of membrane protein, INPP5E, was also examined. Ciliary INPP5E was reduced in Thm1+/− MEF and further reduced in Thm1; Thm2 dko MEF, indicating that Thm1 is required for INPP5E ciliary import and that Thm2 enhances this process. Finally, differentiation of MEF into adipocytes was assessed. Oil Red O-staining of lipid droplets used as a read-out of adipogenesis was increased in Thm1+/− cells and further increased in Thm1; Thm2 dko cells. In summary, our data show that Thm1 mediates retrograde transport of IFT and BBS proteins and ciliary entry of IFT140 and INPP5E, and that Thm2 optimizes Thm1-mediated IFT81 retrograde transport and INPP5E ciliary import. Further, our data imply that Thm2 augments a repressive role of Thm1 in adipogenesis.

A new model for regulation of flagellum length in Trypanosoma brucei.
E. Bertiaux1, B. Morga1, T. Blisnick1, S. Perrot1, B. Rotureau1, P. Bastin1;
1Parasites and Insect Vectors, Institut Pasteur, Paris, France.

Trypanosoma brucei is a flagellated protozoan parasite responsible for sleeping sickness in Sub-Saharan Africa. During its complex life cycle, it undergoes drastic morphological changes accompanied by extensive variations in flagellum length. They can undergo an asymmetric division that produces two daughter cells, one with a flagellum ten times shorter than the other one. Here, we have investigated the mechanisms controlling flagellum length. We show that the total amount of IFT proteins is directly related to flagellum length, with a fixed concentration of IFT proteins per length unit at all stages of flagellum elongation. To determine whether this relationship is causal or not, we have knockdowned the IFT kinesins to decrease the frequency of IFT. In these conditions, IFT was rate-limiting and the
trypanosomes assembled a shorter flagellum. However, its length still increased after cell division until it became fixed before the cell produced a new flagellum. This indicates that the timing of cell division and flagellum maturation are critical. This was confirmed by blocking cell division, leading to an increase in flagellum elongation, but never beyond the length of the parental one. We propose a new model where flagellum length is regulated by the total amount of IFT, the timing of cell division and the apparently irreversible maturation of the organelle. Finally, we are investigating these parameters during the parasite cycle when trypanosomes develop in the tsetse fly, suggesting the existence of a fourth parameter.

The role of IFT concentration at the base of the flagellum.
J. Jung¹, J. Santi-Rocca¹, C. Fort¹, S. Perrot¹, P. Bastin¹;
¹Trypanosome Cell Biology Unit, Institut Pasteur, Paris, France

Flagella are important organelles required for motility and cellular signalling, found in a brought range of eukaryotes. Flagellum formation is dependent on Intraflagellar Transport (IFT) in order to transport building blocks to the site of assembly at the flagellum tip. IFT proteins are concentrated in an IFT pool found at the base of the flagellum, from where multiprotein complexes (IFT trains) travel bidirectional within the organelle. Trypanosoma brucei is a protozoan parasite responsible for sleeping sickness in Sub-Saharan Africa that relies on flagella and represents an exciting model to study IFT. High-resolution microscopy carried out on live cells revealed that the pool of IFT proteins forms a donut-like structure, of approximately 300nm diameter, that colocalizes with the transition fibers that anchor the basal body to the flagellum membrane. Due to this colocalization, we identified the retinitis pigmentosa TbRP2 protein as a potential candidate in IFT pool maintenance, compartmentalization or control. RP2 is a tubulin cofactor C domain-containing protein that localizes at the transitional fibers in trypanosomes and has been described to be essential for cilia formation in various ciliated organisms. Here we report that TbRP2 forms a similar donut-like structure covering the IFT pool. The TbRP2 signal overlaps with the entire IFT pool and encloses its proximal end. RNAi knock-down of TbRP2 shows a strong effect on IFT distribution. Loss of TbRP2 affects IFT trafficking, consequently leading to cells close to an IFT knock-down phenotype, with construction of shorter flagella, reduced IFT frequency and IFT material accumulating in the flagellum. We propose that TbRP2 is required for correct IFT. It could contribute to the concentration of IFT proteins at the pool or to the assembly of IFT trains. Currently we are using High-resolution live microscopy in order to investigate the dynamics of the IFT pool and the role of TbRP2 in this process.

PKD2-mediated modulation of transition zone protein regulate the nucleation of apical actin network in vertebrate multi ciliated cells.
T. Yasunaga², O. Kretz³, M. Helmstädt³, Ö. Cicek³, T. Huber³, S. Lienkamp³, G. Walz³;
¹Renal Division, University Freiburg Medical Center, Freiburg, Germany, ²Computer Science, University Freiburg, Freiburg, Germany

Cilia are hair-like structures that play important roles during development and tissue maintenance. Although most cells express non-motile primary cilia, a subset of epithelial cells is decorated with multiple motile cilia to generate a directional fluid or particle flow. Due to its accessibility and genetic...
tractability, the epidermis of the Xenopus embryo has become a model system to characterize the molecular programs that control ciliogenesis in multi-ciliated cells (MCCs). Cilia are microtubule-based organelles; however, their assembly relies on an intact cortical actin network. The most apical layer of this network contains highly branched actin bundles that surround the axoneme-nucleating basal bodies in a mesh-like fashion. The subapical layer contains short actin filaments that connect neighboring basal bodies to establish synchronized beating patterns. We have previously shown that ciliary transition zone (TZ)-associated molecules (such as NPHP4) recruit formins (such as Daam1) to organize the subapical actin network, suggesting that the subapical actin network helps to shape the TZ. Here, we show that Xenopus pkd2 (trpp2), a calcium permeable TRP channel, is required for normal transition zone and subapical actin network organization. Knockdown of pkd2 causes a ciliogenesis defect that was in contrast to the knockdown of nphp family members not due to altered basal body migration to the apical cell surface. The cilia of pkd2 morphants exhibited an extended TZ structure and a concurrent loss of the subapical actin network. Further analysis showed that the TRPP2-interacting adaptor and actin-capping protein CD2AP acts down-stream of Pkd2. Analysis of the subcellular localization using GFP-fusion of CD2AP demonstrated its association with the TZ. Upon the knockdown of pkd2, CD2AP preferentially accumulated at the tight junction accompanied by an increased nucleation of actin network at the tight junction. Based on these observations, we propose a model where Pkd2 interacts with CD2AP at the transition zone to control the nucleation of actin structures within the subapical actin network.

Actin redundancy in Chlamydomonas reinhardtii is necessary for flagellar protein trafficking.
B. Jack\textsuperscript{1}, D.M. Mueller\textsuperscript{1}, A.L. Tetlow\textsuperscript{1}, P. Avasthi\textsuperscript{1,2};
\textsuperscript{1}Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS, \textsuperscript{2}Ophthalmology, University of Kansas Medical Center, Kansas City, KS

Flagella of the unicellular green alga Chlamydomonas reinhardtii are nearly identical to cilia of vertebrate cells and provide an excellent model to study ciliogenesis. These biflagellated cells have two actin genes: one which encodes conventional actin (IDA5) and the other encodes a divergent novel actin-like protein (NAP1). Previously, we described a role for actin in the regulation of flagella-building intraflagellar transport machinery and now probe how actin redundancy contributes to this process due to the availability of a nap1 mutant Chlamydomonas strain. Treatment with Latrunculin B, a potent actin polymerization inhibitor, on the nap1 mutant background effectively eliminates all functional filamentous actins in the cell. We find that actins are an absolute requirement for flagellar growth when the preexisting pool of flagellar precursors is depleted. Nap1 mutants treated with Latrunculin B also showed reduced protein synthesis during regeneration, though this cannot account for the complete lack of flagellar growth when the preexisting pool of flagellar precursors is depleted. Finally, cells without functional actins exhibit slowed incorporation of the existing pool of flagellar precursors during flagellar regeneration as well as loss of the flagellar composition-regulating protein, NPHP4 at the transition zone. Both of these results suggest actins are required for proper flagellar gating. These experiments demonstrate that each stage of flagellar biogenesis requires redundant actin function to varying degrees, with trafficking most significantly impaired upon total actin loss. By leveraging genetic tools and powerful flagellar assays in Chlamydomonas, our data now support a model in which cytoplasmic trafficking of newly synthesized proteins destined for cilia/flagella requires functional actins in addition to microtubules.
Formation of Microvilli and Cilia in the Zebrafish Pronephros Requires an Actin-binding Bioactive Peptide Amidating Enzyme.

D. Kumar¹, R.T. Thomason²,³, M. Yankova¹,⁴, J.D. Gitlin⁷, R.E. Mains⁵, B.A. Eipper¹,⁵, S.M. King¹,⁴;
¹Department of Molecular Biology and Biophysics, University of Connecticut Health Center, Farmington, CT, ²Eugene Bell Center for Regenerative Biology and Tissue Engineering, Marine Biological Laboratory, Woods Hole, MA, ³University of Virginia, Charlottesville, VA, ⁴Electron Microscopy Facility, University of Connecticut Health Center, Farmington, CT, ⁵Department of Neuroscience, University of Connecticut Health Center, Farmington, CT

The assembly of membranous extensions such as microvilli and cilia in polarized cells is a tightly regulated, yet poorly understood, process. Peptidylglycine α-amidating monoxygenase (PAM), a well conserved membrane enzyme essential for the synthesis of amidated bioactive peptides, was recently identified in motile and non-motile (primary) cilia. Knockdown and knockout approaches revealed an essential role for PAM in ciliogenesis in Chlamydomonas, Schmidtea and mouse. In mammalian cells, changes in PAM levels alter both secretion and organization of the actin cytoskeleton. Here we further explore the PAM-actin relationship using Pam-null mutant zebrafish (generated using CRISPR/Cas9 genome editing), mammalian tracheal epithelial cells and Chlamydomonas. Lack of Pam in zebrafish recapitulates the ultimately lethal edematous phenotype observed in Pam⁺/− mice and reveals additional defects. The pam⁺/− zebrafish embryos display cystic kidneys, hydrocephalus, small eyes and massive edema, but do not exhibit either laterality defects or altered otolith biomineralization, both of which depend on motile ciliary function during early development. However, there is an initial striking loss of microvilli and subsequently impaired ciliogenesis in the pronephros which also becomes highly dilated. Furthermore, we observed undocked basal bodies and cytosolic axonemes lacking a ciliary membrane in the apical cytoplasm of mutant pronephric epithelial cells; a similar phenotype was seen previously in the ventral epithelium of PAM-deficient planaria. So why can the pam⁺/− embryos assemble cilia at early time points but not later in development? Although pam⁺/− zebrafish have no Pam enzymatic activity at 4 days post-fertilization or beyond, pam mRNA is maternally loaded into early zygotes and thus amidated products may be generated at very early developmental stages. Furthermore, it is possible that maternally-derived amidated peptides are stored in the yolk and thus available for several days until depleted. In multiciliated mouse tracheal epithelial cells, we find that vesicular PAM staining colocalizes with apical actin, below the microvilli. In PAM-deficient Chlamydomonas, the actin cytoskeleton is dramatically reorganized and expression of an actin paralogue is upregulated. Biochemical assays reveal that the cytosolic PAM C-terminal domain interacts directly with filamentous actin (k_d = 600 ± 150 nM), but does not alter the rate of actin polymerization or disassembly. Our results point to a critical role for PAM in organizing the actin cytoskeleton during development which could in turn have an impact on both microvilli formation and ciliogenesis. Supported by DK032949, DK044464 and GM051293 (NIH).

The role of FBF1 in Drosophila Ciliogenesis.
Q. Wei1, Y. Hou1, Z. Wu1;
1Key Laboratory of Insect Developmental and Evolutionary Biology, Shanghai Institute of Plant Physiology and Ecology, Shanghai, China

Drosophila melanogaster possesses diverse ciliary types and assembly modes (IFT-dependent or IFT-independent), is an excellent model organism for cilia research. Here, we investigated the role of Drosophila transition fiber protein FBF1. We found that FBF1 is exclusively expressed in ciliated cells (both sensory neurons and male germ cells) in Drosophila. As expected, FBF1 is associated with the basal body transition fiber region in Drosophila, localizes distal to the centriole but below the transition zone. To understand the function of FBF1, we created FBF1 null mutants by using CRISPR-Cas9 system. Consistent with our previous reports in C.elegans, deletion of FBF1 does not affect the normal localization of transition zone protein MKS1 and MKS6, but results in IFT trafficking defects in Drosophila. Consequently, FBF1 mutant flies have short sensory cilia and show severely uncoordinated phenotype. our results indicate that Drosophila FBF1 is essential for IFT-dependent sensory cilia formation through an evolutionary conserved function in IFT trafficking.

Protein dynamics of intraflagellar transport complex recruitment to basal bodies in multiciliated cells.
J.V. Hibbard1; J.B. Wallingford1;
1Department of Molecular Biosciences, The University of Texas at Austin, AUSTIN, TX

Proper cilia formation and function require the bi-directional trafficking of protein cargo along the axoneme microtubules in a process called intraflagellar transport (IFT). This process is powered by kinesin and dynein motors, and the conserved 22-member IFT complex acts as an adaptor between motors and cargo proteins. To function in ciliogenesis, the IFT proteins must accumulate at the basal body. However, the mechanisms by which these 22 proteins are brought together and accumulated at the basal body are currently unclear. Using live imaging in vertebrate multiciliated cells, we are studying the localization, complex interaction, and protein dynamics of IFT complex formation and basal body recruitment. Using Fluorescence Recovery After Photobleaching (FRAP), we investigated the kinetics of IFT protein recruitment to the basal body in multiciliated cells. We find that IFT proteins quickly recover, but the total recovery differs between IFT-A and IFT-B proteins. Complementing both the localization and dynamics experiments, we will be employing quantitative modeling to better understand the mechanism by which IFT is accumulated in multiciliated cells.

IFT140 is required for anterograde IFT of several subgroups of flagellar membrane proteins in *Chlamydomonas*.

T. Picariello¹, J. Brown², G. Swank³, D. Cochran³, O. King³, G.J. Pazour⁴, G.B. Witman⁵;
¹Radiology, University of Massachusetts Medical School, Worcester, MA, ²Biology, Salem State University, Salem, MA, ³Neurology, University of Massachusetts Medical School, Worcester, MA, ⁴Program in Molecular Medicine, University of Massachusetts Medical School, Worcester, MA

IFT140 is a “core” subunit of the IFT-A complex which, together with the IFT-B complex and the BBSome, is a component of the IFT trains that transport cargos and transduce signals in flagella. Mutations in human IFT140 result in ciliopathies such as Mainzer-Saldino Syndrome and Jeune-Asphyxiating Thoracic Dystrophy.

We analyzed a novel *Chlamydomonas* mutant (ift140-1) which produces no detectable IFT140 by western blotting. *ift140-1* cells lack flagella and show decreased levels of peripheral and core IFT-A components (IFT139 and IFT122, respectively). The levels of IFT-B proteins and their localization were unaffected by IFT140 loss. Basal body and transition zone ultrastructure also were unaffected in *ift140-1* cells. IFT140 contains predicted N-terminal WD-repeat domains and C-terminal TPR-like domains. To investigate the functions of these domains, we generated a construct that encodes GFP-tagged IFT140 lacking the N-terminal WD domains and used it to transform the *ift140-1* mutant. Transformed cells, referred to as IFT140ΔWD-G-20C, expressed subnormal levels of the truncated IFT140, but still recovered the ability to form half-length flagella that were motile and had normal axonemal ultrastructure. Live-cell TIRF microscopy of IFT140ΔWD-G-20C cells revealed that anterograde and retrograde IFT velocity were decreased by ~5% and ~40%, respectively, relative to control cells. The substantial decrease in retrograde IFT velocity suggests that the IFT140 WD-repeat domains may function in the interaction of the IFT particle with dynein 1b, the retrograde IFT motor, or in the activation of dynein 1b at the flagellar tip. Anterograde and retrograde IFT frequency also were significantly decreased, a phenotype that was more pronounced in longer flagella. We also saw more static IFT particles in ‘long’ IFT140ΔWD-G-20C flagella, which may account for the decreased IFT frequency in these flagella. MS/MS analysis of the IFT140ΔWD-G-20C flagellar membrane + matrix fraction highlighted roles for IFT140 in both anterograde and retrograde IFT. Importantly, loss of the IFT140 WD-repeat domains resulted in complete loss of a small group of proteins from the fraction and a substantial decrease in the level of GTPases and membrane-associated proteins, including myristoylated and geranylgeranylated proteins. Our work provides the first large scale analysis of changes to the flagellar proteome resulting from mutation of an IFT-A component and indicates a critical role for IFT-A in the anterograde trafficking of a wide variety of signaling and membrane-associated proteins. Defective trafficking of these proteins may be responsible for the multitude of phenotypes associated with *IFT140* mutation in humans.

Cryo-EM structure of anterograde intraflagellar transport trains.

M. Jordan¹, D. Diener¹, L. Stepanek¹, G. Pigino¹;
¹Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany

Cilia are ubiquitous microtubule based eukaryotic organelles that have fundamental motility, signalling and sensing function. For its assembly and maintenance, the cilium requires bidirectional intraflagellar
transport (IFT) of building blocks to and from its assembly site at the tip. Transport proceeds on microtubule tracks, driven by oppositely directed motors: the anterograde kinesin-2 and the retrograde dynein-1b. Both motors bind to IFT protein complexes organised into large structures called IFT trains, which function as adaptors for ciliary cargos. Retrograde dynein motors are loaded as cargos onto anterograde trains and are transported to the tip where they initiate and power retrograde transport. Using cryo-electron tomography and subtomogram averaging we reveal the tripartite architecture of the IFT machinery in situ in cilia of Chlamydomonas. Our reconstructions reveal the relative positions of the IFT protein complexes and possible interactions with cargos.

The molecular architecture of the yeast spindle pole body core determined by Bayesian integrative modeling.
1Department of Bioengineering and Therapeutic Sciences, The University of California, San Francisco, San Francisco, CA, 2Department of Chemistry, University of Cambridge, Cambridge, United Kingdom, 3Department of Biochemistry, University of Wisconsin, Madison, WI, 4Department of Biochemistry, University of Washington, Seattle, WA, 5Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, 6California Institute for Quantitative Biosciences, The University of California, San Francisco, San Francisco, CA, 7Department of Pharmaceutical Chemistry, The University of California, San Francisco, San Francisco, CA

Microtubule organizing centers (MTOCs) form, anchor and stabilize the polarized network of microtubules in a cell. The central MTOC is the centrosome that duplicates during the cell cycle and during mitosis assembles a bipolar spindle to capture and segregate sister chromatids. Yet, despite their importance in cell biology, the physical structure of MTOCs is poorly understood. Here we determine the molecular architecture of the core of the yeast spindle pole body (SPB) by Bayesian integrative structure modeling based on in vivo FRET, small-angle X-ray scattering (SAXS), X-ray crystallography, electron microscopy and two-hybrid analysis. The model is validated by several methods that include a genetic analysis of the conserved PACT domain that recruits Spc110, a protein related to pericentrin, to the SPB. The model suggests that calmodulin can act as a protein cross-linker and Spc29 is an extended, flexible protein. The model led to the identification of a single, essential heptad in the coiled coil of Spc110 and a minimal PACT domain. It also led to a proposed pathway for the integration of Spc110 into the SPB.

Coupling of Polo kinase activation to nuclear localization by a bifunctional NLS is required during mitotic entry.
D.O. Kachaner1, D. Garrido1, K. Normandin1, H. Lavoie1, V. Archambault1;
1University of Montréal - IRIC, Montréal, QC

Introduction: Successful cell division requires the spatiotemporal coordination of multiple events by master regulator enzymes. Defects in its regulation can lead to cancer. Discovered in Drosophila, the
Polo kinase (called Plk1 in humans) has emerged as a conserved master regulator of multiple processes during cell division including mitotic entry, centrosomes maturation, kinetochore function, spindle assembly and cytokinesis. Polo is composed of an N-terminal Ser/Thr kinase domain (KD) and a C-terminal Polo-Box domain (PBD), which mediates protein interactions with substrates and localization to different subcellular structures. In addition, the PBD and KD can interact and inhibit each other, and this reciprocal inhibition is relieved when Polo is phosphorylated at its activation loop. How Polo is regulated for its multiple functions during cell division is not completely understood.

Results: Here, we have elucidated the molecular mechanism for the spatiotemporal regulation of Polo kinase during mitotic entry. We discovered that phosphorylation of Polo at its activation loop site triggers its nuclear import during prophase. This import depends on a Nuclear Localization Signal (NLS) in the kinase domain that is masked by the PBD when Polo is inactive, and that becomes exposed when the activation loop is phosphorylated. In addition, by mediating the interaction of the kinase domain with the PBD, the NLS is required for reciprocal inhibition of both domains of Polo. Disruptions in this mechanism have profound consequences. Preventing the nuclear localization of Polo leads to a failure of Polo to trigger nuclear exclusion of the CDK1-activating phosphatase Cdc25 during prophase, and induces multiple mitotic defects. Using transgenic flies expressing different mutant forms of Polo, we show that coordination of Polo activity and localization is essential in the developing animal.

Conclusion: Our study uncovers an elegant mechanism coupling Polo activation and nuclear localization in mitotic entry and demonstrates the importance of this mechanism in vivo. It brings new understanding of the spatiotemporal mechanisms linking major regulatory enzymes during mitotic entry, namely Polo, Cdc25 and Cdk1. The dual role of an NLS motif in regulating both localization and activity, and its allosteric regulation by phosphorylation, are novel concepts that could apply to other proteins.

Upstream open reading frames control Plk4 translation and centriole biogenesis.
P. Phan¹, S. Hutcherson¹, V. Daggubati¹, A.J. Holland¹;
¹Molecular Biology and Genetics, Johns Hopkins University School of Medicine, Baltimore, MD

Centrioles are microtubule-based structures that contribute to the formation of the centrosome, the major microtubule-organizing center of the cell. It is critical that centriole duplication happens precisely once per cell cycle to ensure genomic integrity following cell division. Centriole duplication is regulated by the conserved kinase Polo-like kinase 4 (PLK4) and overexpression of PLK4 promotes centriole overduplication and spontaneous tumorigenesis in mice. Previous work from our lab and others have shown that PLK4 regulates its own stability through self-phosphorylation to promote its degradation by the proteasome. Here, we show that in addition to this post-translational control, PLK4 expression is also subject to tight translational control due to the presence of upstream open reading frames (uORFs) in the 5′ untranslated region (5′UTR) of the PLK4 mRNA. Human PLK4 mRNA contains two uORFs in the 5′UTR. The 5′ proximal uORF1 is a positive-acting element that suppresses translation reinitiation at downstream uORF2, while uORF2 is an inhibitory element that blocks PLK4 expression. Elimination of both uORFs increases PLK4 protein expression and leads to centrosome amplification. Importantly, the presence of uORFs in the 5′UTR of PLK4 mRNA is conserved amongst vertebrates, suggesting that the mechanism of translation reinitiation involving uORFs may be a conserved feature controlling PLK4 expression. Together, our findings uncover a new layer of regulation that acts in concert with post-translational control, to reduce the abundance of PLK4 and limit centrosome duplication to once per cell cycle.

Albatross/FBF1 integrates centrosome dynamics.
A. Inoko1, T. Kiyono2, M. Inagaki3, Y. Hayashi1;
1Department of Cell Biology, Aichi Cancer Center Research Institute, Nagoya, Japan, 2Division of Carcinogenesis and Cancer Prevention, National Cancer Center Research Institute, Tokyo, Japan

The centrosome is tiny but functionally important organelle that alters their fashions as: centriole duplication, spindle formation and primary cilia formation. Each event is regulated by known key enzymatic reactions, but how these events are comprehensively conjugated is still unknown. Recent reports indicated that primary cilia formation is ascribed to distal appendage proteins including FBF1, the synonym of our-identifying Albatross, but contribution of Albatross to other centrosomal function is not determined. Here we show novel function of Albatross at the opposite, proximal side of centrosomes. By our preceding advantages of specific antibodies, full-length Albatross genes and refined knockdown experiments with add-back, we found that this proximal localization is responsible for centriolar duplication through the recruitment of SAS6, a cartwheel protein of centrioles. Moreover, Albatross contributes to centrosome separation by recruiting mitotic kinase Plk1 on its S348 phosphorylation with possible Cdk1-priming, which was postulated from SSP consensus sequence on Albatross. Finally, this mitotic phosphorylation-dependent binding and its function was confirmed by immunoprecipitation against Plk1-PBD, mitotic Phos-tag assay and rescue experiments with the phospho-defective mutant of Albatross. Taken together, we conclude that Albatross is a novel platform integrating spatially and mechanistically independent centrosomal functions, including primary cilia formation, centriole duplication and centrosome separation.

t3421, a mutation in a novel protein required for centrosome matrix assembly in the one-cell stage C. elegans embryo.
A.C. Erpf1, N. Memar1, R. Schnabel1, T. Mikeladze-Dvali1;
1Biocenter, Ludwig-Maximilians-University Munich, Munich, Germany, 2Institute of Genetics, Technical University Braunschweig, Braunschweig, Germany

Centrosomes, the primary microtubule organizing centres (MTOC) of animal cells, consist of a pair of centrioles surrounded by pericentriolar-material (PCM). As in many metazoans, in the nematode C. elegans, spindle bipolarity of the zygote is established by means of sperm derived centrioles, which mature to a centrosome by recruiting maternally contributed PCM components. Spindle-defective protein-5 (SPD-5/CDK5RAP2/CNN), the major PCM scaffold protein in C. elegans, forms a PCM core at non-mitotic centrosomes. SPD-5 through its ability to self-organize, assembles a PCM matrix at mitotic entry, onto which other PCM proteins are loaded. It has been shown that PCM matrix expansion is regulated through the phosphorylation of SPD-5 by Polo Kinase-1 (PLK-1/Plk-1/polo) (Woodruff, J. B. et al. Science, 348, 808-812, 2015). However, how the non-mitotic SPD-5 core is recruited to the centrosome and its contribution the PCM matrix expansion at mitotic entry remains unknown.

Among a set of temperature-sensitive embryonic lethal mutations, we identified the mutant allele t3421, which causes defective spindle assembly in early embryos. Live cell imaging of embryos at a restrictive temperature, revealed the formation of monopolar spindles during the first cell cycle, followed by an abnormal cytokinesis, as well as tri- or tetrapolar divisions in the second cell cycle. Our current work suggests that paternally contributed centrioles are defective in the process of PCM matrix expansion.
assembly during the first mitotic divisions. In particular SPD-5 is absent from centrosome core prior to mitotic entry. As a consequence SPD-5 recruitment during mitosis and the dynamic expansion of the mitotic PCM is severely compromised. We mapped t3421 to a gene coding for an unknown coiled-coil domain protein. Despite its role in the maintenance of the non-mitotic PCM core and centrosome matrix recruitment, the unknown protein predominantly localizes to centrioles. We also present evidence that t3421 strongly enhances a mild PLK-1 loss of function phenotype.

We propose that the novel protein is part of the centrosome core, which acts as a scaffold facilitating SPD-5 and PLK-1 interaction, to allow robust PCM matrix expansion at mitotic entry.

**CEP135 Isoforms Regulate Centrosome Number in Breast Cancer Cells.**

D. Ganapathi Sankaran¹, C.G. Pearson¹;

¹Cell and Developmental Biology, University of Colorado School of Medicine, Aurora, CO

Centrosomes are microtubule-organizing centers comprised of a pair of centrioles surrounded by the pericentriolar material (PCM) that nucleates and organizes cytoplasmic microtubules. Normal cells typically possess one or two centrosomes. In contrast, centrosomes can be numerically amplified in breast cancer cells by an event called centrosome amplification. Centrosome amplification is detrimental as it promotes hallmarks of cancer including genome instability and cellular invasion. Likewise, we find that centrosome amplification in breast cancer cells increases microtubule density and nucleation capacity. Centroseome numbers are controlled by centriole duplication and homeostasis occurs in normal cells by preventing centriole overduplication that leads to centrosome amplification. However, it is not known how centriole duplication is misregulated to promote centrosome amplification in cancer cells. CEP135 is a conserved centriolar protein important for centriole duplication. We identified a short isoform of CEP135 (CEP135<sub>mini</sub>). The full length CEP135 (CEP135<sub>full</sub>) isoform promotes centriole duplication whereas the CEP135<sub>mini</sub> isoform represses it. The transcript and protein levels of CEP135<sub>full</sub> relative to CEP135<sub>mini</sub> (CEP135<sub>full:mini</sub> ratio) are elevated in breast cancer cells. Furthermore, decreasing the CEP135<sub>full:mini</sub> ratio is sufficient to reduce centrosome amplification in breast cancer cells. Thus, the regulation of these two isoforms may play an important role in controlling centriole duplication and centrosome amplification. This led us to ask how the isoforms are generated and if this mechanism can be utilized to alter the CEP135<sub>full:mini</sub> transcript ratio. We found that the CEP135<sub>mini</sub> isoform is produced by alternative polyadenylation. It utilizes a predicted, non-consensus poly A signal (AATATA) for its transcription termination, while the CEP135<sub>full</sub> isoform utilizes a consensus poly A signal for its transcription termination. Polyadenylation signal usage is often misregulated in cancer cells suggesting that the altered usage of the CEP135 poly (A) signals promote increased CEP135<sub>full:mini</sub> transcript ratio in breast cancer cells with amplified centrosomes. We propose that the altered usage of CEP135 and other centrosome component poly (A) signals regulates centrosome amplification and its microtubule organization capacity in breast cancer cells.

C. elegans FZR-1, a Co-Activator of Anaphase Promoting Complex, Acts as Genetic Suppressor of zyg-1 in Regulating Centrosome Assembly.
J.C. Medley\textsuperscript{1}, L.E. DeMeyer\textsuperscript{1}, M. Song\textsuperscript{2};
\textsuperscript{1}Biological Sciences, Oakland University, Rochester, MI

The centrosome is the primary microtubule-organizing center in animal cells, and is vital for the maintenance of genomic integrity. For the fidelity of cell division, the centrosome must duplicate only once per cell cycle, and duplicated centrosomes establish bipolar spindles for accurate chromosome segregation. Aberrant centrosomes are often associated with human disorders including cancers and microcephaly, where extra centrosomes lead to chromosome missegregation and abnormal cell proliferation. Levels of centrosome proteins are shown to be critical for proper centrosome number and function. Overexpressing key centrosome factors leads to centrosome amplification, while depleting these factors results in a failure of centrosome duplication. In this regard, protein turnover by proteolysis provides a vital mechanism for proper levels of centrosome factors. In this study, we investigate how the anaphase promoting complex/cyclosome (APC/C) and a cofactor FZR-1 (a homolog of human Cdh1) regulates centrosome assembly in C. elegans embryos. The APC/C complex is an E3 ubiquitin ligase that orchestrates the sequential degradation of cell cycle regulators during mitosis and early interphase. FZR-1/Cdh1 modulates the APC/C at late mitosis and events in G1 during the time when centrosomes duplicate by recognizing destruction motifs (D- and KEN-box). Through genetic screening, we identified fze-1 as a suppressor of zyg-1, encoding a conserved kinase ZYG-1/Plk4 that is essential for centrosome duplication. The fze-1 missense mutations restore centrosome duplication and embryonic viability of zyg-1(it25ts) mutants. As the APC/C complex is also shown to suppress the phenotype of zyg-1 mutants, FZR-1 is likely to regulate centrosome assembly as a part of the APC/C complex. Our quantitative analyses revealed that both centrosomal and cellular SAS-5 levels are significantly increased in zyg-1; fze-1 double mutants, compared to zyg-1 mutants, suggesting that SAS-5 can be a putative substrate targeted by APC/CFZR-1-mediated proteolysis. As ZYG-1 is required for the localization of SAS-5 to centrosomes, hyper-accumulation of SAS-5 might compensate for the loss-of-function of zyg-1. Furthermore, our IP experiment indicates a physical interaction between SAS-5 and FZR-1 in C. elegans embryos. Finally, we show that FZR-1 is enriched at nuclei and associated with spindles and centrosomes. Together, our results show that FZR-1 negatively regulates centrosome assembly in close association with ZYG-1 in C. elegans embryos. FZR-1 depletion results in elevated levels of centrosome factors, thereby compensating impaired ZYG-1 function in centrosome duplication, functioning as part of the APC/C complex to control protein stability in a cell cycle dependent manner.

Centrosome number homeostatic mechanisms.
R. Sala\textsuperscript{1}, T. Stearns\textsuperscript{1,2};
\textsuperscript{1}Biology, Stanford University, Stanford, CA, \textsuperscript{2}Genetics, Stanford University, Stanford, CA

The centrosome is the major microtubule organizing center in animal cells. It consists of two centrioles with associated pericentriolar material and appendage structures, and functions as the basal body for the formation of the primary cilium. Centrosomes duplicate once per cell cycle and segregate on the mitotic spindle. Normally, cells have one centrosome (two centrioles) in interphase, and two centrosomes (four centrioles) at mitosis. In contrast, cancer cells often have extra centrosomes, a
phenotype that is correlated with genome instability, aggressiveness, poor prognosis, and recurrence of some tumors. It has been shown that when cells experimentally-depleted of centrioles are allowed to re-form centrioles, they initially make a greater-than-normal number by de novo formation, followed by a return to the normal number over relatively few cell cycles, suggesting that a mechanism to maintain centrosome number homeostasis exists. We consider three possible homeostatic mechanisms: 1) limited duplication of centrioles in S phase, 2) asymmetric segregation of centrioles at mitosis, and 3) centriole elimination. To test these, we induced centriole amplification in RPE1 cells expressing centrin-GFP and tetracycline-inducible Plk4, a positive regulator of centriole duplication. We confirmed that these cells amplify centrioles, and gradually return to the normal number of centrosomes. Labeling cells in S phase with an antibody against SASS6, a marker of new daughter centrioles, showed that duplication is not limited to a subset of centrioles, with SASS6 co-localizing with each centrin focus. Further evidence for lack of a duplication limit was the presence of centriole doublets at mitosis, as expected if each centriole was able to duplicate. Proliferation of cells with amplified centrioles was reduced compared to the appropriate controls, suggesting either increased cell cycle length or cell death specifically associated with amplification. Live imaging revealed no significant difference in time in mitosis between control and centrosome-amplified cells. Instead, we found a significant delay in the length of interphase. Lineage tracking and live imaging experiments are in progress to determine centrosomes fate and cell cycle dynamics. In conclusion, our research has the potential to uncover the mechanisms responsible for centrosome number homeostasis, an important defense against cancer progression.

Correlative STORM/EM analysis of the centriole distal appendage architecture.
M. Bowler1, D. Kong2, J. Loncarek1;
1National Cancer Institute, National Institute of Health, Frederick, MD

The centriole plays a vital role in a variety of cellular processes including microtubule organization, chromosome alignment, and the formation of motile and primary cilia. The process of ciliation relies on specialized centriolar structures known as distal appendages, which localize to the distal end of the oldest centriole. When visualized by electron microscopy, distal appendages appear as “120 nm long electron dense structures emanating from the centriole microtubule walls, consisting of a of small “stem” and an electron dense “head”. If observed from the proximal centriole end, distal appendages display a clockwise twist of “66 degrees with respect to the vector connecting centriole outer microtubules. Distal appendages contain several proteins: Odf2, CCDC41/Cep83, CCDC123/Cep89, SCLT-1, FBF-1, and Cep164. Previous studies have demonstrated the recruitment hierarchy for these proteins showing that Odf2 and CCDC41 accumulate first, recruiting CCDC123 and SCLT-1. SCLT-1 is then needed for the recruitment of FBF-1 and Cep164. Due to the small size of appendages, conventional light microscopy does not provide the resolution to reveal the precise localization of distal appendage proteins (DAPs) on appendages. Here we combine the strengths of two powerful imaging techniques-Stochastic Optical Reconstruction Microscopy (STORM) and electron microscopy (EM)- to unravel the localization and dynamics of several DAPs in RPE-1, Hela, and mIMCD3 cells. STORM analysis revealed that each DAP has a unique nine-fold symmetrical pattern, which appears conserved across cell lines. Correlative STORM/electron microscopy analysis revealed the position of STORM signals with respect to the centriole wall and the characteristic distal appendage electron densities (stem and head). Cep164 signal localizes outermost and encircles the appendage head in a hook-like pattern. Cep164 units touch laterally homogenizing the space between the two electron dense EM signals. FBF-1 has a lobular appearance and co-localizes with the electron-dense appendage head. SCLT-1 and FBF-1 are localized at

Sunday-124
the same distance from the centriole wall. CCDC41 appears as a discrete signal closest to the centriole. Its signal overlaps with Odf2, which is localized around centriole wall in a more uniform pattern. Finally, our analysis reveals the dynamic nature of DAPs during cell cycle. From G1 till late G2 the appendage structure is maintained. From prophase till metaphase the outermost proteins Cep164 and FBF-1 are mostly lost, while the inmost proteins CCDC41 and SCLT-1 remain associated with the centrioles. Our study provides the most detailed analysis of distal appendage architecture to date.

mRNA is a dynamic component of the pericentriolar material in Drosophila early embryos.
P.V. Ryder¹, D.A. Lerit¹;
¹Department of Cell Biology, Emory University, Atlanta, GA

Aberrant centrosome function underlies pathologies with profound significance for human health, including growth deficiency syndromes and cancer. Centrosomes function as microtubule organizing centers, build the mitotic spindle, form the basal body to template cilia in ciliated cells, and serve as platforms for signaling cascades including cell cycle signaling. The centrosome consists of a pair of centrioles surrounded by a protein matrix termed pericentriolar material (PCM). The composition and quantity of PCM determines the microtubule nucleating activity of the centrosome and changes rapidly in cycling cells. The mechanisms responsible for rapid changes to centrosome composition and structure are incompletely understood. Intriguingly, a screen for localized mRNA in Drosophila early embryos identified multiple mRNA transcripts enriched near the spindle poles. Mutations to several of these genes disrupt centrosomes and/or the mitotic spindle, suggesting that mRNA enrichment at the centrosome may be an unexplored mechanism to modulate centrosome function. To test this hypothesis, we combined single molecule fluorescence in situ hybridization (smFISH) with quantitative imaging in Drosophila early embryos to measure the centrosome enrichment of several model mRNAs throughout the cell cycle. Here, we report that centrosome-related mRNAs, including Centrocortin (Cen) and Pericentrin-like protein (Plp), are enriched at centrosomes labeled by the pericentriolar material marker, Centrosomin-GFP. Our data suggests that Cen mRNA moves from a diffuse centrosomal enrichment to clustered peri-centrosomal structures during the syncytial divisions of the early embryo. We conclude that centrosomal mRNAs are dynamic during development and enriched at bona fide centrosomes. We are currently investigating the functional significance of centrosome-localized mRNA, which will inform our understanding of the regulation of this crucial organelle.

Centrocortin regulates actin-related processes in the early Drosophila embryo including axial nuclear expansion in a Rho1-dependent manner.
C. Blake-Hedges¹, L. Kao¹, C. Zheng¹, T.L. Megraw¹;
¹Department of Biomedical Sciences, College of Medicine, Florida State University, Tallahassee, FL

In the early Drosophila embryo, many important changes occur during development, including the dynamic actin cytoskeleton rearrangements that control axial nuclear expansion. This process involves movement of the nuclei along the anterior-posterior axis so that they become evenly spaced during the early syncytial mitotic cycles. The mechanism behind this movement is poorly understood, but requires nonmuscle myosin II and the subsequent phosphorylation of its regulatory light chains (RLC). Rho kinase, which is activated by the GTP form of Rho1, regulates RLC phosphorylation and is also required for axial
expansion. Centrocortin (Cen), which is associated with the centrosome and the actin cleavage furrows in the early embryo, is necessary for accurate cleavage furrow formation. Cen mutants display defective cleavage furrows due to disruption in the actin cytoskeleton surrounding the early embryo nuclei. This disorganization of actin leads to inappropriate centroskeleton interactions between multiple nuclei as evident by linked microtubule spindles. In this study, we aimed to establish a link between the Rho1 pathway, Centrocortin, and axial expansion in order to elucidate the system behind axial expansion. We found that Cen interacts physically with multiple actin regulators such as Filamin, Formin, and other actin-associated proteins through mass spectrometry analysis. A hemizygous mutant of Cen combined with a heterozygous mutant of Rho1 results in severe axial expansion failure, indicating a cooperative role for both proteins. The hatch rate of hemizygous Cen mutants is slightly, but significantly, lower than wildtype, while the hatch rate of the double Cen Rho1 mutants is drastically lower indicating a strong interactive role for both of these proteins during early embryogenesis. These data indicate that Cen is in a complex with other actin regulators in the Rho1 pathway in order to regulate the actin dynamics of the early Drosophila embryo.

Characterization of centrosome amplification in the unique cell types of the placenta.
M. Stratton1, T. Stearns1,2
1Biology, Stanford University, Stanford, CA, 2Genetics, Stanford University School of Medicine, Stanford, CA

The centrosome is the microtubule-organizing center of animal cells, and is composed of a pair of centrioles and pericentriolar material. Centrioles are required for cillum formation and mitosis, and their number is tightly controlled. As with chromosomes, centrioles are duplicated once and only once per cell cycle, and are segregated equally in mitosis. In most mitotically cycling cells, these processes are coupled, such that chromosome and centriole number are equivalent. However, the two processes are uncoupled in some differentiated cell types, resulting in amplification of either centrioles or the genome without canonical cell cycle progression. Amplification is often critical to the function of these differentiated cell types; for example, the amplification of centrioles in multiciliated cells is required for the subsequent formation of the hundreds of motile cilia that define that cell type. We are interested in addressing how DNA replication and centriole duplication are uncoupled from the cell cycle, and from each other, in terminally differentiated cells.

We have chosen to focus on trophoblast giant cells (TGCs), a terminally differentiated cell type in the placenta. TGCs undergo modified cell cycles through a process known as endoreduplication, in which the genome is amplified many-fold without cell division. TGCs are important in placental development, specifically for implantation of the embryo and placental remodeling during pregnancy, and some subtypes of TGCs are highly invasive. TGC invasion defects contribute to disease states such as preeclampsia and accreta in which TGCs fail to migrate to the proper location in the placenta. Prior to this work, little was known about the centrosome cycle in TGCs. We show that centriole number in TGCs in vitro increases as nuclear area increases, throughout differentiation. The amplified centrioles in TGCs have known markers of centrosomal maturation, including distal and subdistal appendages, centriolar cap, and pericentriolar material. The TGC centrioles have the potential to act as functional microtubule-organizing centers, but do not form a primary cillum in culture. We are testing whether centriole and genome copy number increase in tandem during differentiation, or whether they are independently amplified. Interestingly, inhibition of either process with specific drugs suggests that centriole duplication and DNA replication can be uncoupled in TGCs. Lastly, we are investigating whether amplified centrosomes in TGCs are present in the developing placenta in vivo. We hypothesize...
that amplified centrosomes in TGCs might contribute to their highly invasive phenotype, based on previous work showing that increased invasiveness is associated with centrosome amplification in cultured cancer cells.

Kinetochore Assembly and Functions 1

Investigating the contribution of phospho-Histone marks to Aurora B kinase activity at kinetochores.

A.J. Broad1, J.G. DeLuca1,2; 1Biochemistry and Molecular Biology, Colorado State University, Fort, CO, 2Institute for Genome Architecture and Function, Fort Collins, CO

Dynamic, regulated interactions between kinetochores and spindle microtubules result in amphitelic attachment of sister chromatids, which facilitate proper chromosome bi-orientation prior to cell division. Essential for the regulation of kinetochore-microtubule attachments is the centromere-localized chromosome passenger complex (CPC), which is composed of Survivin, Borealin, INCENP, and Aurora B kinase. In early mitosis, Aurora B kinase phosphorylates kinetochore substrates to reduce the stability of kinetochore-microtubule interactions, thereby preventing premature stabilization of any incorrect connections that form. Centromere recruitment of Aurora B kinase is proposed to depend on two histone modifications: Haspin kinase phosphorylation of histone H3 at Thr3 (H3-pT3) and Bub1 kinase phosphorylation of histone H2A at Thr120 (H2A-pT120). A major premise of the current model describing centromeric CPC recruitment is that phosphorylated H3 and H2A spatially overlap, and this region of overlap directs CPC recruitment to inner centromeres. Contrary to the proposed model, however, immunostaining experiments reveal that H3-pT3 localizes to the inner centromere, while H2A-pT120 distinctly localizes to kinetochores in a “paired dot” pattern. Thus, it is unclear if the “overlapping phospho-mark” model accurately describes centromeric CPC recruitment. In addition, Aurora B kinase and other members of the CPC, including Borealin and INCENP, have been localized distinctly to kinetochores in addition to the inner centromere. How Aurora B kinase is recruited specifically to kinetochores, and whether H2A-pT120 and/or H3-pT3 are required, remains unknown. Here, we set out to determine the contribution of H2A-pT120 and H3-pT3 to the recruitment of Aurora B kinase and additionally, to the activity of Aurora B towards kinetochore substrates. We find that each individual histone phospho-mark is sufficient to recruit the CPC, and localization of CPC components does not, in fact, require a combination of the two histone modifications. Furthermore, such overlap is not required for Aurora B kinase activity towards kinetochore substrates. However, we find that Bub1 kinase activity is essential for kinetochore-associated Aurora B activity independent of its contribution to pH2A-mediated recruitment of Sgo1. In sum, our results suggest that distinct molecular pathways are responsible for the recruitment and activity of Aurora B at centromeres and kinetochores.

Aurora B association with nucleosomes, not transcription, regulates its centromere localization and proper SAC response in human cells.
C. Ferras¹, M. Cruz¹, M. Alba Abad¹, N. Galjart³, J. Arulanandam², H.J. Maiato¹;
¹Chromosome Instability Dynamics Lab, IBMC/I3S, Porto, Portugal, ²Cell Biology, Wellcome Trust Centre for Cell Biology, Institute of Cell Biology, Edinburgh, , United Kingdom, ³Genetics, Erasmus MC, Rotterdam, Netherlands

Despite the prevailing dogma that transcription in higher eukaryotes is repressed during mitosis, recent studies provided evidence that some level of transcription might still take place. In line with this hypothesis, the master mitotic regulator Cyclin B1 has been suggested to be actively transcribed during mitosis and to be required for a robust spindle assembly checkpoint (SAC), a signaling mechanism that controls the fidelity of mitosis by detecting unattached kinetochores. Furthermore, in vitro studies using Xenopus oocyte extracts have suggested that the localization and activation of Aurora B (required for proper SAC response and error correction) is dependent on centromeric mitotic transcription. However, whether active transcription is required for spindle assembly checkpoint response and Aurora B localization/activity in animal somatic cells remains unknown. Here we use deep sequencing and live cell imaging of human cells in culture to investigate the role of transcription during a prolonged mitosis. Our initial analysis using a well-known transcription inhibitor (Actinomycin D) that intercalates DNA revealed that Aurora B was indeed de-localized from the centromeres. This loss affected mitotic timing and cell fate after nocodazole treatment. However, inhibition of transcription independently of DNA intercalation did not significantly alter cell fate, mitotic duration nor Aurora B localization. Moreover, we found other DNA intercalating agents phenocopied the Actinomycin D effect. In vitro electrophoretic mobility shift assay using reconstituted nucleosome core particles (NCPs) from recombinant histones showed that DNA intercalating agents reduced the interaction of CPC core complex (that include the Aurora B) with nucleosomes. Finally, RNA-seq analysis of cells treated with Actinomycin D failed to reveal de novo transcription of mitotic genes during a prolonged mitosis. Overall our data suggest that centromere structure, rather than transcription, regulates Aurora B localization and SAC response in human cells.

Dual Roles of the Chromosomal Passenger Complex at Centromeres.
J. Haase¹, M. Bonner¹, H. Halas¹, A.E. Kelly¹;
¹National Cancer Institute, National Institutes of Health, Bethesda, MD

The Chromosomal Passenger Complex (CPC) localizes to centromeres in early mitosis to activate its subunit Aurora B kinase. Aurora B is required for outer kinetochore assembly as well as correction of erroneous kinetochore-microtubule attachments. However, it is unclear if centromeric CPC localization contributes to these functions beyond the activation of Aurora B. Here, we show that an activated CPC that cannot localize to centromeres supports functional assembly of the outer kinetochore, but is unable to correct errors in kinetochore-microtubule attachment in Xenopus egg extracts. We find that CPC has two distinct roles at centromeres: one to properly phosphorylate the Aurora B substrate Ndc80 to regulate attachment, and a second, kinase-independent role in the proper loading of CENP-C and the CENP-H-I-K-M complex to the inner kinetochore. Although a fully assembled inner kinetochore is not required for outer kinetochore assembly, we find it is essential to recruit tension indicators, such as
BubR1 and 3F3/2, to erroneous attachments. Thus, centromeric CPC is necessary for tension-dependent removal of erroneous attachments, and for the kinetochore composition required to detect tension loss.

It is well established that Aurora B kinase promotes chromosome bi-orientation in cell division by regulating kinetochore-microtubule (MT) interactions. The mechanism by which Aurora B performs its function is still not clear. Isolated kinetochore proteins and kinetochore particles with phosphomimetic mutations at known Aurora B target sites show reduced affinity to MTs and increased detachment from MTs under force, supporting a model where Aurora B triggers detachment directly. In contrast, kinetochore MT shortening rather than detachment was observed after Aurora B activation by inhibitor washout in vivo, suggesting that Aurora B modulates MT dynamics by triggering depolymerization. To distinguish between two models, we developed an optogenetic approach using a photocaged chemical inducer of protein dimerization to recruit Aurora B to individual kinetochores at metaphase. MT depolymerization at the targeted kinetochore would lead to poleward movement, whereas detachment would lead to anti-poleward movement. We found that the targeted kinetochore moved poleward, inducing the sister kinetochore to move anti-poleward. Our results provide direct evidence for a model in which phosphorylation of Aurora B substrates at kinetochores in vivo promotes depolymerization of kinetochore MTs. Our experimental approach also highlights the potential of manipulating kinetochores with light.

Measuring NDC80 binding reveals the molecular basis of tension-dependent kinetochore attachments.
T. Yoo\(^1\), C. Yu\(^1\), D.J. Needleman\(^1\);
\(^1\)School of Engineering and Applied Sciences, Harvard University, Cambridge, MA

During cell division, chromosome motion is driven by coupling the dynamic ends of microtubules to the kinetochore. Erroneous kinetochore-microtubule attachments are corrected to prevent chromosome mis-segregation. The mechanism of error correction remains poorly understood, but is believed to be based on a tension-dependent interaction between microtubules and the kinetochore. The NDC80 complex is the predominant coupler of the kinetochore to microtubules, and is thus directly implicated in tension sensing for error correction. The lack of techniques to quantify the attachment of the NDC80 complex to microtubules in vivo has been a major obstacle to investigate this possibility. Here, we present a method, based on fluorescence lifetime imaging microscopy and Förster resonance energy transfer (FLIM-FRET), to quantitatively measure the fraction of NDC80 complexes bound to microtubules at individual kinetochores in living human tissue culture cells. We found that the fraction of NDC80 bound is positively correlated with the distance between sister kinetochores, a proxy for centromere tension. This positive correlation was significant enough to account for the change in NDC80 binding in the course of error correction. Moreover, we found that Aurora B displacement from centromere
eliminates the tension dependency of NDC80 binding. These results argue that error correction results from the tension-dependent modulation of NDC80 binding affinity by centromere-localized Aurora B kinase.

Coordination between discrete MAD1 domains is required for efficient mitotic checkpoint signaling.
W. Ji¹, Y. Luo¹, E. Ahmad¹, S. Liu¹;
¹Biological Sciences, University of Toledo, Toledo, OH

As a sensitive signaling system, the mitotic checkpoint ensures faithful chromosome segregation by delaying anaphase onset when even a single kinetochore is unattached. The key signal amplification reaction for the checkpoint is the conformational conversion of open MAD2 (O-MAD2) into closed MAD2 (C-MAD2). The reaction was suggested to be catalyzed by an unusual catalyst, a MAD1:C-MAD2 tetramer, but how the catalysis is executed and regulated remains elusive. Here we report that in addition to the well-characterized middle region (MIM), both amino- and carboxyl-terminal domains (NTD and CTD) of MAD1 also contribute to the mitotic checkpoint. In contrast to MIM that stably associates with C-MAD2, MAD1-NTD and CTD surprisingly bind to both O-MAD2 and C-MAD2 in vitro, suggesting their interactions with both substrates and products of the O-C conversion. MAD1-NTD also interacts with CTD. MPS1 kinase interacts with and phosphorylates both NTD and CTD. The phosphorylation reduces the NTD:CTD interaction and their interactions with MPS1. Mutating CTD phosphorylation sites including Thr716 also compromises MAD2 binding and the checkpoint responses. Our results have uncovered previously unknown interactions of MAD1-NTD and CTD with MAD2 conformers and their regulation by MPS1 kinase, providing novel insights into the mitotic checkpoint signaling.

Plk1 anchors the inner kinetochore against tension.
R.F. Lera¹, A. Dennee¹, M.E. Burkard¹;
¹Dept. of Medicine, Carbone Cancer Center, University of Wisconsin, Madison, WI

In early mitosis, Polo-like kinase 1 (Plk1) is recruited to the kinetochore, where it stabilizes microtubule attachments at the outer kinetochore for proper chromosome segregation during anaphase. Its other kinetochore roles are less clear. We previously reported that bulk Plk1 localizes to the inner kinetochore, near chromatin, and functions at this location to ensure high-fidelity chromosome segregation. Here, we evaluate this phenotype in detail to discover the functional defect, which is readily achieved through partial inhibition of Plk1 in RPE1 cells. Partial inhibition preserves most essential functions but causes chromosomes to mis-segregate on bipolar spindles in anaphase. Strikingly, we find that lagging chromosomes, but not segregated chromosomes, lack kinetochore proteins, including Hec1, Knl1, CENP-T, CENP-C, and CENP-A. However, CENP-B is relatively preserved. Importantly, these effects are reproduced with alternate methods of Plk1 inhibition and with both tagged and antibody-detected endogenous CENP-A, confirming a bona fide effect of Plk1 inhibition on CENP-A retention at the inner centromere. The disrupted kinetochores are observed prior to anaphase even though Plk1 activity is not required to initially recruit these kinetochore components. Live cell imaging reveals asymmetrical protein loss from sister kinetochores after midline chromosome

Sunday-130
alignment. The sisters then migrate towards the pole faced by the retained kinetochore. The disrupted kinetochores are silent to the mitotic checkpoint, as demonstrated by concomitant absence of the checkpoint proteins BubR1 and Mad1 at the kinetochore, explaining how cells can proceed into anaphase with misaligned chromosomes. Although Plk1 can indirectly mediate Aurora B localization to the centromere, inhibition of Aurora B fails to phenocopy the defect, suggesting that Plk1-dependent signaling through this kinase does not mediate the effect. These findings support a model where Plk1 is required to tightly anchor the kinetochore to chromatin against tension. Loss of this tight anchoring leads to stochastic disruption of some but not all kinetochores in metaphase; presumably those that are weakly anchored and/or have the most tension. This metaphase defect leads to poleward migration of the sister pair towards the retained kinetochore, but this pair is insufficient to trigger the mitotic checkpoint, enforcing chromosome mis-segregation. Additionally, lagging anaphase chromosomes are commonly generated when a kinetochore is disrupted just before anaphase onset. We conclude that a key inner-kinetochore function of Plk1 is to stabilize the mitotic kinetochore at its root.

PP1-87B antagonizes Polo kinase and C(3)G, a transverse element of synaptonemal complex, in maintaining sister chromatid co-orientation in metaphase I in *Drosophila* oocytes.

L. Wang¹, A. Das², K. McKim³;  
¹Rutgers University, Waksman Institute, Piscataway, NJ, ²Department of Biology, University of Pennsylvania, Philadelphia, PA

In meiosis I, a unique mechanism called co-orientation ensures that sister chromatids co-orient and segregate to the same pole at metaphase I. In budding yeast, co-orientation is generated by a complex called Monopolin, while in fission yeast and mice, co-orientation has been shown to be mediated by specialized kinetochore proteins, Moa1 and MEK1N, functioning with meiosis specific cohesin, Rec-8, to regulate sister chromatid co-orientation. Even though this meiosis specific co-orientation is needed for chromosome segregation, knowledge of the mechanism remains limited. Here we show that *Drosophila* protein phosphatase PP1-87B is required for sister chromatid co-orientation. In PP1-87B depleted oocytes, sister centromeres separate, implying defective co-orientation. In fact, this sister centromere separation in PP1-87B depleted oocytes, is suppressed by co-depletion of Polo kinase or a synaptonemal complex (SC) protein C(3)G, indicating that antagonistic mechanisms are involved in co-orientation. We have also found that maintenance of co-orientation in PP1-87B depleted oocytes is microtubule-dependent, unlike the co-orientation defect in the absence of kinetochore protein SPC105R, which is due to Separase-dependent loss of cohesion. Taken together we propose a mechanism where PP1-87B establishes proper sister chromatid co-orientation in meiosis I, by inhibiting Polo kinase and possibly structural chromatin components like the SC. We further hypothesize that maintenance of this co-orientation requires careful regulation of microtubule dynamics. This is the first report showing a functional role of the centromeric SC after prophase. However, whether C(3)G and Polo Kinase interact directly or function through different pathway to antagonize PP1-87B in maintaining co-orientation after metaphase I remains to be tested.

Fin1-PP1 promotes the translocation of the Chromosomal Passenger Complex in early anaphase.
M.H. Bokros¹, Y. Wang¹;
¹Biomedical Sciences, Florida State University, Tallahassee, FL

The chromosomal passenger complex (CPC) is translocated from chromosomes to the spindle during anaphase, and Aurora B/Ipl1 kinase is one subunit of this conserved complex. Previous studies from yeast and mammalian cells indicate that CPC is essential for accurate chromosome segregation, because the CPC promotes bipolar chromosome attachment and spindle elongation. However, the molecular mechanism for CPC translocation during early anaphase and the function of this translocation remain poorly defined. Protein phosphatase 1 (PP1) antagonizes Aurora B/Ipl1, and Fin1 is a regulatory subunit of PP1 in budding yeast S. cerevisiae. Our recent data indicate that kinetochore association Fin1-PP1 is cell cycle regulated and this association promotes the silencing of the spindle assembly checkpoint, which monitors chromosome attachment and prevents anaphase onset. Here, we report that yeast mutant cells lacking Fin1 show compromised CPC spindle translocation during anaphase. Moreover, we found that premature CPC translocation leads to chromosome mis-segregation in the presence of syntelic attachment. Our data indicate that Fin1-PP1 promotes CPC translocation, and the premature CPC translocation causes chromosome mis-segregation.

Board Number: B213
Interdependent centromeric and microtubule bound pools of the CPC enable kinetochore phosphorylation and resolution of merotelic attachments.
P. Trivedi¹, T. Stukenberg²;
¹Department of Cell Biology, University of Virginia, Charlottesville, VA, ²Department of Biochemistry and Molecular Genetics, University of Virginia, Charlottesville, VA

The attachments of kinetochores to microtubules are tightly regulated to prevent merotelic kinetochore attachments, which generate anaphase lagging chromosomes, micronuclei and genomic instability. The chromosome passenger complex (CPC) prevents and repairs merotelic attachments by phosphorylating the Ndc80 complex, which connects spindle microtubules to kinetochores. It is unclear how inner-centromeric CPC can phosphorylate Ndc80 in the outer kinetochore, which can be 500nm away. Two models have been suggested. First that the CPC is anchored at inner centromeres but then stretches to phosphorylate kinetochores or second, that the CPC directly binds kinetochore localized Sgo1. We provide evidence for a third model using assays that eliminated both of these mechanisms. Specifically, the centromeric pool activates Aurora B kinase within non-centromeric CPC (from the cytoplasm), which can then diffuse from centromeres to phosphorylate kinetochores. We identified a novel microtubule binding activity in the CPC on the Borealin subunit, which became a critical tool to test this model. Consistent with our model of outer kinetochore phosphorylation by diffusible non-centromeric CPC, we show that microtubule-binding site on the Borealin subunit of the CPC is required for efficient phosphorylation of the outer kinetochores, resolution of merotelic attachments and for maintenance of taxol dependent spindle assembly checkpoint arrest. We suggest that microtubule structures near kinetochores direct the diffusion of soluble activated CPC towards kinetochore substrates to control the amount of kinetochore phosphorylation.

SkA3 phosphorylated by CDK1 binds Ndc80 and recruits Ska to kinetochores to promote mitotic progression.
Q. Zhang¹, Y. Chen¹, H. Liu¹;
¹Biochemistry and Molecular Biology, Tulane University, New Orleans, LA

The spindle and kinetochore-associated (Ska) protein complex is required for accurate chromosome segregation during mitosis and consists of two copies each of Ska1, Ska2, and Ska3 proteins. The Ska complex contains multiple microtubule-binding elements and promotes kinetochore-microtubule attachment. The Ska1 C-terminal domain (CTD) recruits protein phosphatase 1 (PP1) to kinetochores to promote timely anaphase onset. The Ska complex regulates, and is regulated by, Aurora B. Aurora B phosphorylates both Ska1 and Ska3 to inhibit the kinetochore localization of the Ska complex. Despite its multitude of functions at kinetochores, how the Ska complex itself is recruited to kinetochores is unclear. It is unknown whether any mitotic kinases positively regulate the localization of the Ska complex to kinetochores. Here, we show that Cdk1 phosphorylates Ska3 to promote its direct binding to the Ndc80 complex (Ndc80C), a core outer kinetochore component. We also show that this phosphorylation occurs specifically during mitosis and is required for the kinetochore localization of the Ska complex. Ska3 mutants deficient in Cdk1 phosphorylation are defective in kinetochore localization but retain microtubule localization. These mutants support chromosome alignment but delay anaphase onset. We propose that Ska3 phosphorylated by Cdk1 in mitosis binds to Ndc80C and recruits the Ska complex to kinetochores where Ska1 can bind both PP1 and microtubules to promote anaphase onset.

MPS1 N-terminal domains interact to regulate kinetochores levels and normal mitotic progression.
S.T. Pachis¹, Y. Hiruma², M. Ubbink³, A. Perrakis², G.J. Kops¹;
¹Hubrecht Institute, Utrecht, Netherlands, ²Division of Biochemistry, Netherlands Cancer Institute, Amsterdam, Netherlands, ³Leiden Institute of Chemistry, Leiden University, Leiden, Netherlands

The spindle assembly checkpoint (SAC) is a mitotic cellular surveillance system that protects faithful chromosome segregation by safeguarding the transition to anaphase. Only when they are all attached to the mitotic spindle can cells start to segregate their chromosomes, ensuring in this way that the two daughter cells that arise contain complete and identical copies of the genome. MPS1 (Monopolar Spindle 1), the most upstream component of the pathway, is a kinase that gets recruited to the kinetochore of unattached chromosomes, a multi-complex scaffold that is assembled to facilitate the interaction with the mitotic spindle. Once localized to kinetochores, MPS1 phosphorylates several target substrates and activates the signalling cascade which results in halting mitotic progression. Domains in the N terminus of MPS1, the NTE (N Terminal Extension) and TPR (Tetratricopeptide Repeat) domains, are important for MPS1 recruitment and binding to kinetochores, though the exact contribution of each remains unclear. MPS1 displays a high turnover rate on kinetochores, a property that is crucial for SAC inactivation in metaphase as stable microtubule-kinetochore attachments displace MPS1. In this study, we examine the interplay between MPS1 N-terminal domains and how this contributes to the regulation of its localization and interaction with the kinetochore. We show by NMR that the NTE and TPR domains are able to directly interact with each other. A mutant of MPS1 containing an extra copy of the NTE
domain was designed to bypass the regulatory effect of the interaction with the TPR domain. Expression of this mutant leads to an increased accumulation of MPS1 on kinetochores which persists even in the presence of microtubule attachments. This results in SAC signalling in metaphase and problems in inactivating the SAC. Further experiments are being done to determine whether MPS1 turnover on kinetochores is affected in this mutant. We conclude that the NTE-TPR interaction we detected is involved in regulating MPS1 levels on kinetochores. Perturbing this interaction potentially affects dynamic localization of the SAC kinase, without which cells cannot inactivate the SAC and normal mitotic progression is abrogated.

Spatiotemporal regulation of spindle assembly checkpoint kinase MPS1.
T.E. Kuijt1, D.H. Staijten1, A.T. Saurin2, G.J. Kops1;
1Hubrecht Institute, Utrecht, Netherlands, 2Division of Cancer Research, Jacqui Wood Cancer Centre, Dundee, United Kingdom

Error-free chromosome segregation depends on detection and correction of erroneous chromosome-spindle microtubule attachments, and the ability to delay cell division until all chromosomes have established correct attachments. MPS1 kinase is essential for establishing and maintaining these processes during mitosis. Weakened MPS1 signalling causes genome instability and promotes tumour progression. Despite the central importance of MPS1 for guarding genome stability, little is known about temporal dynamics and mechanisms of its activation and inactivation at relevant locations in the cell. We have developed a highly specific FRET-based biosensor that allows the monitoring of MPS1 activity in living cells. We show that in mitosis MPS1 activity reaches beyond the kinetochore by placing the biosensor on chromatin. Using this tool we measure the dynamics of MPS1 activity in cells progressing through mitosis unperturbed. We measured rapid MPS1 activation before cells undergo mitotic entry and in prometaphase MPS1 activity gradually decreased. Microtubule-attachments to kinetochores repress MPS1 activity and in metaphase no MPS1 activity was measured using the chromatin-targeted biosensor. Before mitotic entry we measured MPS1 activity throughout the nucleoplasm using a diffusible nuclear localised biosensor. In prometaphase we measured cytoplasmic activity of MPS1 revealing MPS1 activity is not restricted to chromatin and kinetochores during mitosis. Finally, we show that on metaphase kinetochores, residual MPS1 activity is present. Currently we are investigating the dynamics of MPS1 activity at kinetochores in response to microtubule attachments and regulators of MPS1 activity. Furthermore, we will investigate differential activity of MPS1 in healthy and tumour cells and tissues.

Monitoring Aurora B kinase activity in response to changes in kinetochore-microtubule attachment stability during mitosis.
J.A. DeSimone1,2, D.A. Compton1,2;
1Norris Cotton Cancer Center, Lebanon, NH, 2Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH

Faithful chromosome segregation is mediated by the bi-oriented attachment of replicated chromosomes to spindle microtubules through kinetochores. Proper regulation of these kinetochore-microtubule (k-MT) attachments is essential for mitotic fidelity. Microtubules dynamically attach to and detach from
kinetochores and the stability of these attachments must be precisely regulated within a narrow range. k-MT attachments must be stable enough to support chromosome movement and satisfy the spindle assembly checkpoint (SAC), but sufficiently unstable to allow for the correction of erroneous attachments. k–MT attachment stability is determined by various microtubule binding proteins and cell cycle regulators that act to either stabilize or destabilize k-MTs. A growing body of evidence suggests that a core control network of mitotic kinases is responsible for integrating inputs from multiple sources and adjusting the set point for k–MT attachment stability during each stage of mitosis. A central component of this network is Aurora B kinase. Here, we test whether Aurora B is responsive to changes in k–MT attachment stability throughout mitosis. Local Aurora B kinase activity is quantitatively measured at the kinetochore in living cells using a Mis12-targeted fluorescence resonance energy transfer (FRET)–based biosensor. Aurora B activity is highest on unattached kinetochores and on unaligned prometaphase kinetochores with decreased inter-kinetochore distance (IKD). As cells transition from prometaphase to metaphase, there is a significant decrease in Aurora B activity, corresponding with a 35% increase in k-MT half-life. Using the microtubule stabilizing drug taxol, we were able to monitor Aurora B kinase activity under conditions of perturbed microtubule dynamics. Low dose (5nM) taxol treatment did not significantly alter Aurora B activity at metaphase kinetochores, despite a 21% increase in k-MT half-life and a 0.2 ± 0.1 μm decrease in IKD. These data suggest that Aurora B activity changes during the prometaphase-metaphase transition, but the kinase is not responsive to further stabilization of k-MT attachments or decreased IKD in metaphase. We also tested whether Aurora B responds to increased activity of a downstream target, MCAK. We previously demonstrated that UMK57 activates MCAK activity and decreases k-MT half-life during metaphase by 30%. Increasing MCAK activity using UMK57 treatment significantly increased Aurora B activity in both prometaphase and metaphase cells without changing IKD. These data suggest that Aurora B activity is responsive to changes in MCAK activity. Future studies will be aimed at determining whether this change in attachment stability acts as a “sensing mechanism” for the modulation of Aurora B activity.

Glycogen Synthase Kinase 3 maintains mitotic arrest by regulating mitotic checkpoint complex levels.
M. Rashid1, W.R. Taylor1;
1Biological Sciences, University of Toledo, Toledo, OH

The cell cycle is regulated by checkpoints which ensure genomic integrity and proper cell division. We are investigating the role of a multifunctional ser/thr kinase, glycogen synthase kinase 3 (GSK3), in regulation of the mitotic checkpoint. Our data show that in multiple cancer cell lines spindle toxin induced mitotic arrest is relieved by GSK3 inhibitors SB 415286 (SB), RO-81220 (RO) and lithium chloride. GSK3 knockout mammalian cells and GSK3 knockout mouse embryo fibroblasts show reduced mitotic index compared to wild type cells in the presence of taxol. Mitotic arrest is dependent on the mitotic checkpoint complex (MCC), composed of Mad2, BubR1, Cdc20 and Bub1. Our data show that GSK3 targets the MCC to regulate mitotic arrest. Co-treatment of GSK3 inhibitors with spindle toxins showed decreased levels of Mad2, BubR1 and Bub1 localization at the kinetochores compared to spindle toxin only. MCC assembly also decreased with SB when treated with taxol, compared to taxol only. The data implies that GSK3 plays a role in maintaining the mitotic checkpoint. Additionally, time-lapse imaging of cells co-treated with taxol and SB show a role for GSK3 in mitotic checkpoint strength regulation. Overexpression of GSK3 in mammalian and MEFs cells show an increase in mitotic index in the absence of any spindle toxins. The Wnt-signaling pathway and the PI3K/Akt signaling pathway are upstream
regulators of GSK3, negatively regulating GSK3 activity. Our data shows that inhibiting Wnt-signaling and PI3K/Akt-signaling in the presence of taxol, induces a longer mitotic arrest compared to taxol alone. This suggests that GSK3 is regulated upstream by the Wnt- and the PI3K/Akt signaling arcs to control the strength of the mitotic checkpoint. Our observations indicate a novel regulator of the checkpoint and novel insight in connecting growth-signaling pathways with mitosis.

The role of kinetochore-mediated regulation of Protein Phosphatase 1 activity in the correction of syntelic attachments in budding yeast.
B. Roy¹, J. Sim¹, V. Verma¹², A. Fontan¹, A.P. Joglekar¹;
¹CDB, University of Michigan, Ann Arbor, MI, ²Biology Department, University of Massachusetts Amherst, Amherst, MA

Bipolar attachment of two sister kinetochores on a chromosome to microtubules emanating from opposite spindle poles ensures accurate chromosome segregation during cell division. Sister kinetochores that are syntelically attached, i.e. attached to microtubules emanating from the same spindle pole, detach using the Aurora B kinase. Aurora B (Ipl1 in budding yeast) is thought to detect and destabilize syntelic attachments by sensing the absence of centromeric tension arising from the mutually opposing forces produced by sister kinetochores with bipolar attachment. However, the mechanistic basis of such a tension-sensitive correction mechanism is unknown. Here we provide evidence suggesting that budding yeast kinetochores regulate Protein Phosphatase 1 (Glc7 in yeast) activity to selectively stabilize bipolar attachments. We discovered that a conserved patch of four basic residues in close vicinity of the Glc7 recruitment motif in the kinetochore protein Spc105/KNL1 is essential for Glc7 activity in the kinetochore. Substitution of these basic residues with non-polar Alanine residues reduced Glc7 activity, as evidenced by a significantly higher recruitment of the Bub3-Bub1 complex by metaphase kinetochores. Strikingly, this substitution also significantly improved the correction of syntelic attachments: it partially suppressed the growth-defect due to temperature-sensitive mutations in Ipl1 or due to the mutation of the Ipl1 phosphorylation sites in microtubule-binding kinetochore proteins (ndc80-6A and dam1-3A). Importantly, the improvement in the correction of syntelic attachments was not due to the upregulation of the Bub1-Shugoshin pathway. Mutation of the basic residues suppressed growth-defects due to the deletion of either Shugoshin or the kinase domain of Bub1, which licenses Shugoshin recruitment. To understand the functional significance of the basic residues in Spc105, we reasoned that yeast kinetochores may modulate Glc7 activity by neutralizing the basic residues using phosphorylation. Consistent with this reasoning, phospho-mimetic mutation of putative Cdk1 and Ipl1 phosphorylation sites located downstream of the basic patch also marginally improved the correction of syntelic attachments. These and other data suggest an alternative mechanism for the correction of syntelic attachments in budding yeast: the kinetochore up-regulates Glc7 activity to stabilize proper attachments against a constant, tension-independent Ipl1 kinase activity.

Identification and characterisation of spindle checkpoint silencing components in *Schizosaccharomyces pombe*.
S. Soper Ni Chafraidh¹, I. Leontiou¹, K. May¹, P. Amin¹, I. Yuan¹, K. Hardwick¹;
¹Biology, University of Edinburgh, Edinburgh, United Kingdom

During cell division, the spindle-assembly checkpoint (SAC) is an important mechanism which ensures proper segregation of chromosomes into daughter cells by delaying anaphase onset until all chromosomes are correctly attached to the mitotic spindle via their kinetochores. This reduces the risk of aneuploidy, which is associated with severe consequences such as birth defects and cancer. Once all kinetochores have been properly attached the SAC is rapidly silenced, allowing the cell to progress through anaphase.

Several SAC silencing factors have been identified to date but the mechanisms by which silencing occurs remain unclear. This project aims to identify factors involved in SAC silencing and to characterise their functions. Genetic screening is being carried out in fission yeast (*Schizosaccharomyces pombe*) to identify silencing defective mutants. In designing this screen we aimed to improve upon previous screens by avoiding false positives due to mutations that cause prolonged mitotic arrest for reasons unrelated to checkpoint silencing defects, e.g. disruption of kinetochore function. An ectopic synthetic checkpoint mechanism (SynCheck) developed as part of previous work in the lab is being used to spatially separate checkpoint activation from the kinetochore (Yuan *et al.*, 2016). This involves co-tethering KNL1*scp7* and Mps1 kinase, providing a platform for the recruitment and activation of Bub proteins, which promotes Mad1-Bub1 complex assembly and SAC-mediated metaphase arrest.

Our screen has produced a list of candidate silencing factors including Eaf6, Sol1, and Reg1, a known regulator of the confirmed silencing factor Protein Phosphatase 1, PP1^Dis2^. Assays to confirm and characterise the checkpoint silencing roles of these factors are underway. In addition, we are analysing the actions of PP1^Dis2^ in silencing SynCheck arrests. Several spc7 alleles, defective in the recruitment of PP1^Dis2^, are being tested for their ability to generate and silence SynCheck arrests. This work includes pull-downs of PP1^Dis2^ to check what factors are associated with it in different mutant backgrounds. These studies will greatly enhance our understanding of the molecular mechanism(s) of spindle checkpoint silencing.

Factors Required for Centromere Formation.
K. Kitagawa¹, R. Kitagawa¹, Y. Niikura¹;
¹Department of Molecular Medicine, Greehey Children’s Cancer Research Institute, UT Health San Antonio, San Antonio, TX

Centromeres are critical chromatin structures that mediate chromosomal segregation during mitosis. In most eukaryotes the centromere is a single chromosomal locus that attaches to microtubules to ensure delivery of one copy of each chromosome to each daughter cell during cell division. Centromere identity does not rely on specific DNA sequences, but rather, is associated with large arrays of repetitive DNA. Centromere specification is thought to occur via deposition of the centromere-specific histone H3
variant, CENP-A. After DNA replication, “old” centromeric nucleosomes are distributed to the replicated chromatids. The deposition of newly synthesized CENP-A occurs at the centromere in the G1 phase in mammals. While this regulatory mechanism is crucial for proper centromere inheritance and function, the mechanism mediating precise CENP-A deposition remains poorly understood. We have demonstrated that CENP-A deposition at the centromere requires ubiquitylation on lysine 124 mediated by CUL4A-RBX1-COPS8 E3 ligase. Introduction of K124R mutation of CENP-A abrogates centromeric localization of CENP-A, while addition of a mono-ubiquitin at the C-terminus of CENP-A K124R restores its centromeric localization (Dev Cell, 2015). We have shown that CENP-A K124 ubiquitylation is epigenetically inherited through dimerization between rounds of cell division. We found that overexpression of mono-ubiquitylated CENP-A, but not wild-type CENP-A, creates ectopic functional centromeres (neocentromeres) at non-centromeric regions, which induces substantial chromosome instability (Cell Reports, 2016). Our working hypothesis is that ubiquitylation of CENP-A is a key requirement for building up protein complexes of the kinetochore. Our preliminary IP-MS with Flag-tagged mono-ubiquitin-fused CENP-A identified dozens of proteins (including MCM2, MCM2, SMC2 and SMC4) that specifically bind to ubiquitylated CENP-A. We will determine the function of isolated factors in formation of the centromere.

**CG10126, a calcium-binding microtubule-associated protein, is a target of EGFR signaling and promotes mitosis during Drosophila development.**

S. Spencer\(^1\), Q. Nie\(^1\), B. Setu\(^1\);

\(^1\)Biology, Saint Louis University, Saint Louis, MO

The Epidermal Growth Factor Receptor (EGFR) is a receptor tyrosine kinase that regulates signaling pathways critical for development and proliferation in Drosophila. EGFR activity is also highly upregulated in a number of human cancers, making identification of its downstream targets important for understanding both basic cellular processes and disease states. We have identified CG10126, a Drosophila ortholog of the human proteins Calcyphosine (CAPS) and Calcyphosine-like (CAPSL), as a transcriptional target of EGFR signaling. Calcyphosine encodes a calcium-binding protein upregulated in several human cancers, but little is known of its function. Here we examine the role of its Drosophila ortholog, CG10126, during development.

To examine CG10126’s function in flies, we expressed RNA interference constructs at various points in embryonic and larval development. Reducing the level of CG10126 in eye imaginal discs produced adults with small eyes, and while reducing its level ubiquitously in embryos was generally lethal, rare escapers were dramatically reduced in size. To further examine the role of CG10126, we used mass spectrometry to identify the binding partners of CG10126 in the presence or absence of calcium. Specifically in the presence of calcium, CG10126 bound α- and β-tubulin and several spindle assembly proteins, suggesting that it may influence formation of the mitotic spindle. Consistent with this, embryos with reduced CG10126 show a diminished number of mitotic nuclei and abnormal spindle structures. Also in keeping with this, epitope-tagged forms of CG10126 colocalize along the microtubule spindle during mitosis, and in vitro assays suggest that G10126 enhances the rate of microtubule polymerization specifically in the presence of calcium.

Calcium is indispensable for cell cycle regulation (Parry, H., McDougall, A. & Whitaker, M. Biochem Soc Trans 34, 385-388, (2006); Roderick, H. L. & Cook, S. J. Nat Rev Cancer 8, 361-375, (2008)), but Ca\(^{2+}\) also
destabilizes microtubules (Lee and Timasheff, 1977). Our results suggest that CG10126 may promote progression of the cell cycle by enabling spindle assembly even in the presence of the increased calcium levels present during mitosis.

Microtubule-associated tumor suppressor ATIP3 controls Kif2A and aurora kinases to maintain mitotic spindle length.
A. Nehlig¹, C. Seiler¹, C. Nahmias¹;
¹INSERM U981, Gustave Roussy Institute, Villejuif, France

Maintaining the integrity of the mitotic spindle is essential to ensure proper chromosome segregation and normal cell division. Any defect in spindle length or symmetry leads to aneuploidy, which is a hallmark of cancer. ATIP3 is a Microtubule-Associated-Protein encoded by candidate tumor suppressor MTUS1 gene whose expression is markedly down-regulated in aggressive breast tumors of the triple-negative subtype. ATIP3 presents potent anti-growth and anti-metastatic effects, making it an interesting therapeutic target for novel anti-cancer strategies (1-3).
Over the past few years our group has been focusing on the molecular aspects of ATIP3. We have shown that in interphase, ATIP3 localizes at the centrosome and along the microtubule (MT) lattice (1). ATIP3 is a potent MT stabilizer whose depletion increases MT dynamic instability at the plus ends through direct interaction with End-Binding protein EB1, a major marker/regulator of MT dynamics (4, 5). During mitosis, ATIP3 co-localizes with the mitotic spindle and spindle poles. Time-lapse videomicroscopy analyses have shown that ATIP3 delays mitosis by increasing the time spent in metaphase. However, the role of ATIP3 in cell division remains unknown.
Our recent results indicate that ATIP3 depletion induces several mitotic abnormalities, including multipolar and asymmetric spindle as well as reduced spindle length. We provide evidence that ATIP3 effects on the mitotic spindle involve the depolymerizing kinesin Kif2A and the mitotic kinase Aurora A (AurKA). We show that ATIP3 maintains spindle length in metaphase by decreasing Kif2A recruitment at the poles. Of interest, ATIP3 interacts with Kif2A in an AurKA-dependent manner. Whether a novel ATIP3-Kif2A-AurKA axis is involved in spindle integrity is under investigation. Together these results may shed light on novel mechanisms regulating mitotic spindle integrity and may deepen our understanding of how loss of ATIP3 may promote aneuploidy, with major consequences in breast cancer.

Preparing frozen Xenopus egg extracts for the study of spindle assembly mechanisms.
J. Takagi¹, Y. Shimamoto¹²;
¹Center for Frontier Research, National Institute of Genetics, Shizuoka, Japan, ²Department of Genetics, Sokendai University, Shizuoka, Japan

Cell-free extracts prepared from Xenopus laevis eggs are a powerful experimental tool to study various aspects of cell cycle events, such as DNA replication, nuclear organization, and spindle assembly.
However, the utility of this system is often hampered by its low storage stability and high variation in quality. Although frozen stocks may circumvent these problems and are used for researches, they typically lack spindle assembly activity. Here, we discuss a simple two-step method for preparing frozen egg extracts that retain a nearly-endogenous spindle assembly activity. Freshly prepared, cytostatic factor-arrested extracts were processed for the frozen preparation by using a centrifugal filter-based dehydration and slow sample cooling. With the choice of optimal preparation parameters, including the centrifugation period, speed, and filter mesh size, the freeze-stocked extracts cycled through interphase back into metaphase, assembling bipolar spindles in a size, shape, and number that are comparable to those of the freshly prepared extracts. This further allowed us to perform a microneedle-based micromanipulation experiment for tens of spindles in single extract preparations and compare the results among different preparation batches. Our data suggest the existence of a scaling mechanism between the spindle size and stiffness. The extracts are also capable of assembling microtubule asters with Taxol. We anticipate that this method would not only help reveal mechanisms that are masked by sample variation, but also make Xenopus extracts more accessible to researchers.

UBAP2L/PQN-59 is a novel Plk1 regulator, required for chromosome segregation in human cells and C. elegans embryo.
L. Cirillo1, S. Abbatemarco1, F. Schwager2, M. Gotta3;
1Department of Cellular Physiology and Metabolism, University of Geneva, Geneve, Switzerland

Humans display a diploid karyotype of 44 autosomes and 2 sexual chromosomes. In proliferating cells, this considerable amount of DNA is replicated in 92 fragments, called chromatids. During mitosis, each chromatid must be represented once in each daughter. How a single cell achieves such a level of accuracy in chromosome segregation is a question that fascinated scientists for decades. Plk1 (Polo Like Kinase 1) is a conserved serine/threonine kinase, which regulates several aspects of mitosis. One of these aspect is the chromosome alignment and segregation. In early mitosis Plk1 accumulates at kinetochores, promoting stable kinetochore-microtubules attachment. Then, Plk1 is removed from kinetochores through ubiquitination. Reduced levels of PLK1 allow chromosome separation and anaphase onset. However, the exact mechanism through which Plk1 functions is not fully understood. Here, we provide evidences that both the uncharacterized protein PQN-59 and its human orthologue UBAP2L regulate PLK1 in C. elegans embryo and human cells. UBAP2L/ PQN-59 depletion causes defects in chromosome alignment and, in human cells, precocious removal of Plk1 from kinetochores and lower levels at centrosomes. In both C. elegans and human cells UBAP2L/ PQN-59 knock-down results in the formation of Plk1 cytoplasmic aggregates providing a possible explanation for the phenotypes observed. We propose UBAP2L/ PQN-59 as a novel regulator of Plk1, counteracting Plk1 aggregation during mitosis.

Investigating the functional role of the GAPVD1-CK1δ/ε interaction.
R.X. Guillen1, J. Chen1, J.R. Beckley1, K.L. Gould1;
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Human casein kinase 1 delta (CK1δ) and epsilon (CK1ε) are members of a conserved family of ubiquitously expressed serine/threonine kinases that regulate multiple processes including Wnt
signaling, vesicular trafficking, circadian rhythm, and ribosome maturation. Inhibition of CK1ε using two small molecule inhibitors (SR1277 and SR3029)1 results in a 6-fold increase of mitotic cells exhibiting multipolar spindles, as well as 7-fold and 50-fold increases of mitotic cells with misaligned and unaligned chromosomes, and a significant increase in the percentage of multipolar spindle poles containing no centrioles. These results suggest CK1ε function to promote chromosome alignment, spindle polarity and pericentriolar-material cohesion in mitosis. We sought to investigate the molecular mechanism by which CK1ε may modulate chromosome alignment by determining their interacting partners and substrates. As observed in fixed cells with indirect immunofluorescent microscopy, CK1ε and CK1α endogenously tagged with a fluorescent, multifunctional affinity purification (MAP2) tag localize to centrosomes, the nucleus and throughout the cytoplasm. MAP-tagged CK1ε and CK1α from asynchronous and mitotic cell populations was used as bait to purify and identify associated proteins by mass spectrometry. GTPase-activating protein and VPS9 domain-containing protein 1 (GAPVD1) was consistently the most abundant interacting protein in the purifications of both enzymes. By conventional co-immunoprecipitation, we found that GAPVD1 and CK1ε associate throughout the cell cycle and biochemical experiments showed that GAPVD1 interacts directly with the kinase domain of CK1ε. GAPVD1 contains a GAP domain at the N-terminus and GEF domain at the C-terminus. We found that GAPVD1 is a substrate of CK1ε in vitro and in vivo, with all of the phosphorylation sites located between the GAP and GEF domains. Our results suggest that GAPVD1 is a key interacting partner and substrate of CK1ε and may potentially relate to CK1ε’s function in mitosis.

Controlling candidate physical inputs to the spindle assembly checkpoint.
J.A. Kuhn1,2, E.G. Ter Steege1,3, S. Dumont1,2,4,
1Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, 2Tetrad Graduate Program, University of California, San Francisco, San Francisco, CA, 3Cancer, Stem Cells, and Developmental Biology, University of Utrecht, Utrecht, Netherlands, 4Cell and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

To ensure accurate chromosome segregation, the spindle assembly checkpoint (SAC) prevents anaphase until chromosomes correctly attach to the spindle. The SAC detects some aspect of plus-end microtubule attachment to the kinetochore, and generation of tension is not sufficient to satisfy the SAC without it. However, we do not know whether tension is necessary to satisfy the SAC, and this is in part due to the difficulty of controlling tension in otherwise native end-on attachment scenarios. Here, we use laser ablation to change tension in real time, and we currently monitor SAC satisfaction. By detaching a kinetochore-fiber from the spindle for timescales relevant to SAC responses, we show that the SAC is insensitive to loss of tension when attachments are otherwise not detectably changed. What about end-on attachment the SAC detects and how it integrates this information remain unclear, and to address these questions we are developing assays to control end-on attachment features and test signal integration mechanisms. Together, we hope that the ability to control physical parameters of attachments will help push our understanding of what cues the kinetochore integrates to control cell cycle progression.

Tension-dependent anaphase A in the C. elegans embryo.

G. Maton¹, N. Gareil¹, J.C. Canman², J. Dumont¹;
¹Institut Jacques Monod UMR-CNRS 7592, Universite Paris Diderot, Sorbonne Paris Cite, Paris, France,
²Department of Pathology and Cell Biology, Columbia University Medical Center, New York, NY

Accurate chromosome segregation is essential for maintaining genome integrity across meiotic and mitotic divisions. During this process, a microtubule-based spindle is organized and is linked to chromosomes through the kinetochores. Kinetochore microtubules generate the forces necessary for chromosome alignment in metaphase and for sister chromatid segregation during anaphase. In most cell types, anaphase consists of two distinct processes, referred to as “anaphase A” and “anaphase B”. Anaphase A is the movement of sister chromatids toward the spindle poles due to the shortening of kinetochore microtubules. Anaphase B corresponds to the separations of the two spindle poles from one another. During the first division of the Caenorhabditis elegans embryo, sister chromatid segregation is mainly driven by anaphase B, which primarily depends on cortically anchored dynein that pulls on astral microtubule minus-ends. This in turn generates pulling forces on the two opposite spindle poles. However, genetically reducing dynein-mediated cortical pulling forces significantly decreases spindle pole elongation during anaphase, but does not prevent chromosome segregation. This suggests that alternative mechanisms of force production involved in chromosome segregation must exist in the C. elegans embryo.

By analyzing chromosome segregation in the C. elegans one-celled zygote, we found that in parallel to the anaphase B-driven spindle elongation, the pole to chromosome distance reproducibly decreases during the first 40 seconds following anaphase onset. Therefore, a brief anaphase A step participates in chromosome segregation in the C. elegans embryo. We found that reducing the cortical pulling forces through RNAi-mediated depletion of the dynein cortical anchor proteins, led to a prolonged anaphase A. Furthermore, mechanically or genetically disrupting the anaphase central spindle led to a similar increase in the duration of anaphase A. As decreasing cortical pulling forces or disrupting the central spindle both ultimately lead to a reduced tension within the spindle and lead to prolonged anaphase A, we propose that anaphase A is regulated by tension in C. elegans embryos. Functional analysis demonstrated that the kinesin-13 KLP-7 (ortholog of MCAK) and the kinetochore SKA complex are required for anaphase A in the C. elegans embryo. Overall, our results suggest that a link exists between tension exerted on the spindle and the regulation of kinetochore-microtubule dynamics during anaphase A in C. elegans. We are currently analyzing the molecular details of the tension-dependent anaphase A.

Measuring force responses in the mitotic spindle.

M. Anjur-Dietrich¹, D.J. Needleman¹,²;
¹Applied Physics, Harvard University, Cambridge, MA, ²Molecular and Cellular Biology, Harvard University, Cambridge, MA

The mitotic spindle is a self-assembled microtubule structure that associates with chromosomes and mediates the separation of genetic material during cell division. Force plays an important role during mitosis, from physically moving, aligning, and separating chromosomes to acting on regulatory signaling.
pathways. To understand the role of forces in mitosis, it is important to not only understand the molecular underpinnings, but also to make direct measurements of forces throughout the cell cycle. Using magnetic tweezers, forces on the order of 100s of piconewtons can be exerted on intracellular particles to measure force responses during the course of mitosis. To increase precision, we are building on previous work that used wire grids to create tunable, localized magnetic fields by individually controlling the current through each wire. The goal is to probe dynamics of mechanical properties, force generation mechanisms, and force-responsive signaling pathways using the magnetic grid to applied targeted and direct forces.

Cell cycle progression and mitotic spindle assembly following light-induced release of proteins from photodegradable hydrogels.
J.S. Bisht1,2, P.J. LeValley2,3,4, B.E. Noren2,4, M. Tomschik1, A.M. Kloxin3, J.S. Oakey2,4, J.C. Gatlin1,2;
1Department of Molecular Biology, University of Wyoming, Laramie, WY, 2Cell Division Group, Marine Biological Laboratory, Woods Hole, MA, 3Department of Chemical and Biomolecular Engineering, University of Delaware, Newark, DE, 4Department of Chemical Engineering, University of Wyoming, Laramie, WY

Targeted manipulation of molecular processes in closed biological systems is often experimentally advantageous. This is typically achieved by using specific modalities of light microscopy in combination with photolabile proteins that have been engineered to change conformation in response to specific wavelengths. Here we describe the application of a novel photodegradable hydrogel technology that was developed to spatially and temporally control the release of unmodified recombinant proteins. Light-induced release of a nondegradable cyclin B from sea urchin (cyclin B Δ90) from hydrogel “posts” into cell-free interphase extracts (derived from X. laevis eggs) was sufficient to induce nuclear envelope breakdown and accumulation of mitosis-specific protein phosphorylation events. In agreement with previous observations, spindle assembly following Xenopus cyclin B1 (dm) addition to bulk interphase extract was indeed perturbed, suggesting that additional components are necessary to recapitulate the process accurately. We found that addition of a minimal protein mixture was sufficient to induce cell cycle progression of interphase extract into a mitosis-like state capable of assembling spindles with near normal morphology and chromosome alignment. This three component cocktail included Xenopus cyclin B1 (dm), a phosphomimetic mutant of Arpp19 (a greatwall kinase substrate and inhibitor of PP2A-B55), and the chromokinesin XKid. Our results demonstrate the utility of the approach and indicate that a surprisingly small number of proteins is required to induce cell cycle progression and transform interphase extract into spindle assembly competent extract.

The middle region of BUBR1 binds to MAD2 and p31comet.
J. LaBelle1, W. Ji1, K. Wang1;
1Biology Department, University of Toledo, Toledo, OH

Chromosome mis-segregation results in aneuploidy, which is common in many solid tumors. The Spindle Assembly Checkpoint (SAC) is a signal transduction pathway that prevents chromosome mis-segregation by monitoring kinetochore-microtubule attachments. Unattached kinetochores activate the SAC and delay metaphase-to-anaphase transition in cells. The effector of the SAC pathway is the Mitotic
Checkpoint Complex (MCC) which is composed of MAD2, BUBR1, BUB3, and CDC20. The MCC is likely assembled at unattached kinetochores and then diffuses into the cytoplasm to bind and inhibit the Anaphase Promoting Complex/Cyclosome (APC/C), hence causing inhibition of the metaphase to anaphase transition. It was previously thought that the N terminus of BUBR1 (1-486 residues) was sufficient for the assembly and function of the MCC; however, recent evidence suggested that the middle region of BUBR1 also binds to CDC20 and contributes to MCC regulation. Interestingly, the middle region of BUBR1 is largely invisible in the near atomic resolution structures of human MCC:APC/C complexes solved last year, indicating flexibility or heterogeneity. Here, we report that the middle region of BUBR1 (487-700 residues) directly interacts with Mad2 and p31\textsuperscript{comet} in vitro. We also show that the N terminus of BUBR1 binds to p31\textsuperscript{comet}. p31\textsuperscript{comet} is known as a mitotic checkpoint silencing protein, but preliminary data suggested it does not simply compete with MAD2 for BUBR1 binding. We hypothesize that the middle region of BUBR1 may contribute to the stability of the MCC and/or its association with the APC/C. We are conducting in vitro pull down assays and live cell imaging with BUBR1 deletion and overexpression constructs to test this hypothesis.

Protein phase separation or coacervatation has emerged as a potential mechanism to regulate biological functions. We have shown that coacervation of a mostly unstructured protein, BuGZ, promotes assembly of spindle and its matrix. BuGZ in the spindle matrix binds and concentrates tubulin to promote microtubule assembly. It remains unclear, however, whether BuGZ could regulate additional proteins to promote spindle assembly. Here we report that BuGZ promotes Aurora A activation in vitro. Depletion of BuGZ in cells reduces the amount of phosphorylated Aurora A on spindle microtubules. BuGZ also enhances MCAK phosphorylation. The two zinc fingers in BuGZ directly bind to the kinase domain of Aurora A, which allows Aurora A to incorporate into the coacervates formed by BuGZ in vitro. Importantly, BuGZ coacervation activity promotes Aurora A phosphorylation in Xenopus egg extracts. These suggest that BuGZ coacervation promotes Aurora A activation in mitosis.

Study on the function of BubR1 in zebrafish model system.
J. Park\textsuperscript{1}, H. Lee\textsuperscript{1};
\textsuperscript{1}Biological Sciences, Seoul National University, Seoul, Korea, South

BubR1 is a spindle assembly checkpoint (SAC) protein that has two distinct roles in mitosis: SAC signaling and chromosome congression. This checkpoint protein is conserved in eukaryotes, yet considerable differences among species exist. Unlike other vertebrates, interestingly, zebrafish has two BubR1 orthologues: BubR1-N and BubR1-C. Two separated orthologues may be able to perform functions in a similar or not similar manner to those found in mammals. Until now, functions of zebrafish BubR1s in
mitosis have been uncovered. Here we show that depletion of BubR1-N results in shortened mitotic timing and increase of lagging chromosomes. Moreover, we found that BubR1-N has acetylation sites that may be involved in regulating SAC signaling, like its orthologue in mammals. Our results indicate that BubR1-N has the roles in SAC signaling. Future studies involve investigating knock-out phenotypes of two different forms of zebrafish BubR1s. This will lead us to understand the evolution of BubR1 and its function in vertebrates.

Induction of outer radial glia by the random spindle orientation causes severe microcephaly in the Aspm mutant mice.
I. Fujita¹, T. Suetsugu¹, C. Kishida¹, Y. Tsunekawa¹, D. Konno¹, A. Fujimori², F. Matsuzaki¹; ¹Center for Developmental Biology, RIKEN, Kobe, Hyogo, Japan, ²Department of Basic Medical Sciences for Radiation Damages, NIRS, Chiba, Japan

ASPM/MCPH5 is one of the major responsible genes for microcephaly in human, and plays an important role in the spindle formation during neural progenitor mitoses. However, it is known that in mouse model system, mutations in the Aspm gene lead to only a modest reduction in brain size, implying that the spindle abnormalities caused by the Aspm mutations may have different impacts on the brain development in rodents and primates. One of the prominent features of the cortical development in gyrencephalic mammals is the emergence of non-apical neural progenitors, outer radial glia (oRG), residing in the outer subventricular zone (OSVZ) at the later stage of the development. To mimic this situation in mice, we used LGN mutant mice, in which the random spindle orientations frequently transform apically dividing radial glia into ectopic oRG-like cells without affecting neural differentiation or cell survival. In the Aspm mutant mice, we found that neural progenitors exhibited p53-dependent apoptosis in a low frequency. Surprisingly, the rate of apoptosis in the Aspm mutant was dramatically increased by inducing oRG-like cells by the LGN mutation. The Aspm LGN double mutant showed a severe reduction in brain size with a decrease in the number of neurons. We propose that the developmental scheme with the OSVZ and oRG is susceptible to spindle malformations in neural progenitors. These findings will help us understand the mechanism underlying a serious microcephaly in the gyrencephalic mammals due to the spindle abnormalities.

Characterization of a novel myosin light chain in mitosis.
I. Ramirez¹, J.Z. Torres¹; ¹Chemistry and Biochemistry, Univeristy of California, Los Angeles, Los Angeles, CA

Cell division is a highly regulated process that ensures the proper distribution of genetic material to daughter cells. The mitotic microtubule spindle is a structure that is critical for chromosome congression and chromosome segregation, which is important for the fidelity of cell division. We recently performed a screen for mitotic microtubule interacting proteins and identified a Novel Myosin Light Chain (NMLC) as a putative mitotic microtubule binding protein. Here I present data on the characterization of NMLC and its role in cell division. Immunofluorescence microscopy experiments indicated that NMLC localizes to the spindle poles in a cell cycle dependent manner, only during mitosis. Biochemical purifications and mass spectrometry analyses further indicated that NMLC associates with known spindle pole proteins. Interestingly, depletion of NMLC by siRNA treatment led to defects in chromosome congression during
early mitosis and to aneuploidy in post-mitotic cells. Based on these preliminary data, we hypothesize that NMLC is a novel myosin light chain that functions in spindle pole homeostasis, which is important for proper chromosome congression and segregation during cell division. Future experiments will be focused on testing this hypothesis.

The mitotic checkpoint is a cellular safeguard that prevents the missegregation of chromosomes. Checkpoint failure can lead to abnormal chromosome numbers (aneuploidy), a key characteristic of cancer cells. The accurate control of mitotic checkpoint protein abundances is crucial for the proper functioning of this pathway, and misexpression of checkpoint genes is common in cancer cells. Yet, little is known about factors that control the expression of mitotic checkpoint genes in any organism. We use CRISPR/Cas9-mediated scar-less genome editing in fission yeast to map the regulatory regions of key mitotic checkpoint genes. To identify the minimal region that is necessary and sufficient for proper expression, we transplant the coding sequence of checkpoint genes with differently sized upstream and downstream regions to exogenous loci. To identify the quantitative influence of sub-regions, we delete or exchange these regions at the endogenous locus, and study the influence on mRNA and protein abundance. Our data suggest that, at least for some mitotic checkpoint genes, the regulatory sequences are centered on the transcript, or even the coding sequence. Once our mapping is completed, we aim to determine the relevant features or protein-interaction partners of the crucial regions that we have identified. Given the high conservation of the mitotic checkpoint, we expect that some findings will be applicable to other eukaryotes. This work expands the so far largely protein-centric view of mitotic checkpoint function to the underlying gene expression control, and contributes to a better understanding of non-coding elements in the genome.

Kinesin-12 generates essential force during C. elegans acentrosomal spindle assembly through regulation by TPX2-like protein MESP-1.
I.D. Wolff5, S.M. Wignall6,
5Molecular Biosciences, Northwestern University, Evanston, IL

Meiotic divisions in the female gamete, or oocyte, proceed using a microtubule-based spindle that is formed in the absence of centrosomes. Although this unique acentrosomal spindle organization is conserved in oocytes of many species, including humans, the molecular mechanisms underlying force generation in the absence of centrosomes is poorly understood. Our previous work in C. elegans oocytes has shown that upon depletion of either KLP-18/kinesin-12 or MESP-1 (meiotic spindle-1), microtubule minus ends converge into a single monopolar aster and the spindle does not reach bipolarity, suggesting that these proteins produce an essential outward force on microtubules during spindle assembly. In addition, KLP-18 does not localize to spindle microtubules in the absence of MESP-1, indicating that MESP-1 performs a Kinesin-12 targeting role analogous to TPX2 (1). Following on these findings, we are
now investigating the basis of this force generation by testing an interaction between purified KLP-18 and MESP-1 and the resulting activity on microtubules. First, we found that MESP-1 has both microtubule binding and bundling activity, similar to TPX2. Additionally, we expressed and purified segments of the KLP-18 C-terminal stalk domain and performed pulldown experiments, demonstrating that MESP-1 binds to a region near the middle of the KLP-18 stalk. In parallel analysis using these same KLP-18 fragments, we found that while the entire C-terminal stalk was unable to bind and bundle microtubules, a smaller C-terminal fragment and a stalk construct lacking a putative “hinge” region in the center both had microtubule binding and bundling activity. Putting these findings together, we hypothesize that during acentrosomal spindle assembly in C. elegans oocytes, MESP-1 binds to the central region of the KLP-18 stalk, potentially unfolding it and activating the motor’s C-terminal microtubule binding site. Together with the motor domain, this C-terminal domain would then allow KLP-18 to crosslink spindle microtubules and generate the outward force necessary to achieve bipolarity. Altogether, we propose a new mechanism of Kinesin-12 regulation by a TPX2-like adaptor protein and shed light on the interplay between essential motors and their regulatory proteins during acentrosomal cell division. Topoisomerase II inhibitor mediated upregulated Topo IIα SUMOylation and Aurora B kinase regulation.
N. Pandey1, M. Yoshida1, D. Keifenheim2, D.J. Clarke2, Y. Azuma1;
1Department of Molecular Biosciences, University of Kansas, Lawrence, KS, 2Department of Biological Sciences, University of Minnesota, Minneapolis, MN

Type II Topoisomerase (Topo II) is a unique enzyme that resolves DNA tangles and is essential for accurate chromosome segregation during anaphase. In addition to its role in chromosome segregation, recent evidence indicates that perturbation of the Topo II catalytic cycle in yeast results in a mitotic delay. Supporting that finding, we discovered in Xenopus egg extracts (XEEs) that the α isoform of Topo II is post-transnationally modified with SUMO protein (SUMOylation), which can regulate Aurora B kinase recruitment to mitotic centromeres. Aurora B recruitment at centromeres is regulated via the interaction between SUMOylated Topo IIα and Haspin. Aurora B is an essential kinase component of the chromosome passenger complex (CPC) and is known to be crucial for faithful chromosome distribution to daughter cells during mitosis. SUMOylation of Topo II is conserved among eukaryotes and its role in Aurora B centromeric recruitment is observed in both budding yeast and XEE. We sought to examine whether the mitotic delay observed with a defective catalytic cycle of Topo II is caused by SUMOylation-dependent Aurora B regulation. Supporting that we found the catalytic inhibitor of Topo II (ICRF-193), which has been shown to increase SUMOylation of Topo IIα in somatic cells, causes a mitotic delay in somatic cells. In XEE assays, the addition of ICRF-193 to mitotic XEE increased Topo IIα SUMOylation. Intriguingly, ICRF-193 also promotes Aurora B upregulation at the mitotic centromere and its mislocalization on chromosome arm regions in a SUMOylation dependent manner. These results suggest that ICRF mediated increased Topo IIα SUMOylation and Aurora B upregulation/mislocalization can contribute to mitotic delay observed in somatic cells. Supporting this notion, ICRF-193 induced mitotic delay in somatic cells can be bypassed by an Aurora B inhibitor. With these result, we propose that ICRF-193 mediated mitotic checkpoint activation is initiated by SUMOylation-dependent Aurora B
regulation. Currently, we are investigating potential Aurora B targets that might be responsible for the ICRF-193 mediated mitotic delay.

**Human centromeres produce non-coding alpha satellite RNAs that are chromosome-specific and required for centromere protein loading.**
S.M. McNulty¹, L.L. Sullivan¹, B.A. Sullivan¹²;  
¹Department of Molecular Genetics and Microbiology, Duke University, Durham, NC, ²Division of Human Genetics, Duke University, Durham, NC

Centromeres serve as the chromatin foundation for the kinetochore and are essential for proper chromosome segregation. In humans, the centromere on each chromosome is defined by a homogenous, repetitive array of alpha satellite DNA. Although alpha satellite DNA was originally thought to be transcriptionally inert, the presence of histone marks at the centromere compatible with active transcription and the known role of non-coding centromeric RNA in other organisms suggest transcription and the resulting transcripts may also be involved in human centromere function. Recent studies confirmed the presence of alpha satellite transcripts, but the exact origin of these non-coding RNAs was unclear, as well as their involvement in the centromere-kinetochore assembly cascade. Using cytological and molecular techniques that allow alpha satellite arrays on different chromosomes to be molecularly distinguished from each other, we have demonstrated that each chromosome produces unique non-coding RNAs that localize in cis to their site of production. Alpha satellite RNAs bind at least two key centromere proteins: CENP-A, the centromere-specific histone variant, and CENP-C, a component of the constitutive centromere-associated network of proteins that bridge the centromere and the kinetochore. Targeted depletion of alpha satellite RNAs from a single chromosome leads to 30% loss of CENP-A due, at least in part, to deficient loading of new CENP-A-containing nucleosomes. CENP-C levels are also reduced by nearly half at the targeted centromere. Importantly, loss of alpha satellite RNA from a single chromosome does not affect the centromeric RNA or protein levels at any other centromere in the cell, highlighting the cis-regulatory nature of these non-coding RNAs, but it does lead to cell cycle arrest prior to mitosis. Collectively, these findings implicate non-coding alpha satellite RNA as an essential player in centromere maintenance and underscore the ability of a single defective centromere to alter cell cycle progression.

**Negative regulatory network between the three aurora kinases protects mouse gamete euploidy.**
A.L. Nguyen¹, A. Gentilello¹, K. Schindler¹;  
¹Genetics, Rutgers University, Piscataway, NJ

The Aurora kinases (AURKs) are conserved serine/threonine kinases that regulate chromosome segregation. Mitotic cells require two AURKs (A, B), while mammalian germ cells require a third: (C). The meiosis-specific expression of AURKC has lead to a hypothesis that AURKC functionally replaced AURKB in oocytes. Whether AURKB is required for female meiosis remains unknown. To determine if AURKB is required during female meiosis we utilized an oocyte-specific Cre driver (GDF9) to excise exons 2-6 in the murine Aurkb locus. We compared phenotypes of wild-type mice to that of AURKB or AURKC single knockouts. These studies revealed that AURKB is required for meiosis. In contrast to oocytes lacking
Aurk, oocytes lacking Aurkb were aneuploid. Surprisingly these Aurkb/- oocytes had increased AURKC activity in addition to abnormal AURKC localization on the chromosome arms in metaphase II, suggesting a requirement for AURKB to restrict the activity of AURKC in vivo. To test this hypothesis, we generated mice with one copy of Aurk in the Aurkb/- oocyte background to ask if reducing AURKC levels could rescue the failure phenotype; utilizing oocytes without AURKB and AURKC (double knockout) as controls. Reduction of Aurk in half partially rescued the number of eggs that were aneuploid but did not rescue the Met II mis-localization of AURKC. The aneuploidy defect and mis-localization of AURKC seen in Aurkb/- oocytes could only be rescued by complete removal of Aurk, supporting our hypothesis that AURKB is a negative regulator of AURKC. Surprisingly, double knockout oocytes were euploid and indistinguishable from WT. Here we show that AURKA, the homolog restricted to spindle poles, compensates for the loss of AURKB and AURKC by binding to the Chromosomal Passenger Complex and by phosphorylating AURKB/C substrates. Interestingly, this compensation is dependent on the absence of AURKC as its endogenous expression restricts AURKA to spindle poles. Therefore, these data also imply that AURKC negatively regulates AURKA by preventing its localization to chromosomes in wild-type oocytes. We speculate that AURKB has been retained in oocytes to ensure that AURKC activity is spatially restricted and that this restriction keeps the balance of counteracting AURKA/AURKC activity in check. These studies show, for the first time, the ability for AURKA to functionally complement AURKB/C in vivo. Importantly, these data shed new light on a negative regulatory network among the kinases, which may be critical for generating euploid gametes. This work was supported by grants from the NIH (F31HD089591: A.L.N.; R01GM112801-02: K.S.).

Premature mitotic entry induces replicative helicase unloading, fork collapse, and genome instability.
L. Deng1,2, J. Walter3,4, D. Pellman1,2,4,5;
1Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, 2Cell Biology, Harvard Medical School, Boston, MA, 3Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA, 4Howard Hughes Medical Institute, Boston, MA, 5Broad Institute of MIT and Harvard, Cambridge, MA

DNA replication errors that generate complex chromosomal rearrangements are thought to be important drivers of genome evolution. Although the events that trigger these errors are not well understood, one candidate is premature mitotic entry before the completion of DNA replication. Using a cell-free DNA replication system in Xenopus egg extracts, we found that mitotic cyclin-dependent kinase (CDK) induces fork collapse at stalled DNA replication forks, resulting in complex genomic rearrangements. Upon mitotic CDK addition, the replicative CMG (Cdc45/Mcm2-7/GINS) helicase was ubiquitylated on its Mcm7 subunit and unloaded from stalled forks by the p97 ATPase. Loss of CMG protection resulted in fork breakage, followed by complex end-joining events involving deletions and DNA replication template switching. Together, these experiments define a mechanism by which premature mitotic entry can generate DNA replication-based genomic instability.

Chromosome dynamics simulations reveal the role of condensin and cohesin in building the bottle-brush chromosome architecture.
J.G. Lawrimore\textsuperscript{1,2}, A.B. Doshi\textsuperscript{2}, B.S. Friedman\textsuperscript{2}, A. Fulp\textsuperscript{2}, E.Y. Yeh\textsuperscript{2}, K.S. Bloom\textsuperscript{2};
\textsuperscript{1}Curriculum in Genetics and Molecular Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, \textsuperscript{2}Biology Department, University of North Carolina at Chapel Hill, Chapel Hill, NC

Despite their similar molecular structure, cohesin and condensin occupy geometrically distinct regions in mitotic chromosomes across eukaryotes. In budding yeast, this separation is apparent at the pericentric region, the cohesin and condensin-rich region surrounding the centromere. Mitotic chromosomes of higher eukaryotes, and the pericentric region of budding yeast, contain a high density of radial chromatin loops extending from an axial core region, causing the chromosome to resemble a bottle-brush. We constructed novel chromatin dynamics simulations modeling cohesin as a slip ring and condensin as either a static or dynamic loop extruder on a bottle-brush model of the pericentric region. Centromere simulations in which condensin persistently binds to chromatin while cohesin passively slides along chromatin recapitulate the geometric separation observed in live cells. Critically, the physical segregation of condensin and cohesin relies on an extensional force on the chromatin. In the pericentric region of budding yeast, the main extensional force is provided by the mitotic spindle. In the highly condensed chromosomes of higher eukaryotes, and to a lesser extent in the pericentric region of budding yeast, this extensional force is provided the repulsion of the high number or densely packed radial loops extending from a central axis.

The physical segregation of cohesin and condensin within the pericentric region predicts the motion of chromatin within the pericentric region would be deferentially regulated by cohesin and condensin based on the chromatin’s position. We found the dynamics of a 10 kb lacO/LacI-GFP array placed 1.8 kb from CEN15, which co-localized with pericentric cohesin, is primarily confined by cohesin. In contrast, we found the dynamics of a 5.5 kb tetO/TetR-GFP array within a conditionally dicentric plasmid, which co-localizes with condensin, is primarily confined by condensin. We constructed chromatin dynamics simulations of the dicentric plasmid to explore how several molecules of cohesin and condensin could directly alter the plasmid’s dynamics. Simulations containing condensin resembled wild-type experimental dynamics, whereas simulations lacking condensin resembled the plasmid dynamics of cells containing the temperature sensitive condensin mutation, brn1-9. These studies support a model where condensin persistently binds to chromatin while extruding loops, while cohesin slides along chromatin. Extensional force on the chromatin centers condensin within the chromosome’s axis, while cohesin can slip along the chromatid to diffuse to the less crowded radial edges of chromatin loops.

S.T. Sparapani\textsuperscript{1}, C. Bachewich\textsuperscript{1};
\textsuperscript{1}Biology, Concordia University, Montreal, QC

Candida albicans is an important fungal pathogen of humans that causes superficial to life-threatening systemic infections under immune-compromised conditions. Cell proliferation is critical for survival in the host and infection. However, the networks controlling the cell cycle in C. albicans are poorly understood. To this end, we focused on defining the regulation of the metaphase-to-anaphase

Sunday-150
transition. This is characterized by separation of sister chromosomes through activation of the protease separase. Separase activity is dependent in part on degradation of a separase regulator, securin. Securin is targeted for degradation by the Anaphase Promoting Complex/Cyclosome (APC/C) and its cofactor Cdc20p. However, in C. albicans, only homologues of APC/C cofactors Cdc20p and Cdh1p are characterized, and show conserved as well as novel features. Further, C. albicans lacks a sequence homologue of securin. Collectively this suggests unique features of metaphase-to-anaphase regulation in C. albicans, which may be exploited for new drug target discovery. In order to explore this further, we characterized a homologue of separase, ESP1. Eip1p-depleted cells arrested in metaphase, consistent with Esp1p functioning as a separase. We next explored the hypothesis that C. albicans contains a divergent securin, which may be revealed through identifying the interacting factors of separase, a conserved securin target. Affinity purification of Esp1p from Cdc20p-depleted cells and mass spectrometry revealed Orf19.955p, or Esp1p-Interacting Protein 1 (Eip1p), an uncharacterized protein with no mammalian homologue and specific to Candida species. Co-immunoprecipitation confirmed interactions between Eip1p and Esp1p. Depletion of Eip1p in strains carrying GFP-labelled Histone H2B or b-tubulin resulted in disorganized chromosomes with some fragmentation, and a higher proportion of cells in anaphase. This suggests Eip1p functions in mitosis and chromosome organization. Since eip1/eip1 strains were viable, yet grew poorly, EIP1 is not essential. Eip1p contains putative destruction and KEN boxes, suggesting regulation via degradation like other securins. Consistent with this, Eip1p was reduced when CDC20 was overexpressed, or when cells were blocked in early anaphase via depletion of the polo-like kinase Cdc5p. Finally, Eip1p function was further explored using affinity purification and mass spectrometry. Esp1p, the phosphatase Cdc14p and additional novel proteins were uncovered. Collectively, our results demonstrate that the metaphase-to-anaphase transition in C. albicans involves a novel, Candida-specific protein, Eip1p. The data suggests it may be a functional homologue of a securin, providing important implications for variation in cell cycle circuitry and cell growth.

Condensin complexes promote chromosome movement during mitosis.
K.R. Salmon1,2, D.A. Compton1,2;
1Norris Cotton Cancer Center, Lebanon, NH, 2Biochemistry and Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH

Mitosis is a highly-regulated process that ensures the accurate formation of two genetically identical daughter cells. An important characteristic of mitotic cells is the compaction of genetic material into discrete chromosomes to facilitate their alignment and faithful segregation (Ono et al., 2004). This compaction is produced by the activity of two independent condensin complexes. To better understand the role of condensin complexes in chromosome movement during mitosis, we knocked down the essential condensin subunit CAP-D3 in Condensin II. This led to decreased expression of other condensin subunits in both condensin complexes. Cells depleted of condensin subunits significantly delayed the completion of mitosis and exhibited disrupted chromosome movement. Chromosome oscillations around the metaphase plate were significantly reduced with some chromosomes displaying no perceivable movement. To understand the basis for this change in chromosome motion, we examined the effect of condensin depletion on molecules with known roles in driving chromosome oscillation. We observed no change in the localization or function of the kinesin Kif18A. However, the depletion of CAP-D3 disrupted the polar ejection force generated by the chromokinesins Kid and Kif4A. Neither Kid nor Kif4A localized to mitotic chromosomes in condensin-depleted cells. Thus, the condensin complexes are required for loading of Kid and Kif4A onto mitotic chromosomes. Without these chromokinesins,
Abnormal chromosome karyotypes are a defining characteristic of most cancers. In some malignant tumors, such as esophageal and cervical cancers, tetraploidy is suggested to be an unstable intermediate that triggers aneuploidy, leading to tumorigenesis and tumor progression. Although chromosome stability depends on the proper progression of mitosis, exact knowledge of the mitotic machinery in tetraploid cells has remained elusive. To understand mitosis in tetraploid cells, we examined the response of diploid and tetraploid tumor cells to anti-mitotic drugs. We induced tetraploid tumor cells by treating synchronized HeLa cells with hesperadin, an Aurora B inhibitor that induces mitotic slippage. In both diploid and tetraploid cells, tubulin-binding agents, such as paclitaxel (PTX) and nocodazole (Noc), had similar efficacy and induced apoptosis in prolonged mitosis or the subsequent G1 phase. On the other hand, monastral (Mona), an inhibitor of Eg5 (also known as KIF11), which plays an essential role in centrosome separation during mitosis, induced apoptosis more effectively in diploid cells than in tetraploid cells. Live cell–imaging analysis revealed that, after Mona treatment, approximately 90% of tetraploid cells underwent cell division, whereas only 30% of diploid cells did. Untreated tetraploid cells, which have four centrosomes in mitosis, formed multipolar spindles in approximately half of the cells, but under Mona treatment formed bipolar spindles in most of the cells. Untreated tetraploid cells also tended to generate unequal-sized daughter cells, whereas unequal division was rare in Mona-treated tetraploid cells. Regardless of Mona treatment, tetraploid cells exhibited a similar rate of G1 progenies that showed positive for 53BP1 or γ-H2AX foci after cell division, which indicates that multipolar and bipolar division in tetraploid cells evoked a comparable level of DNA damage response. As a consequence of multipolar division, tetraploid cells generated a sub-tetraploid population with reduced chromosomal content, and after prolonged culture converted to near-diploid cells. On the other hand, Mona-treated tetraploid cells maintained clear tetraploid chromosome contents after 7 days of culture. These data indicate that Eg5 inhibition in tetraploid cells suppressed unequal or multipolar division and caused tetraploid cells to accumulate. Our results suggest that, by controlling the cell division property in tetraploid cells, Eg5 activity dictates the conversion into near-diploid cells or the maintenance of tetraploid cells. Our results provide insight into the mechanism of how tetraploidy leads to aneuploidy and genomic instability.

Rapid degradation and 3D CLEM of condensin uncouple chromatin compaction from chromosome architecture in mitotic cells.
K. Samejima1;
1Wellcome centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

Condensin is essential for chromosome formation in Xenopus extracts, fission yeast and mouse oocytes. However in somatic cell systems, chromosomes do form in condensin-depleted cells, but are structurally compromised and fail to segregate at anaphase. Here we have studied the role of condensin in vertebrate mitosis by combining auxin-mediated rapid depletion of condensin subunit SMC2 (condensin I and II) with chemical genetics to obtain near-synchronous mitotic entry of chicken DT40 cells. We analysed the outcomes by live-cell and fixed-cell microscopy methods, including 3D correlative light and serial block face scanning electron microscopy. Cultures rapidly depleted of condensin fail to form individualized mitotic chromosomes. The chromatin is compacted normally, but positioned to one side of a bent mitotic spindle. Kinetochores fail to form stable amphitelic attachments to microtubules and cultures exhibit a robust spindle assembly checkpoint-mediated delay in mitosis, eventually undergoing mitotic slippage. Experiments titrating the auxin concentration reveal that differing condensin levels are required for anaphase chromosome segregation, organization of condensin and topoisomerase IIα on the chromatid axes, and formation of a normal chromosome architecture.

The determinants and consequences of cohesion fatigue.
H.R. Sapkota1,2, J.R. Daum1, E. Wasiak1, G. Gorbsky1,2;
1Cell Cycle and Cancer Biology, Oklahoma Medical Research Foundation, Oklahoma City, OK, 2Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Cells delayed at metaphase of mitosis undergo cohesion fatigue, an unscheduled and asynchronous separation of chromatids while cells remain in mitosis. All cell types examined exhibit cohesion fatigue, but the rate of fatigue varies between even closely related cell lines. It is unclear what renders these cells to show strong differences in the rates of cohesion fatigue. In addition, the molecular causes of cohesion fatigue are unknown. Herein we investigated the roles of microtubule dynamicity, and the strength and the abundance of Cohesin protein complex in affecting rates of cohesion fatigue. Furthermore, we studied if and how the Cohesin complex was breached during cohesion fatigue. Finally we looked at the consequences of cohesion fatigue in contributing to aneuploidy and genomic instability; we tested the potential of cohesion fatigue to induce chromosome segregation defects and generate micronuclei.

To alter microtubule dynamics we used microtubule stabilizers and destabilizers at low concentrations that only marginally affected normal mitosis. However when combined with treatments that induced metaphase arrest, alteration of microtubule stability led to significant changes in the timing of cohesion fatigue. In HeLa cells, stabilized microtubules accelerated the onset of cohesion fatigue while destabilized microtubules delayed the process. We also studied the effects of compromising the Cohesin complex. Deletion of the Cohesin accessory subunit, stromal antigen 2 (SA2), accelerated cohesion fatigue. Mitotic arrest in Nocodazole before release to metaphase arrest reduced the amount of chromosome-bound Cohesin and accelerated fatigue. In contrast, depletion of Wapl, which increases chromosome-bound Cohesin, significantly delayed cohesion fatigue. Surprisingly, we found no
difference in the amount of core Cohesin proteins bound to chromatids, before and after cohesion fatigue. Using rapamycin-induced tethering, we artificially locked the protein-protein interface (gates) between Cohesin ring components. Locking any of the gates did not affect cohesion fatigue. While massive chromatid separation likely generates inviable daughter cells, shorter delays at metaphase can induce exaggerated separation of kinetochores while arms remain attached. Cells delayed at metaphase transiently to allow kinetochore separation then released to allow anaphase onset exhibited mitosis with chromosome segregation defects and formed micronuclei. Thus metaphase delays with kinetochore separation but without chromatid separation can be a source of chromosome instability.

SUMO-mediated regulation of anaphase progression during *C. elegans* oocyte meiosis.
A.C. Davis-Roca¹, N.S. Divekar¹, S.M. Wignall¹, R. Ng¹;
¹Molecular Biosciences, Northwestern University, Evanston, IL

*C. elegans* oocytes utilize a unique chromosome segregation mechanism. Instead of end-on kinetochore attachments, microtubules make lateral associations with chromosomes and segregation depends on a complex of proteins containing AIR-2/Aurora B kinase that forms a ring around the center of each homologous chromosome pair. These rings facilitate congression and then are released from chromosomes in anaphase and left at the spindle midzone, where they begin to disassemble. We are investigating the molecular mechanisms driving the assembly and disassembly of this important protein complex, in order to better understand how it contributes to faithful meiotic chromosome segregation. We previously demonstrated that while AIR-2 usually relocates from the rings to the microtubules in early anaphase, AIR-2 relocalization and ring disassembly are both delayed in response to a variety of meiotic errors, revealing a regulatory mechanism that controls the disassembly of the ring complex and aspects of anaphase progression (1). Now, we have gained new insights into this mechanism, through studies of the small ubiquitin-like modifier SUMO. SUMO had been previously shown to be required for ring assembly, and two different ring components (AIR-2 and KLP-19) can be SUMOylated in vitro (2). We therefore hypothesized that SUMO removal from a ring component/components might serve as a trigger for ring disassembly. In support of this, we found that SUMO is ring-associated until mid-anaphase, when the rings usually disassemble. However, under error conditions when rings are stabilized, SUMO and the SUMO conjugating enzymes GEI-17 and UBC-9 stay associated with the persisting rings, correlating SUMOylation and ring stability. To identify factors that facilitate SUMO removal, we depleted each of the four SUMO proteases in *C. elegans* and found that one of these enzymes, ULP-1, is required for both AIR-2 relocalization to the microtubules and for ring disassembly. Moreover, we found that ULP-1 localizes to the ring structures from prometaphase through early anaphase, and that GEI-17/UBC-9 are removed from the rings before ULP-1. These findings raise the possibility that prior to anaphase, the SUMO conjugating enzymes and proteases compete for substrate, enabling removal of GEI-17/UBC-9 in early anaphase to serve as a trigger for ring disassembly by ULP-1. Consistent with this idea, we found that metaphase SUMO fluorescence intensity is increased following ULP-1 depletion, and that ULP-1 can remove SUMO modifications from multiple ring components in vitro. Altogether, we have revealed a role for SUMOylation in regulating ring disassembly and anaphase progression during anaphase of *C. elegans* oocyte meiosis. (1) Davis-Roca, et.al. A compartmentalized, self-extinguishing signaling network mediates crossover control and faithful chromosome segregation in meiosis.
L. Zhang1,2,3,4, S. Köhler1,2,3,4, R. Rillo-Bohn1,2,3,4, A.F. Dernburg1,2,3,4;
1Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, 2Howard Hughes Medical Institute, Chevy Chase, MD, 3Biological Systems and Engineering Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 4California Institute for Quantitative Biosciences, Berkeley, CA

During meiosis, homologous chromosomes pair, synapse, and undergo crossover recombination. This process leads to the formation of stable interhomolog connections known as chiasmata, which enable homologs to bi-orient and segregate during the first meiotic division. Defects in meiotic chromosome segregation lead to aneuploidy, the primary cause of spontaneous abortion and congenital birth defects in humans. To ensure faithful meiotic chromosome segregation, meiotic crossovers must be tightly regulated. Each chromosome pair typically undergoes at least one crossover event (crossover assurance) but these exchanges are also strictly limited in number and widely spaced along chromosomes (crossover interference). This has implied the existence of chromosome-wide signals that regulate crossovers, but their molecular basis remains mysterious. Recent work from our group suggests that the synaptonemal complex (SC) is a liquid-like compartment that assembles between homologous chromosome axes through phase separation (Rog et al., 2017). The structural proteins of the SC are highly mobile within assembled complexes, and polycomplexes of SC proteins behave as droplets with liquid-like properties in vivo. Additionally, both SCs and polycomplexes are rapidly and reversibly dissolved by aliphatic alcohols such as hexanediols, indicating that their structural integrity depends on weak hydrophobic interactions. These liquid crystalline properties suggested that the SC might act as a conduit for a crossover interference signal. We now characterize a family of four related RING finger proteins in C. elegans. These proteins are recruited to the synaptonemal complex between paired homologs, where they act as two heterodimeric complexes, likely as E3 ubiquitin ligases. Our genetic and cytological analysis reveals that they act with additional components to create a self-extinguishing circuit that controls crossover designation and maturation. Our finding suggests a signal flows through the liquid crystalline channel between the surface of two homologous chromosomes to mediate crossover control and to ensure faithful meiotic chromosome segregation. In addition, we find that these proteins act upstream of other regulators to direct chromosome remodeling in response to crossover formation, which enables stepwise cohesion loss and chromosome segregation. Work in diverse phyla indicates that related mechanisms mediate crossover control across eukaryotes.

Vive la difference! Evolutionary divergence in meiotic chromosome dynamics among nematodes.
R. Rillo-Bohn1,2,3,4, B. Avsaroglu1,2,3,4, J.J. Bayes1,2,3,4, S. Köhler1,2,3,4, A.F. Dernburg1,2,3,4;
1Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, 2Howard Hughes Medical Institute, Chevy Chase, MD, 3California Institute for Quantitative Biosciences (QB3), Berkeley, CA, 4Biological Sciences ans Engineering Division, Lawrence Berkeley National Laboratory, Berkeley, CA

Meiosis is the specialized cell division process essential for sexual reproduction. Studies of meiosis have expanded our understanding of chromosome architecture and dynamics, cell cycle regulation, and
feedback control. The nematode *Caenorhabditis elegans* is a well-established model for investigating meiosis. Its experimental advantages include a small genome compared to most metazoans, a low number of chromosomes (6 pairs), powerful genetics, and germline organization that facilitates temporal analysis of meiotic progression. Our recent work has elucidated circuitry that acts downstream of homolog synapsis to regulate crossover formation, which appears to be widely conserved across eukaryotes (see presentation by Zhang et al.) However, other aspects of meiotic regulation in *C. elegans* are atypical, including homolog pairing and synapsis in the absence of recombination, and the emergence of specialized chromosome regions – “pairing centers” - that mediate nuclear envelope attachment and microtubule-based chromosome movement.

To better understand how these innovations arose during evolution, we are developing the nematode *Pristionchus pacificus* as a comparative model for the cell biology of meiosis. Like *C. elegans*, *P. pacificus* is a self-fertilizing hermaphroditic species that can be readily cultured in the laboratory. Genome editing with Cas9/CRISPR is fairly robust, allowing reverse genetics and epitope tagging, although large knock-ins have been problematic. While germline organization and meiotic progression appear superficially similar between these two nematodes, we have identified major differences in meiotic mechanisms and their interdependence. Unlike the genomes of *Caenorhabditis*, which have lost the recombinase Dmc1 and its cofactors Mnd1 and Hop2, the *Pristionchus* genome has intact copies of these genes. Disruption of *Ppa_spo-11* or *dmc-1* blocks homolog pairing and synapsis. DMC-1 and RAD-51 localize sequentially to meiotic chromosomes; crossing-over and meiotic progression require DMC-1 but not RAD-51. Perhaps most surprisingly, CO designation occurs much earlier in *P. pacificus*, and synapsis depends on crossover designation by COSA-1 and ZHP-3, analogous to the situation in budding yeast but divergent from what is observed in *C. elegans* or mammals.

Through this comparative approach, we are uncovering core features of the meiotic program that are shared by divergent organisms, as well as illuminating how details of this process are modified during evolution.

²Department of Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Pairing of sister chromatids is critical for faithful transmission of chromosomes to daughter cells. Cohesin complexes deposited during S phase establish cohesion, the force holding these duplicated chromosomes together. As cells enter mitosis most cohesin is removed from condensed sister chromatid pairs via the prophase pathway. The removal of cohesin from chromatids via this non-proteolytic pathway occurs mainly along chromatid arms, with the majority of remaining cohesin concentrated at centromeres. As a result, it is commonly reported that the prophase pathway removes cohesin from chromosome arms thereby causing the loss of cohesion between chromatid arms and giving rise to the classical X-shaped depictions of mitotic chromosomes. But we find that arms of sister chromatids are cohered through metaphase. This sister chromatid arm cohesion is readily apparent in mitotic cells undergoing cohesion fatigue, the force-dependent process whereby sister chromatids are pulled apart in an asynchronous and unscheduled manner within cells delayed in prometaphase or metaphase. During cohesion fatigue loss of cohesion begins at centromeres and proceeds lengthwise along paired chromatid arms from centromeres to telomeres. To unravel this paradox we examined chromosome spreads from variant mitotic cell populations. Paired sister chromatids derived from cells arrested in mitosis by the microtubule depolymerizing agent, nocodazole, often formed the classical X-
shaped structure. In contrast paired chromatids from cells arrested in mitosis by inhibition of Cenp-E, the APC/C, or proteasome exhibited arms that retained tightly parallel orientations, indicating that cohesion was retained. Thus the absence of interactions between the mitotic spindle and sister chromatids appears to promote premature loss of chromatid arm cohesion, while the presence of this interaction sustains arm cohesion. In support of this hypothesis, we found that mitotic cells initially treated with nocodazole, then permitted to reform their mitotic spindles by removing nocodazole but restrained from progression past metaphase by proteasome inhibition, underwent cohesion fatigue more rapidly than mitotic cells that were arrested in mitosis by proteasome inhibition alone. We hypothesize that maintenance of chromatid arm cohesion through metaphase is advantageous and may rescue initial unscheduled loss of centromere cohesion should centromere regions loose cohesion during spontaneous prolonged prometaphase or metaphase. Furthermore maintenance of sister chromatid arm cohesion until the onset of anaphase suggests that regulators controlling the scheduled and synchronous loss of cohesion at anaphase onset are likely targeting both centromere and arm cohesin for destruction.

Actin protects mammalian eggs against chromosome segregation errors.
B. Mogessie, M. Schuh
1Meiosis, Max Planck Institute for Biophysical Chemistry, Goettingen, Germany

Chromosome segregation is driven by a spindle that is made of microtubules but is generally thought to be independent of actin. Here, we report an unexpected actin-dependent mechanism that drives the accurate alignment and segregation of chromosomes in mammalian eggs. Prominent actin filaments permeated the microtubule spindle in eggs of several mammalian species, including humans. Disrupting actin in mouse eggs led to significantly increased numbers of misaligned chromosomes as well as lagging chromosomes during meiosis I and II. We found that actin drives accurate chromosome segregation by promoting the formation of functional kinetochore fibers, the microtubule bundles that align and segregate the chromosomes. Thus, actin is essential to prevent chromosome segregation errors in eggs, which are a leading cause of miscarriages, infertility, and Down syndrome.

Persistent DNA-break potential near telomeres contributes to a chromosome-size bias in break initiation.
V.V. Subramanian, P.A. San-Segundo, N.M. Hollingsworth, A. Hochwagen
1Biology, New York University, New York, NY, 2Consejo Superior de Investigaciones Científicas, Instituto de Biología Funcional y Genómica and University of Salamanca, Salamanca, Spain, 3Department of Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY

Infertility, spontaneous fetal loss and birth defects in humans result mainly from chromosome segregation errors during meiosis [1]. Faithful meiotic chromosome segregation requires induction of numerous programmed DNA breaks, and repair of these DNA breaks as crossovers to link previously unattached homologous chromosomes [2]. Consequently, proper control of DNA breakage and repair is critical for maintenance of genome integrity [3]. To avoid excessive DNA damage, DNA break-promoting HORMA-domain protein, Hop1, is removed from the meiotic chromosomes by the evolutionarily conserved synaptonemal complex (SC) [4-6]. Previous
research has shown that this negative feedback regulation of Hop1 and DNA breaks by the SC occurs following break initiation and crossover designation and in a chromosome autonomous manner [4-8]. Using ChIP-seq assays we found that while SC efficiently erases telomere-distal Hop1 in *Saccharomyces cerevisiae*, it is not sufficient to remove Hop1 from large telomere-adjacent regions (TARs; ~100 Kb). Several lines of evidence indicate that when all chromosomes have assembled the SC and telomere-distal breaks are suppressed, DNA breaks continue to form in the TARs. Removal of Hop1 from telomere-distal regions and thereby enrichment of Hop1 in the TARs requires activity of the AAA⁺-ATPase Pch2. In addition to telomere-distal regions, Pch2 also restricts Hop1 from centromeres, where crossover recombination maybe deleterious. As TARs comprise a proportionally large fraction of the small chromosomes in the genome, continued DNA breakage in these domains may contribute to the curiously high recombination rate observed on the small chromosomes [8-10] and thereby promote their accurate segregation in meiosis.

Intrinsic and extrinsic factors contributing to the stability of CENP-A nucleosomes at centromeres.
P.K. Allu¹, A. Das¹,², L.Y. Guo¹, M.A. Lampson², B.E. Black¹;
¹Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA; ²Department of Biology, University of Pennsylvania, Philadelphia, PA

Centromeres are present on each chromosome to orchestrate the accurate transmission of genetic information to daughter cells. Centromeres are epigenetically specified by the presence of nucleosomes containing the histone H3 variant, CENP-A. Nascent CENP-A nucleosome assembly occurs once per cell cycle, following mitotic exit. Once assembled they are exceptionally stable with no measurable turnover, even persisting at the same centromere through disruptive chromatin events like DNA replication (Falk et al., 2015, Science, 348, 699-703). Further, CENP-A nucleosome stability is presumably critical for maintaining centromere identity in slowly dividing cells where typical nucleosome turnover rates would compromise prior to the next round of CENP-A nucleosome assembly the epigenetic centromere mark that they provide. Stability is likely generated through a combination of factors that are either intrinsic (i.e. encoded within the CENP-A protein sequence) or extrinsic (i.e. conferred by direct binding partners). For intrinsic factors, we identified six a.a. residues of the CENP-A protein at its interface with its partner histone, H4, forming hydrophobic stitches that rigidify CENP-A nucleosomes relative to their canonical counterparts containing histone H3 (Sekulic et al., 2010, Nature 467, 347-351). Substitution of all six to the corresponding residues found in histone H3 do not disrupt interactions with the CENP-A
chromatin assembly protein, HJURP, but nonetheless lead to a loss from centromeres (Bassett et al., 2012, Dev. Cell 22, 749-762). We will describe our approach and emerging findings in experiments employing gene editing and CENP-A pulse-labeling to interrogate single a.a. substitutions of the hydrophobic stitch residues to identify those that affect the stability of centromeric chromatin. Indeed, we find that individual substitution of the hydrophobic stitch residues leads to varying reductions in centromere localization, with a subset of them severe. For extrinsic factors, we recently described two forms of stability in asynchronous cell populations conferred within a core centromeric nucleosome complex (CCNC): CENP-C binding across the histone octamer of the CENP-A nucleosome and driving a conformational switch that stabilizes the nucleosome, and CENP-N cross-bridging CENP-A to the nucleosomal DNA (Guo et al., 2017, Nat. Comm. 8, 15775). We are now extending our analysis to synchronized cells to investigate whether or not CENP-C and CENP-N confer CENP-A nucleosome stability consistently through the cell cycle or only at certain key points. A long-term goal of our work is to provide a comprehensive understanding of how epigenetic centromere identity is maintained.

Investigating the Role of CDK-2 in Crossover Recombination in C. elegans.
J. Haversat¹, V. Roberts¹, Y. Kim¹;
¹Biology, Johns Hopkins University, Baltimore, MD

Cyclin-dependent kinases (CDKs) and their activating cyclin subunits play central roles in driving cell cycle progression in eukaryotes. The classical view was that CDK2 is essential for cell cycle progression by controlling the G1/S transition. Studies using CDK2 knockout mice, however, have revealed an unexpected role of CDK2 during meiotic prophase, while demonstrating that CDK2 is dispensable for mitotic cell cycle progression and proliferation. Consistent with its meiotic functions, CDK2 has been shown to localize to telomeres as well as crossover sites during mammalian meiosis. However, the role of CDK2 in meiotic recombination remains unknown. Here report that CDK-2, the C. elegans homolog of CDK2, is localized to the crossover sites during meiotic prophase. Using super-resolution microscopy, we show that CDK-2 colocalizes with COSA-1, a cyclin-like protein that plays a conserved role in crossover formation, raising the possibility that CDK-2 might partner with COSA-1 to function as an active kinase. To determine the role of CDK-2 during meiosis, we employed the auxin-inducible degradation system to rapidly deplete CDK-2 from the C. elegans germline. CDK-2-depleted germ cells exhibit normal homolog pairing, synapsis, and meiotic DNA double-strand break formation. However, germ cells progressively lose COSA-1 foci from the distal end following auxin treatment and exhibit an increase in the number of univalent chromosomes in diakinesis, indicating that CDK-2 is required for crossover recombination. We are currently investigating how CDK-2 promotes crossover formation and will present our current findings.

Different Mechanisms of Micronucleus Formation and Impact to Genomic Stability.
L.A. Sepaniac¹, L.G. Reinholdt², J.K. Stumpff¹;
¹Department of Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, ²Genetic Resource Science, The Jackson Laboratory, Bar Harbor, ME

Micronuclei contain whole or fragmented chromosomes excluded from the main nucleus and are often used clinically as a marker of genomic instability. However, it is not fully understood how micronuclei...
contribute to pathogenesis at the cellular level. Furthermore, micronuclei can form through several mechanisms, and it is not clear whether all micronuclei have similar effects on cellular fitness and transformation. For example, micronuclei that form following improper attachments between chromosomes and microtubules of the mitotic spindle during cell division can lead to severe, but localized DNA rearrangements, called chromothripsis, identified as an early event in tumor formation. In contrast, our own studies of cells containing micronuclei from chromosome alignment defects do not show evidence of early events predicted to lead to chromothripsis, such as division with a pre-existing micronucleus or fragmentation of micronucleated chromosomes.

To test whether the impact of micronuclei on genomic stability vary as a function of 1) how they are formed, or 2) whether cells have p53 activity, we induced micronuclei in two different ways and used quantitative fluorescence microscopy to assess a) whether cells that form micronuclei continue to divide, b) the fate of micronuclei after cell division events, and c) the prevalence of micronuclear envelope rupture. Micronucleus formation was induced in human retinal pigmented epithelial (RPE1) cells by either promoting division with improper attachments via siRNA knock down of MAD2 (mitotic arrest deficient 2), an essential spindle checkpoint protein; or promoting division with unaligned chromosomes via knockout of Kif18A, a kinesin protein. Both conditions were performed with and without siRNA knockdown of p53 for comparison.

Our preliminary data show that micronucleated RPE1 cells resulting from unaligned chromosomes undergo cell cycle arrest (rate of division is reduced by 67% compared to non-micronucleated cells). However, the rate of micronucleated divisions doubles with p53 KD, suggesting that an intact DNA damage checkpoint prevents micronucleated cells from dividing. We also observe that micronuclei which form due to unaligned chromosomes (Kif18A knockout) rarely become reincorporated with the primary nucleus following a subsequent round of division. Interestingly, micronuclei that form due to improper attachments are more likely to rupture (Mad2 KD condition; 29% rupture), compared to those that form due to unaligned chromosomes, (Kif18A knockout; 15% rupture), indicating that the fate of micronuclei indeed differs between mechanisms of formation (p < 0.05).

The cytoplasmic DNA sensor cGAS promotes mitotic cell death.
C. Zieruh1, H. Funabiki1;
1Laboratory of Chromosome and Cell Biology, The Rockefeller University, New York, NY

The cyclic GMP-AMP (cGAMP) synthase cGAS counteracts infections by detecting and binding foreign cytoplasmic DNA. DNA-induced synthesis of cGAMP activates innate immune signalling and apoptosis through the cGAMP receptor STING and the downstream effector IRF3. During interphase the nuclear envelope protects chromosomal self-DNA from cGAS, but the consequences of exposing chromosomes to cGAS following mitotic nuclear envelope disassembly are unknown. Here we demonstrate that cGAS associates with chromosomes during mitosis and binds nucleosomes with even higher affinity than naked DNA in vitro. Nucleosomes nevertheless competitively inhibit the DNA-dependent stimulation of cGAS, and accordingly, chromosomal cGAS does not affect mitotic progression under normal conditions. This suggests that nucleosomes prevent the inappropriate activation of cGAS during mitosis by acting as a signature of self-DNA. During prolonged mitotic arrest, however, cGAS becomes activated to promote cell death, limiting the fraction of cells that can survive and escape mitotic arrest induced by the chemotherapeutic drug taxol. Induction of mitotic cell death involves cGAMP synthesis by cGAS, as well as signal transduction to IRF3 by STING. We thus propose that cGAS plays a previously unappreciated role in guarding against mitotic errors, promoting cell death during prolonged mitotic arrest. Our data also indicate that the cGAS pathway, whose activity differs widely among cell lines, impacts cell fate
determination upon treatment with taxol and other anti-mitotic drugs. Thus, we propose the innate immune system may be harnessed to selectively target cells with mitotic abnormalities.

Developing a *C. elegans* model to study SF3B1-driven Myelodysplastic Syndromes using CRISPR/Cas9 to introduce a point mutation and RNAi-mediated knockdown of sftb1.

N. Tirado-Class	extsuperscript{1}, C.E. Rolle, PhD	extsuperscript{1};

	extsuperscript{1}Science and Mathematics, Capital Community College, Hartford, CT

It is well established that Caenorhabditis elegans is an ideal model system to study the underlying genetic mechanisms of human diseases, particularly developmental diseases. There is a high level of genetic conservation between *C. elegans* and humans. Approximately 65% of human disease genes have orthologs in *C. elegans*. Moreover, these organisms are extremely amenable to genetic manipulation, they are relatively cost effective to maintain in the laboratory, and their developmental processes are well characterized. Myelodysplastic syndromes (MDS) comprise hematologic malignancies that are characterized by dysregulated production of blood cells and poorly formed blood cells. Mutations in SF3B1 were detected in more than 70% of MDS patients with refractory anemia with ring sideroblasts (RARS). SF3B1 is a core component of the U2 small nuclear ribonucleoprotein and it plays a key role in RNA splicing. This study will focus on the most commonly detected SF3B1 mutation in MDS, K700E. First, we performed bioinformatic analyses to determine whether SF3B1 and the K700 amino acid were conserved in *C. elegans*. Sequence homology between sftb1 and SF3B1 is approximately 71%, with sftb1 being 1322 amino acids compared to 1304 amino acids for SF3B1. The lysine residue at position 700 in SF3B1 was also conserved, albeit at position 718 in sftb1. Second, we examined the effect of RNAi-mediated silencing of sftb1 on development, reproduction, growth, and survival. We observed a decrease in overall survival rates following siRNA treatment targeting sftb1 but not control siRNA. This was likely due to impairments in egg laying because we observed altered uterine morphology following RNAi-mediated knockdown of sftb1. Third, we examined the expression patterns of sftb1 in each developmental stage. Finally, we modified a CRISPR/Cas9 vector and a double-stranded DNA repair template to generate offspring carrying sftb1 with the K718E mutation.

Cross-species oncogenomics approach identifies PTPN11 as an oncogene and potential therapeutic target in melanoma.

	extsuperscript{1}Molecular Oncology, Moffitt Cancer Center, Tampa, FL; 
	extsuperscript{2}Biostatistics and Bioinformatics, Moffitt Cancer Center, Tampa, FL; 
	extsuperscript{3}Anatomic Pathology, Moffitt Cancer Center, Tampa, FL; 
	extsuperscript{4}Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Melanoma is a deadly disease carrying many genetic mutations. A major challenge to the development of effective targeted therapies in melanoma is the identification of true “driver” mutations among numerous “passenger” alterations. Several previous studies support using cross-species comparative oncogenomic approaches for cancer gene discovery. It has been shown that mice and humans share several genetic events in the development of cancer and that these events, conserved across different
species, may point to functionally important alterations targeting “driver” genes. Recently, we analyzed melanoma genomes from a mouse model driven by the loss of PTEN and CDKN2A (INK4A/ARF) by whole exome sequencing. This study identified several conserved cross-species orthologous mutations in Kras, Erbb3, and Ptpn11. In this study, we addressed the functional roles of PTPN11 in melanoma tumorigenesis and tumor maintenance, its effect on RAS/RAF/MEK/ERK signaling pathway, and its activation status in human melanoma.

Melanoma displays frequent activation of the RAS/RAF/MEK/ERK signaling pathway, which is intricately regulated by multiple proteins including PTPN11 (Tyrosine-Protein Phosphatase Non-Receptor Type 11, encoding SHP2). Although implicated as an oncogene in multiple cancer types, the oncogenic role of PTPN11 has not been fully established in melanoma. PTPN11 can be activated by receptor tyrosine kinases (RTKs) and/or by point mutations. Although the mutation rate is low (1~3%), we observed activating phosphorylation on Tyr 542 of PTPN11 in 40% (n=15/38) of melanoma specimens and the majority of human melanoma cell lines (n=14), indicating the potential frequent activation of PTPN11 in human melanoma. PTPN11 knock-down suppressed ERK activation in NRAS mutant (WM1361A, 1366, 1346) and BRAF/NRAS wt (WM3211, MeWo, CHL1) melanoma cells, but not in BRAF mutant (1205Lu, IGR1, 983C) cells. Moreover, we have shown that the expression of active PTPN11 E76K mutant drives soft-agar colony growth in vitro, tumor growth in nude mice, RAS/RAF/MEK/ERK activation, and resistance to MEK inhibition; whereas, knock-down of Ptpn11 reduces colony growth and ERK activation.

We generated a tet-inducible, melanocyte-specific, PTPN11 E76K transgenic mouse model in a Pten and Cdkn2a null background and observed melanoma formation. Implantation of melanoma cells derived from this model showed doxycycline dependent tumor growth in nude mice; additionally, withdrawal of doxycycline and subsequent extinction of PTPN11 E76K caused regression of established tumors, supporting a tumor maintenance role of PTPN11. These data support the oncogenic roles of PTPN11 in melanoma by regulating RAS/RAF/MAPK pathway activation and the value of PTPN11 as a novel and actionable therapeutic target.

On the role of kindlin-3 phosphorylation in cancer cells.
K. Bialkowska1, K. Sossey-Alaoui1, E.F. Plow1;
1Molecular Cardiology, Cleveland Clinic, Cleveland, OH

The contributions of integrins to cellular responses depend upon the dynamic regulation of their activation status, which in turn depends on engagement of binding partners by their cytoplasmic tails. It is well-established that not only talin but also kindlin family members are essential for integrin activation, and both must present for optimal integrin activation. Recent studies in have specifically emphasized the vital role of kindlin-3 (K3) in integrin function in hematopoietic and non-hematopoietic cells, including cancer cells. K3 deficiency in hematopoietic cells leads to episodic bleeding, frequent infections and osteopetrosis, consequences of an inability to activate β1, β2 and β3 integrins. Despite this growing evidence, little is known about the regulation of K3 function. To identify posttranslational modification which might regulate K3 function, we used human platelets and human erythroleukemic (HEL) cells. The stimulation of platelets and HEL cells with agonist resulted in significant increase of K3 phosphorylation, as detected by MS sequencing. T482 or S484 were identified as phosphorylation sites and reside in K3 variable region. When expressed in cells, T482S484/AA K3 decreased soluble ligand binding and cell spreading on immobilized fibrinogen when compared to wild-type K3. Thus, our data emphasizes a role of previously unknown K3 phosphorylation, in integrin activation and provides a basis for functional differences between K3 and its two other paralogs. Our previous work showed that in breast cancer cells K3 is a tumor promoter, which regulates cancer progression by influencing the
crosstalk between β1 integrins and transcription factor Twist to increase VEGF production and to control tumor angiogenesis and metastasis. The importance of K3 in tumor progression led us to examine a role of K3 phosphorylation in breast cancer cells. Stable clones expressing phosphomutants of K3 were generated in MDA-MB-231 breast cancer cells. In vitro analyses determined that K3 phosphorylation is important for breast cancer cell spreading, migration and invasion, activation of β1 integrin and Twist upregulation. While expression of WT K3 increased spreading and invasiveness of MDA-MB-231 by ~40%, the spreading and invasiveness of T482S484/AA K3 expressing-cells was comparable to parental cells or cells expressing EGFP alone. T482S484/AA K3 also decreased HUTS-4 binding (antibody binding to activated β1) when compared to WT K3 cells. Also Twist expression was upregulated in WT K3 cells and it was reduced significantly in T482S484/AA K3 cells. These effects lead to the prediction that phosphorylation of K3 is likely to influence on tumor progression and metastasis in vivo.

NRMT1 mutants naturally occurring in human cancers have altered catalytic activity and cause a decrease in N-terminal trimethylation levels.

K.M. Shields1, J.G. Tooley2, C.E. Schaner Tooley3;
1Biochemistry and Molecular Genetics, University of Louisville, Louisville, KY, 2Biochemistry, State University of New York at Buffalo, Buffalo, NY

N-terminal methylation of the alpha amino group of proteins has been documented for over 40 years, but the methyltransferases responsible for this modification, N-terminal RCC1 methyltransferases 1 and 2 (NRMT1 and NRMT2), have just been discovered in the last decade. NRMT1 is the only known eukaryotic N-terminal trimethylase, while its homolog NRMT2 is the only known N-terminal monomethylase. N-terminal methylation has been commonly believed to be a general regulator of protein stability, but the identification of NRMT1 and NRMT2 has led to the discovery that it also regulates protein-DNA interactions. Comprehensive determination of the shared NRMT consensus sequence has indicated over 300 potential substrates for the enzymes, including many involved in DNA repair. It has since been shown that specific loss of NRMT1 impairs nucleotide excision repair (NER) and double-strand DNA break repair, as well as, promotes oncogenic phenotypes in breast cancer cells and leads to premature aging phenotypes in mice. These data also suggest that residual monomethylation from NRMT2 cannot functionally compensate for loss of trimethylation. As mutations of NRMT1 naturally occur in human cancer genomes, the objective of this study was to test if these mutations actually alter enzymatic activity. NRMT1 mutants N209I (endometrial cancer) and P211S (lung cancer) displayed decreased trimethylase and increased mono/dimethylase activity as compared to wild type NRMT1. Closer examination demonstrated that the NRMT1 mutants are capable of trimethylation, but they do so at a much slower rate and with a requirement for higher substrate concentration. NRMT1 is a distributive methyltransferase that dissociates after the addition of each methyl group. Both the N209I and P211S mutations are located in the peptide-binding channel and further strengthen the notion that this structural region helps determine affinity for unmodified vs. previously mono- or dimethylated substrates. Expression of the mutants in wild type NRMT1/2 backgrounds showed no change in N-terminal methylation levels or growth rates, demonstrating they are not acting as dominant negatives. Expression of the mutants in cells lacking endogenous NRMT1 resulted in minimal accumulation of N-terminal trimethylation, indicating the impaired biochemical activities of these mutants cannot be overcome in cells with endogenous substrate levels, even after prolonged exposure. It also suggests N209I or P211S homozygosity could mimic NRMT1 knockdown phenotypes and lead to inefficient DNA repair, mutagenesis, and oncogenic transformation. Alternatively, these mutations could serve as
markers for tumors with increased sensitivity to DNA damaging chemotherapeutics or gamma-irradiation.

**Downregulation of LAT1 (L-type amino acid transporter 1 / SLC7A5) in human cancer.**

A. Oliveira¹, P. Soares-da-Silva¹²;

¹Phyzat Biopharmaceuticals, Porto, Portugal, ²Center for Drug Discovery and Innovative Medicines, MedInUP, Porto, Portugal

L-Type amino acid transporter 1 (LAT1 / SLC7A5) is highly expressed in cancer cells to support their continuous growth and proliferation and has been suggested as a marker of cancer prognosis in different types of cancer (Semin Cancer Biol 15:254-266, 2005). The present study examined the effect of LAT1/SLC7A5 gene downregulation by RNA interference on the function of the transporter in human cancer cells. Target sites within LAT1 gene (NM_003486) were selected from the respective human mRNA sequences. Nucleotide homology searching was performed against nonredundant and dbEST using BLAST via online connection to NCBI. The commercial siRNA S131011000 that targets the human LAT1 mRNA sequence and negative control siRNA commercial sequences NC-S103650318 and NC-S103650325 (Qiagen) were tested. Cells (human liver adenocarcinoma SK-HEP-1, human fibrosarcoma HT-1080 and human bladder carcinoma T24) were cultured for 48 h (in RPMI and DMEM-hg, respectively). LAT1 mRNA and protein expression, inward transport of $[^{14}\text{C}]$-L-leucine, and effects of siRNA anti-LAT1 upon $[^{14}\text{C}]$-L-leucine uptake were analyzed. Antibodies raised against LAT1 and GAPDH were used, and images were obtained by scanning at both 700 nm and 800 nm, with an Odyssey Infrared Imaging System (LI-COR Biosciences). For RT-PCR, total RNA was converted to cDNA and qPCR analysis was made in the StepOnePlus instrument (Applied Biosystems). Primers for LAT1 and for the endogenous control gene GAPDH were used. All cell types expressed LAT1 mRNA and protein. The abundance of LAT1 mRNA differed among the tumor cell lines, being more intense in HT-1080, followed by SK-HEP-1 and T24 cells. The same trend was not verified for protein abundance, with T24 cells expressing more LAT1 protein than the other cell lines. The sodium-independent inward transport of non-saturating concentrations (0.25 μM) of $[^{14}\text{C}]$-L-leucine, the preferred substrate of LAT1, was linear with time for up to 10 min of incubation. In order to determine the kinetics of the transporter, cells were incubated for 1 min with $[^{14}\text{C}]$-L-leucine (0.25 μM) in the absence or in the presence of increasing concentrations of unlabelled substrate L-leucine (1 to 3 mM). The kinetic parameters of $[^{14}\text{C}]$-L-leucine uptake ($K_m$ in mM; $V_{max}$ in nmol/mg protein/min) were determined by non-linear analysis of the specific analysis of inhibition curve for L-leucine and are as follows: SK-HEP-1, $K_m=0.072\pm0.011$, $V_{max}=2.938\pm0.439$; HT-1080, $K_m=0.123\pm0.021$, $V_{max}=5.876\pm0.858$; T24, $K_m=0.120\pm0.013$, $V_{max}=10.346\pm0.996$. Transfection with siRNA against LAT1 gene, but not the negative control siRNAs, reduced the $[^{14}\text{C}]$-L-leucine accumulation in all cancer cell lines. In conclusion, anti-LAT1 siRNA decreased $[^{14}\text{C}]$-L-leucine uptake, possibly by downregulation of LAT1 expression.

Transforming growth factor beta (TGFβ) regulates glutamine metabolism in lung Fibrosis.
M. Choudhury1, X. Yin1, J. Kang1, M. Jung1, M. Andrianifahanana1, E.B. Leof1;
1Pulmonary and Critical Care Medicine, Mayo Clinic, Rochester, MN

Fibroproliferative diseases are a leading cause of morbidity and mortality featuring localized and systematic tissue/organ fibrosis. Nearly 45% of all deaths in the developed world are caused by chronic inflammatory and fibrogenic disorders. Despite the massive impact of fibroproliferative diseases on human health, there are no efficient therapeutic treatment options that directly target the mechanisms of fibrosis due to their inherently complex and often undefined etiology. Cancer cells reprogram their bioenergetics and biosynthetic requirements by altering metabolic pathways to divert nutrients such as glutamine to satisfy the demand for cellular building blocks to fuel cell growth. Accumulated evidence showed that the reprogramming of tumor metabolism is under the control of various oncogenic signals and growth factors. While TGFβ is considered a pleiotropic cytokine due to its ability to impact numerous diseases and biological processes, the role of nutrient metabolism in profibrotic TGFβ signaling is relatively unexplored or unknown. To that end, our studies have identified a previously uncharacterized relationship between upregulation of glutamine transporters (SLCs) and glutaminase I (GLS1; which converts glutamine to glutamate) with TGFβ. Specifically we have found that (i) glutamine transporters SLC1A5 and SLC1A7 as well as GLS1 are induced by TGFβ in both murine and human lung fibroblasts; (ii) while phosphorylation of SMAD3 occurs independently of SLCs or GLS1, fibroblast migration and expression of TGFβ stimulated profibrotic targets including collagen 1, PAI-1, CTGF, fibronectin and α-SMA requires the action of SLC1A5 and GLS1; (iii) by using pharmacologic and genetic approaches, we have demonstrated that upregulation of SLC1A5, SLC7A5 and GLS1 occurs via the canonical SMAD2/3 pathway as well as non-canonical PI3K/Akt/mTOR pathway. Finally we have found a novel mechanistic insight of the regulatory roles of TGFβ in metabolic dysregulation leading to idiopathic pulmonary fibrosis through histone modifications and autophagy, which will inspire a new frontier in the design and development of antifibrotic therapy.

How does MYC make purines?
M. Lafita Navarro1, J. Kilgore2, N. Williams3, L. Zacharias2, R. DeBerardinis3, M. Conacci-Sorrell1;
1Cell biology, UT Southwestern Medical Center, Dallas, TX, 2Biochemistry, UT Southwestern, Dallas, TX, 3Children's Research Institute, UT Southwestern Medical Center, Dallas, TX

Cancer cells rewire their metabolism to obtain energy and anabolic precursors for proliferation. MYC is thought to be a key driver of cancer cell metabolism with its major function attributed to the transcriptional induction of metabolic enzymes. However, it is completely unknown whether MYC can control cellular metabolism by transcription-independent mechanisms. Our group discovered a cytoplasmic transcriptionally-inactive MYC variant named MYC-nick. MYC-nick is a proteolytic byproduct of MYC that promotes survival of cancer cells under stress conditions (such as hypoxia or nutrient starvation) but does not induce cell proliferation. While MYC-nick does not have the ability to bind DNA, it can interact with acetyltransferases. Our working model is that MYC-nick recruits acetyltransferases to promote acetylation of cytoplasmic proteins, thereby regulating their functions. To determine if MYC-nick has the ability to regulate cell metabolism, we performed metabolomics (in collaboration with Dr. Ralph DeBerardinis) comparing the profiles of fibroblasts expressing MYC and
MYC-nick. Unexpectedly, we found that MYC-nick promotes an increase in purines. Utilizing HPLC-Mass spectrometry (in collaboration with Dr. Noelle Williams), we found that MYC-nick expression induces purines in fibroblasts and in human colorectal cancer cells. Moreover, we also found that purines are elevated in human colon cancer tissues, which express high levels of MYC-nick. The most dramatic result was an increase in the levels of deoxyinosine (a mutagenic purine) in every tested biopsy sample of colon cancer.

We propose that MYC-nick increases the production of purines by shunting glycolytic intermediates into the pentose phosphate pathway to promote de novo purine synthesis. We hypothesize that MYC-nick, by acetylating and regulating the activity of glycolytic enzymes (such as aldolase), promotes synthesis of purines in a transcription-independent manner. Currently, we are testing the role of deoxyinosine and other purines on MYC-nick-induced cell survival and mutagenesis.

Alpha1-antitrypsin-derived C-terminal peptide is a potent oxidative stress inhibitor.
A.A. Maslakova1, M.A. Rubtsov3, V.S. Efimova1, O.S. Sokolova1, O.V. Smirnova1, I.V. Orlovsky3; 1Faculty of Biology, Lomonosov Moscow State University, Moscow, Russia, 2Department of Biochemistry/Strategic Management Department, I.M. Sechenov First Moscow State Medical University, Moscow, Russia, 3A.N. Belozersky Research Institute of Physical and Chemical Biology, Lomonosov Moscow State University, Moscow, Russia

Acute-phase protein alpha1-antitrypsin (AAT) has been reported as a biomarker in many tumors. A number of tumor cell lines produce the protein. Tumor-associated proteases cleave AAT at the active site producing a bioactive C-terminal peptide C36, which possesses immune suppressing, serine protease-protecting and mitogenic activity (L. Cercek, B. Cercek, 1992, 1993; Zelvyte I. et al., 2003). According to our previously reported data, C36 can also activate metabolism under certain conditions (Maslakova A., 2016). Recently, an exogenous full-length AAT has been established as an oxidative stress protector in a human placental cell line (Feng Y-L et al., 2016, 2017) at the effective concentration of 50uM. We investigated the oxidative stress-protecting activity of AAT-derived C36 peptide in human cell line DU145 under serum starvation condition using cell-permeable 2′,7′-dichlorodihydrofluorescein diacetate. We used a wider C36 peptide concentration range (10pM-50uM) in order to investigate its potential activity at levels that are much lower than physiological levels for the full-length AAT (around 30uM), that might be closer to true peptide concentrations in tumor microenvironment. Indeed, C36 peptide protects cells from oxidation in a dose-dependent manner starting from as low as 100nM (~34% lower overall oxidation level), while 30-50uM gives a more pronounced effect (~49-56% lower overall oxidation level, respectively). The latter inhibitory level is in a good accordance with the previous data on the full-length protein (Feng Y-L et al., 2016), that has been shown to inhibit p38MAPK signaling pathway (Feng Y-L et al., 2017). Our findings indicate that AAT-derived C36 peptide preserves the site crucial for such activity and can potently protect tumor cell from oxidative stress under serum starvation. The study was supported by RFBR project № 16-34-01095 mol_a (“Structural and functional analysis of SERPINA1 gene transcripts and alpha1-antitrypsin protein isoforms in human tumors cultured cell lines”).

Targeting the Notch1 Transcriptional Activation Domain in T-Cell Acute Lymphoblastic Leukemia.
K.A. Sottriva, L. Shao, K. Pajcini; 1Pharmacology, University of Illinois at Chicago, Chicago, IL

Notch signaling is an evolutionary conserved pathway which allows for communication between neighboring cells. Notch1, one of 4 mammalian Notch receptors, is required for commitment of thymic progenitors to the T-cell fate and has been implicated in T-Cell Acute Lymphoblastic Leukemia (T-ALL). In fact, over 50% of adult T-ALL patients have tumors in which the Notch1 gene has obtained a hypermorphic mutation, and treating human Notch1 addicted T-ALL cell lines with Notch pathway inhibitor Gamma-Secretase Inhibitors (GSI) in vitro leads to growth arrest and apoptosis. The intracellular fragment of Notch1 (ICN) is composed of several domains, one of which is the Transcriptional Activation Domain (TAD). TAD deleted ICN (ICNΔTAD) interferes with signaling from wild type ICN in mice heterozygous for the mutation, resulting in blunted transcriptional activity. There is also evidence that the TAD is involved in T-ALL progression. Bone marrow transplant (BMT) assays have shown that ICN lacking its C terminal portion, thus lacking the TAD, fail to initiate leukemia. Based on this finding, we will target the Notch1 Transcriptional Activation Domain in an effort to uncover a novel method of modulating Notch1 signaling in human T-ALL.

Investigating the Role of PA28y in DNA Base Excision Repair.
B.E. Bundrant, C. Calhoun, L.F. Barton; 1Biology, Austin College, Sherman, TX

Increased levels of reactive oxygen species (ROS) are present in almost all cancers. Since increased levels of ROS can cause serious damage to both DNA and proteins, understanding how cancer cells sustain their altered biology could identify ways to selectively target transformed cells. DNA base excision repair (BER) is the primary pathway responsible for the repair of DNA damaged through oxidation. Oxidative damage to DNA generally induces small base lesions, which if left unresolved, can result in transversion and transition mutations. Disruption of the BER pathway is linked to a variety of cancers, including colorectal, gastric, and lung. The proteasome activator, PA28y, has been previously demonstrated to play an important role in the cellular response to oxidative stress through its degradation of oxidatively-damaged proteins. Moreover, expression of PA28y protein is elevated in many cancers and increases in response to treatment with hydrogen peroxide, an ROS. Here, we identify a novel role for PA28y in the repair of oxidative damage in the DNA. Murine embryonic fibroblasts (MEFs) deficient in PA28y have higher baseline levels of oxidative DNA damage. Additionally, PA28y-deficient MEFs exhibited delays in DNA repair after treatment with hydrogen peroxide. Expression of Proliferating Cell Nuclear Antigen (PCNA), a protein important to base excision repair, was compared between the two cell lines since PA28y has been characterized as an indirect activator of PCNA. Baseline PCNA expression was comparable in PA28y-deficient MEFs, however in response to hydrogen peroxide treatment, PA28y-deficient MEFs exhibited no increase in PCNA expression. Conversely, a six-fold increase in PCNA expression was observed in wild type MEFs, suggesting that PA28y is essential for expression of one of the key proteins induced as part of the cell’s DNA damage response. The inability of PA28y-deficient MEFs to induce a key excision repair protein could suggest a possible mechanism for the difference

Sunday-167
in repair kinetics observed between the two cell lines. Our data reveal an expanded role for PA28γ in the cellular response to oxidative damage, playing an important role in the repair of damaged DNA as well as the degradation of damaged proteins.

The NF45-NF90 complex is required for execution of the mitotic programme and chromosome stability.
S. Nourreddine1, G. Lavoie1, J. Paradis1, K. Ben El Kadhi1, P. Gendron1, S. Carreno1, M. Bouvier1, P.P. Roux1;
1Department of Pathology and Cell Biology, IRIC, University of Montreal, Montreal, QC

ILF2 and ILF3 are essential genes that are upregulated in several types of neoplasms, yet their exact function remains elusive. These genes encode nuclear factor 45 and 90 (NF45 and NF90), which are RNA-binding proteins involved in mRNA processing and translation. Here we show that NF45 and NF90 form a complex that regulates the expression of many mitotic proteins involved in chromosome stability. Depletion of NF45 or NF90 induces pleiotropic cell-cycle defects, including chromosome mis-segregation and frequent failure of cytokinesis, leading to polyploidy or mitotic catastrophe. Cells depleted in NF45 or NF90 fail to synchronize in mitosis in response to spindle poisons, suggesting defects in mitotic spindle checkpoint. Transcriptome analysis revealed that NF45 and NF90 are necessary for the expression of a cluster of mitotic mRNAs, which also associate with the NF45-NF90 complex. Cancer genomics databases indicate that ILF2 and ILF3 are upregulated in breast cancer, and that their expression tightly correlates with the mitotic cluster. Thus, our data uncover post-transcriptional events regulated by the NF45-NF90 complex that are essential for proper mitotic progression and may be particularly relevant in cancer.

The potential prognostic marker BaxΔ2 is generated without mutation at a genetic or transcriptional level.
A.S. Davis1, A. Mañas1, J. Li1, J. Xiang1;
1Biology, Illinois Institute of Technology, Chicago, IL

Proapoptotic BaxΔ2 was originally discovered in colon cancer with high microsatellite instability. BaxΔ2 is a more potent isoform of Bax whose expression was thought to require a mononucleotide deletion (G8 to G7) in the Bax microsatellite region in combination with an alternative splicing event. Interestingly, we have recently found that most BaxΔ2 positive cells were found in healthy tissues and low-grade tumors. After analyzing 50 samples of both normal and tumor tissues for genomic sequencing, we found that the vast majority of the BaxΔ2 positive samples had no microsatellite mutations. One possible explanation was a G7 mutation at the mRNA level, which could happen through transcriptional slippage. To test this, we screened mRNA transcripts from both normal and colon cancer cells. Surprisingly, we found that even though the necessary alternative splicing event is fairly common, point mutations were rarely detected. Our ongoing work involves testing the hypothesis involving Programmed Ribosomal Frameshift, a mechanism by which a ribosome can intentionally skip bases and continue protein expression at a different reading frame (see Manas poster). These results indicate that BaxΔ2 can be generated without mutations at either the genomic or transcriptional levels, and possibly serve as a prognostic marker for cancer therapy.

**Ribosomal frameshift-mediated expression of BaxΔ2 in human tissues and its correlation with cancer stage.**  
A. Mañas1, A.S. Davis1, H. Zhang1, J. Xiang1;  
1Biology, Illinois Institute of Technology, Chicago, IL

BaxΔ2 is a novel pro-apoptotic Bax isoform previously identified in patients with microsatellite instability, especially in HNPC (hereditary nonpolyposis colorectal cancer). As many other cancers are prone to microsatellite mutations, we screened BaxΔ2 expression in nearly a thousand TMA samples covering tumors from a variety of organs, normal adjacent tissues, and normal healthy tissues. We found that, unlike ubiquitous distribution of Baxα, BaxΔ2 is mainly scattered in connective and epithelial tissue, and its expression inversely correlates with tumor grade, being very low or negative in high-grade tumors. Interestingly, a predominant amount of BaxΔ2 was found in normal and normal adjacent tissues. It is well established that production of BaxΔ2 requires an alternative splicing event and a guanine deletion in the microsatellite region. However, we found that the great majority of BaxΔ2-positive tissue/cells contain no microsatellite mutation at either genomic or transcript levels. When the correct alternative splicing event happens in the absence of the microsatellite mutation, it leads to an early stop codon unless a frameshift occurs. Therefore, we propose an expression mechanism involving Programed Ribosomal Frameshift (PRF). PRF is a phenomenon by which a ribosome can purposely skip one or more bases, either backwards (⁻) or forward (+), and continue protein expression at a different reading frame. To test this, we generated a double tagged construct at the N- and the C-termini of BaxΔ2 with no mutation. Only if a +1 PRF event happens will both the N- and C- tags be expressed. We found that, though rare, +1 PRF does happen and leads to expression of BaxΔ2 from constructs with no microsatellite mutation. In conclusion, production of BaxΔ2 can occur without genetic mutation and its expression could serve as a prognostic biomarker.

**Nedd9 influences lung cancer tumorigenesis through regulation of autophagy.**  
A.Y. Deneka1-2, M.C. Kopp3, A.S. Nikonova3, L. Haber1, A. Gaponova1, A. Nagele3, H. Hensley1, E.A. Golemis1;  
1Molecular Therapeutics, Fox Chase Cancer Center, Philadelphia, PA, 2Biochemistry, Kazan Federal University, Kazan, Russia, 3Pulmonary, Allergy and Critical Care, University of Pennsylvania, Philadelphia, PA

Non-small cell lung cancer (NSCLC) has a low survival rate, with metastasis contributing to the vast majority of deaths. Expression of the NEDD9 (HEF1/Cas-L) protein is elevated and promotes metastasis in a large subset of NSCLC tumors and other malignancies. NEDD9 functions as a scaffold for multiple critical effectors in integrin/FAK/SRC and receptor tyrosine kinase signaling cascades, with overexpression enhancing signaling by these pro-oncogenic proteins. However, we found that a Nedd9 constitutive null genotype (Nedd9⁻⁻) enhanced tumor growth in an inducible 129S/Sv-Krastm3Tyj/Trp53tm1Brn (KP) model in which Kras mutation is induced specifically in lung tissue by inhalation of adenovirus bearing the Cre gene. Pathological examination of tissues indicated Nedd9 null genotype also was associated with higher invasive capacity in vivo, including direct invasion to the heart, as well as elevated proliferation rate, decreased apoptotic activity, and changes in the expression of
proteins such as vimentin, associated with mesenchymal status. These results contradicted previous studies in which depletion of NEDD9 by RNAi reduced the growth and invasion of established lung cell lines and tumors, based on cell culture and xenograft assays. To gain insight into these paradoxical results, we performed Reverse Phase Protein Array (RPPA) analysis to characterize signaling in isolated tumors. This revealed numerous tumor-intrinsic changes associated with a Nedd9-/- genotype, affecting GYS1 and other proteins in the glycosgen synthesis metabolic pathway, and including notable upregulation of BECLN1 and ATG3, indicative of elevated autophagy. Subsequent in vitro analysis coupled with immunohistopathological and metabolic analysis of tumor tissue and tumor-derived cells confirmed and extended these results. Overall, our data support a model in which NEDD9 provides critical support for early stages of NSCLC growth, and progression beyond this early stage in the absence of NEDD9 requires extensive metabolic reprogramming. This reprogramming includes upregulation of the AMPK signaling axis and inhibition of the mTOR pathway, resulting in activation of autophagy responses and changes in oxidative phosphorylation and metabolism. Our data for the first time identifies NEDD9 as a regulator of these processes, and emphasizes distinct requirements for NEDD9 in early tumorigenesis versus in established tumors.

Survivin governs mitochondrial architecture by regulating phosphatidylethanolamine (PE) availability.
S.P. Wheatley, A.R. Townley, L. Dunajova, D. McLean; 1School of Life Sciences, University of Nottingham, Nottingham, United Kingdom

Survivin is an essential protein with established roles in mitosis and the inhibition of cell death. It is overexpressed in all cancers and its abundance correlates with tumour resistance to irradiation (IR). In normal cells, survivin expression is confined to the G2 and M phases; however, in cancer cells it is also present during interphase when it can be found in the nucleus, the cytosol and the mitochondria. PE is a phospholipid with a small head-group that facilitates negative curvature of membranes, thereby increasing their accommodation of proteins; thus it is enriched in specific membranes, such as the mitochondrial cristae and the cytokinetic furrow. Here we report the remarkable discovery that mitochondrial survivin regulates phosphatidylserine decarboxylase (PSD) the enzyme that converts phosphatidylserine (PS) to PE, the exclusive source of PE in the mitochondria. Our data suggest that by controlling PSD thereby governing mitochondrial topology and potentially altering cellular metabolism, as well as sensitivity to IR. This novel molecular insight suggests that many of the apparently disparate roles of this “multitasking” protein may be fundamentally linked to membrane architecture, and offers a completely unexpected perspective on its contribution to cancer and other metabolic disorders.

Increased Rac activity is required for Ha-RasV12-induced multilayer cellular aggregates in Madin-Darby canine kidney cells.
M. Tang, C. Han; 1Physiology, National Cheng Kung Univeristy, Tainan, Taiwan

Ha-RasV12 overexpression induced multilayer cellular aggregates during confluence in MK4 cells (inducible Ras harboring MDCK cells). Because activation of Yes-associated protein (YAP) induced cellular transformation, epithelial-mesenchymal transition (EMT) and loss of contact inhibition, we examined
whether the activation of YAP mediated Ha-RasV12 induced-multilayer cellular aggregates. We found that Induction of Ha-RasV12 triggered YAP nuclear translocation and subsequently YAP-targeted gene expression. However, verteporfin (VP), a YAP/TEAD binding inhibitor, failed to prevent Ha-RasV12-induced multilayer cellular aggregates. Overexpression of Cav1 inhibited Ha-RasV12-induced YAP activation and multicellular cell aggregates, whereas knockdown of Cav1 in MDCK cells only resulted in activation of YAP, but not cellular aggregates and cellular transformation. Activities of Rac and RhoA, both associated with cell extrusion, were increased in Ha-RasV12 overexpressed MK4 cells. EHT1864 (Rac inhibitor) abolished multilayer cellular aggregates in Ha-RasV12-overexpressed MK4 cells, whereas Y27632 (ROCK inhibitor) induced multilayer cellular aggregates in MK4 cells. However, neither EHT1864 nor Y27632 inhibited Ha- RasV12-induced YAP nuclear localization. Taken together, these data indicate that Cav-1 downregulation is required for Ha-Ras V12-induced YAP activation and cellular transformation. However, only Cav1 downregulation and Rac activation, but not YAP activation, are required for Ha-Ras V12-induced multilayer cellular aggregate.

The role of InHibitor of Growth (ING) 2 in Breast Cancer Treatment.
K.T. Riabowol¹, D.I. Udenwobe¹,², E. Kornaga³, X. Feng³,⁴, K. Tae-sun¹;
¹Biochemistry and molecular Biology, University of Calgary, Calgary, Canada, ²Biochemistry, University of Nigeria, Nsukka, Nigeria, ³Translational Research Laboratory, Tom Baker Cancer Centre, Calgary, Canada, ⁴Oncology, BC Cancer Agency-Vancouver Island Center, Victoria, Canada

Breast Cancer is the most frequent form of women's cancer, affecting 1 in 8 during their lifetime with >24,000 new cases in women and >200 diagnosed in men in Canada in 2017. Although curable if detected early, breast cancer still accounts for 13% of all cancer-related deaths in Canada, underscoring the need for additional accurate predictors of early breast cancer development. Our lab discovered the first ING gene (ING1) and found that it was inactivated in breast tumours and breast cancer cell lines. INGs contain a conserved PHD domain and ING PHD domain/H3K4me3 binding targets the ING2-mSin3A-HDAC1/2 complex to the nucleosome to mediate gene repression. We hypothesised that expression of ING2 in breast epithelial cells might serve as a harbinger of cellular transformation, and levels of ING2 may have clinical value. Our studies indicate that normal breast epithelial cells did not express detectable levels of ING2 while all breast cancer cell lines examined expressed significant levels of ING2. Over-expression of ING2 repressed the induction of ING1, but ING1 over-expression did not affect ING2 levels. Consistent with an oncogenic role, Her2+ breast cancer cells showed a considerably higher ING2 levels and a significant correlation between ING2 and Her2/Neu levels. Elevated levels of ING2 also correlated with an increased sensitivity of breast cancer cells to SAHA that is known to target ING2. Furthermore, higher levels of ING2 was noticed in triple negative breast cancer samples relative to normal breast epithelium. The expression of ING2 in breast cancer cells correlated with the association of Myeloid zinc finger 1 with the ING2 promoter. Our data suggest that ING2 out-competes ING1, reducing its tumour suppressive effect, to induce cellular transformation and might serve as a novel biomarker for breast cancer diagnosis.

To Understand the Structural Role of Pyruvate Kinase M2 in Epigenetic Mechanism.
K. Verma, A. Patel; 1Kusuma School of Biological Sciences, Indian Institute of Technology, Delhi, Delhi, India, 2Kusuma School of Biological sciences, Indian Institute of Technology, Delhi, Delhi, India

Cancer cells undergo metabolic reprogramming characterized by high glucose consumption and lactate production. This phenomenon of aberrant metabolism is known as aerobic glycolysis or the Warburg effect. Pyruvate Kinase, the terminal glycolytic enzyme is the master regulator of glycolytic flux and plays a pivotal role in regulating the cellular metabolism. Pyruvate Kinase M2 (PKM2) is an oncofetal isoform generated as a result of alternative splicing of the PKM mRNA transcript. It exhibits a low basal activity and thus diverts the glycolytic intermediates in the anabolic pathways for sustained cell proliferation conferring growth advantage to the cancer cells. Recently the non-glycolytic or nuclear function of PKM2 has come into prime focus. PKM2 exacerbates cancer progression by exerting its role as a key nuclear protein kinase phosphorylating plethora of nuclear proteins. On oncogenic/mitogenic stimulation dimeric PKM2 undergoes nuclear translocation wherein it binds to the promoter regions of oncoproteins and initiates an array of epigenetic modifications. Studies have reported that the nuclear PKM2 modulate the gene expression by phosphorylating Histone H3 of the nucleosome complex that ensues a cascade of epigenetic changes. However the structural details and the mechanistic regulation of this interaction is still elusive. In our study we have tried to gain a structural insight of the PKM2 interaction with the nucleosome and Histone H3. Fluorimetry experiments and Surface Plasma Resonance (SPR) results reveal a direct interaction of PKM2 with the Histone H3. Electrophoretic mobility shift assay using non—denaturing polyacrylamide gel suggest that PKM2 interacts with the reconstituted FAM-labelled nucleosome. Thus, our results establish that PKM2 directly binds to the nucleosome. We aim to decipher the architecture of the PKM2-nucleosome complex using X-ray crystallography and cryo-electron microscopy. Structural intricacies of the PKM2 with nuclear proteins or nucleosome may help us to understand the mechanism of PKM2 mediated epigenetic changes. Furthermore this study will indirectly help us decipher the PKM2 driven oncogenicity as well as possible targets or pathways of cancer in context with the cancer cell metabolism.

Wnt/β-catenin signaling, genomic instability and DNA break formation in hematopoietic cells: Role of Topoisomerase IIα.
M.F. Vargas¹, G.D. Ugarte¹, D.A. Verdugo¹, M.E. Lemus¹, B.I. Bustos¹, G.V. De Ferrari¹;

Wnt/β-catenin signaling has an essential function in hematopoiesis and deregulation of its activity is a key factor in the development of leukemia. Here we studied Wnt/β-catenin signaling on genomic instability and DNA strand break formation and examined β-catenin interaction with topoisomerase IIα (Topo IIα), as this enzyme plays an important role in cleavage and re-ligation of double-stranded DNA during replication, transcription and DNA damage repair. Using single cell electrophoresis (Comet assays) and γ-H2AX immunofluorescence staining, we observed a significant dose-dependent increase in DNA breaks in KG-1 human hematopoietic cells treated with CHIR (98014), a specific Wnt/β-catenin signaling pharmacological activator. Treatment of cells with the drug induced the co-localization between β-catenin with γ-H2AX foci and also between β-catenin with Topo IIα. Interestingly, activation of the signaling cascade enhanced γ-H2AX co-localization with Topo IIα protein. We finally confirmed the interaction of β-catenin with Topo IIα by co-immunoprecipitation experiments. Our results suggest that sustained transcriptional stress induced by the signaling cascade is responsible for genomic instability and DNA strand break formation in hematopoietic cells and as such may participate during malignant transformation to leukemia.

**Characterization of the Interferon Regulatory Factor 4 Pathway in Melanoma Cells.**

U. Sobhiafshar¹, N. Yildiz¹, A.B. Tufan¹, E. Yilmaz¹, M.C. Ayhan³, C. Yerinde³, E.E. Erkan¹, N. Emre¹;

¹Laboratory of Genome Regulation, Department of Molecular Biology and Genetics, Boğaziçi University, Istanbul, Turkey

Melanoma skin cancers have poor prognosis at the metastatic stage despite recent advances in targeted therapies and immunotherapy. Therefore, identification of novel pathways and therapy targets is highly desirable. Like most cancers, abnormal gene regulatory and epigenetic mechanisms are also linked to melanomas.

Interferon regulatory factor 4 (IRF4) is a transcriptional regulator with crucial roles in the development and functioning of immune cells, and is implicated in malignant transformation. We have previously demonstrated the critical role of IRF4 in mature B-cell-derived cancer cells, and unraveled its mechanisms of action. These and related other studies, therefore, highlighted IRF4 pathways as therapy targets in cancer. Beyond immune cells, genetic association studies linked variation at the IRF4 locus with pigmentation phenotypes and skin cancers. Recent work also identified the role of IRF4 in the pigmentation process of normal melanocytes. However, despite the observed genetic associations and expression, the role of IRF4 in melanoma remains largely unexplored.

Therefore, we set out to characterize the functions of IRF4 in melanoma cells using cell and molecular biological, and genome-wide approaches. In order to identify the genome-wide targets of IRF4 in melanoma cell lines, we have performed chromatin immunopreipitation sequencing (ChIP-seq) and transcriptomic (RNA-seq) assays, and analyzed them integratively. Complemented with The Cancer Genome Atlas (TCGA) data analyses, our data point to a role of IRF4 in epigenetic regulation of melanoma cells, among other cancer- and development-related pathways. In parallel studies, we have taken a candidate approach to identify the upstream regulators of IRF4 expression in melanoma cells. Here, our results uncover a known melanoma master transcription factor and a major signaling pathway with therapeutic targeting options as upstream regulators of IRF4 expression. Furthermore, our preliminary cell biological studies implicate IRF4 as a critical factor in melanoma cell proliferation and survival.

Taken together, our work on IRF4 is mechanistically complementing at the cellular and molecular level the published genetic studies on melanoma patient samples, delineating this novel pathway in melanoma cells, and therefore will potentially be pointing to new therapy strategies in melanoma.

**HPV16 E6 and E7 Oncoproteins are Negative Regulators of Invadopodia Activity but Promote Migration in Head and Neck Squamous Cell Carcinoma.**

C.N. Kahue¹, R.J. Jerrell¹, A. Parekh¹,²,³,⁴;

¹Department of Otolaryngology, Vanderbilt University Medical Center, Nashville, TN, ²Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, TN, ³Department of Biomedical Engineering, Vanderbilt University Medical Center, Nashville, TN, ⁴Department of Cancer Biology, Vanderbilt University Medical Center, Nashville, TN

Human papilloma virus (HPV)-positive head and neck squamous cell carcinomas (HNSCC) are frequently diagnosed at low tumor stages but with positive nodal metastatic disease in contrast to HPV-negative tumors of the same region. The mechanisms that regulate tumor progression of HPV-positive head and
neck cancers are poorly understood. The ability to degrade the extracellular matrix (ECM) is thought to be necessary for the spread of tumor cells. Invadopodia are actin-rich cellular protrusions that facilitate extracellular matrix (ECM) degradation and have been implicated in tumor cell invasion and metastasis in HPV-negative HNSCCs. Thus, we sought to compare the invasive phenotypes of HPV-negative and positive head and neck cancer cell lines in vitro. Using a panel of HPV-negative and HPV-positive cell lines, we found that in general, the HPV-negative cells exhibited more invadopodia activity. Selecting one representative cell line from each group, we found specifically that both invadopodia numbers and ECM degradation are significantly increased in HPV-negative SCC-25 cells compared to HPV-positive SCC-47 cells. To determine if this difference was dependent on HPV status, the HPV-specific oncoproteins E6 and E7 were overexpressed (OE) and knocked down (KD) with lentiviral particles in SCC-25 and SCC-47 cells, respectively. A reversal of results was noted with a significant decrease in invadopodia formation and degradation area in SCC-25 OE cells and vice versa in SCC-47 KD cells. Given these differences in invasiveness, transwell migration assays were used to assess migration patterns as a potential etiology for early metastasis. Increased migration was observed in the SCC-47 cells compared to the SCC-25 cells; however, SCC-47 KD cells migrated less than SCC-47 control cells. Thus, despite the clinical findings that HPV-positive HNSCCs metastasize early, our data suggest that tumor progression occurs through an alternative mechanism that is not dependent on invadopodia-mediated degradation of ECM but instead favors increased cell migration.

Oncocytomas are benign tumors of epithelial origin. To determine origin of tumor formation we sequenced benign oncocytomas, which revealed two subtypes and pathogenic mitochondrial mutations in electron transport chain (ETC) as a common factor in the two subtypes (Joshi et al., 2015). Therefore, we aimed to determine if pathogenic mitochondrial ETC mutations are 1) the driver mutations in these tumors; 2) responsible for limiting tumorigenesis. Metabolomics of human renal oncocytomas showed modest increase in levels of (S)-2-hydroxyglutarate (2HG), an oncometabolite implicated in epigenetics regulation. Oncocytomas showed higher GSSG/GSH ratio when compared to normal kidney tissue, suggesting oxidative stress in these tumors. Oncocytoma primary cells were observed to be highly glycolytic. They used glutamine to generate αKG and citrate via reductive carboxylation, and produced 2-HG at elevated levels. Epigenome sequencing of the patient samples is underway to identify epigenetic changes, which might be responsible for the tumor initiation. To check the effect of ETC impairment in tumorigenesis, ETC was genetically impaired by CRISPR knock out of complex II subunit, SDHB in \textit{Kras}\textsuperscript{G12D}, \textit{p53}\textsuperscript{7/} driven mouse lung cancer cell line or chemically inhibited by using complex I inhibitor in \textit{Kras}\textsuperscript{G12D}, \textit{p53}\textsuperscript{7/} driven lung tumor mouse model. The deletion of SDHB significantly reduced the growth of cancer cells both in vitro and in an allograft mouse model by induction of ROS mediated DNA damage and G2-M growth arrest. The growth of the SDHB knock out cancer cells was partially rescued by the treatment with ROS scavenger, N-acetyl cysteine. The chemical inhibition of complex I
increased the mice survival rate by reducing the lung tumor burden and producing fibrotic, slow growing tumors. Our studies suggest that ETC pathogenic mutations may initiate tumors by oxidative stress and epigenetic regulations but ETC functions are preserved in aggressive tumors for growth.

Tissue explant imaging reveals spatially coordinated migration patterns in the tumor core.  
R. Staneva¹, F. El Marjou¹, A.G. Clark¹, D. Matic Vignjevic¹;  
¹Institut Curie, Paris, France

Invasion of cancer cells into the stroma is a critical step in the malignant progression of carcinoma and can lead to metastasis. Cancer cell invasion is associated with an increased migratory capacity of cells leading to their dissemination to distant tissues. Until now, cancer cell migration has been described at the so-called “invasive front”, the region where cancer cells reach stromal tissue. The core of tumors has been considered as a relatively immobile tissue. However, due to the lack of technology required to image the tumor core in real time, this has never been directly addressed. In order to investigate cancer cell dynamics in a native tumor core, we use a mouse model which gives rise to spontaneous aggressive intestinal carcinoma. We explore cell migration phenotypes in tumor explants using ex vivo long-term 3D imaging by two-photon microscopy. We find that cancer cells in the tumor core are not stationary, as previously thought, but are rather remarkably dynamic and migrate with a range of cell speeds and persistence. Moreover, we observe a correlation between migration direction and distance between cells, where cells close together have a correlated direction of migration and move in local "currents". Such collective behaviors of neighboring cells give rise to large-scale tissue dynamics, such as collective streaming and vortex-like migration features. Although cells exhibit stop-and-start migration patterns with intermittent pauses, we do not observe any substantial cell pausing during division. This suggests that dividing cells in cancer tissues can still flow with their neighbors during division. This study represents the first investigation of the live dynamics of cells in the tumor core of spontaneously developing tumors. Our work will help understand collective behaviors of cells in the tumor core and sheds light on cancer migration as well as other dynamics systems, such as developing organisms.

A novel window for high resolution imaging of the lung reveals mechanisms of metastatic breast cancer progression.  
L. Borriello¹,², S. Voiculescu³, Y. Wang¹,²,⁴, M.H. Oktay¹,⁴,⁵, J.S. Condeelis¹,²,⁴, D. Entenberg¹,²,⁴;  
¹Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ²Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ³Department of Surgery, Albert Einstein College of Medicine, Bronx, NY, ⁴Integrated Imaging Program, Albert Einstein College of Medicine, Bronx, NY, ⁵Department of Pathology, Albert Einstein College of Medicine, Bronx, NY

It has become clear that the tumor microenvironment dominates the metastatic phenotype of tumor cells. In addition, the cell biology mechanism behind tumor cell dissemination from the primary tumor is becoming well understood thanks to high resolution multiphoton intravital imaging. Imaging shows that therapeutic agents, including cytotoxic chemotherapy and receptor tyrosine kinase inhibitors, have the ability to alter this microenvironment to either promote or reduce metastatic dissemination from the
primary tumor. Unknown however, is if the mechanism of tumor cell dissemination from the primary tumor is conserved in metastatic tumors and if the above treatments impact the metastatic site differently from the primary tumor, essential information for the design of long term treatment strategies. Each of the major metastatic sites (bone, lung, and liver) are inaccessible internal organs limiting analysis to standard assays (FACS, histopathology, etc.) which destroy the tissue and thus only give single time point, snap-shot analyses without vital information about the tumor microenvironment. Only intravital imaging through implantable imaging windows gives the ability to return to the tissue multiple times over course of disease progression and treatment. The lung, the central metastatic site in breast cancer patients, is the most difficult organ to study using intravital microscopy due to its perpetual motion. Recent advances in intravital microscopy have enabled visualization of the live intact lung, but are limited in time over which they can be utilized (hours) and require major, invasive surgeries. Both of these limitations reduce their usefulness to the study of single cell events in the lung and are susceptible to introducing artifacts. We have addressed these limitations by developing an implantable, permanent, lung imaging window which allows high-resolution multiphoton imaging of the intact, breathing (without ventilation), murine lung over days to weeks of repeated imaging. This window does not use vacuum to immobilize the lung tissue, thereby avoiding artifacts associated with vacuum lung windows. Using our new window, we have documented over weeks, and for the first time, tumor cell arrival, the cell motility steps used during extravasation, tumor cell survival, dormancy, and progression to micro-metastases, all at subcellular resolution. Further, we have observed, for the first time, the presence and intravasation activity of the Tumor MicroEnvironment of Metastasis (TMEM) in metastatic lung lesions directly demonstrating use of the same mechanism of tumor cell dissemination from metastatic lung tumors as observed in the primary tumor opening new strategies for the treatment of metastatic tumors to prevent metastatic progression and death.

Metastasis is the main cause of mortality and morbidity in cancer patients, because it spreads beyond the site of origin, leading to damage in distant organs and tissues. Key steps of the metastatic cascade involve intravasation and extravasation, where single tumor cells from the primary tumor intravasate into the bloodstream and extravasate into the stroma of secondary organs to form metastatic colonies. Previously, we have shown that inhibiting cancer cell extravasation is a realistic target for halting cancer metastasis when invadopodia function is inhibited. We have also recently determined that extravasating cancer cells release extracellular vesicles (EVs) in vivo. Using intravital imaging, we determine that cancer cell EV release leads to significant cell volume loss and a reduction in metastatic potential. Cell membrane blebbing is the main cellular mechanism of EV generation and release. Since cell death pathways such as apoptosis and necroptosis also induce membrane blebbing and release EVs, we hypothesized that modulating these cell death pathways leads to cell volume reduction and inhibition of cell extravasation.

Various metastatic cancer cell lines were cultured and injected into the chorioallantoic membrane (CAM) of chicken embryos for imaging and quantifying circulating EVs. Staurosporine (STS) and dimethyl fumarate (DMF) were used to induce cancer cell apoptosis and necroptosis respectively. We performed
intravital imaging of cancer cell EV release, extravasation, and metastatic colony formation by high-resolution confocal microscopy. To quantitate EVs, we used nanoscale flow cytometry to analyze blood samples from the CAMs and conditioned media. We observed an increase in circulating EVs and reduced extravasation and metastatic colony formation rates when membrane blebbing was modulated. Although pro-apoptotic cancer cells exhibited an increase in cancer cell EV release that resulted in reduced extravasation rates, extravasating cancer cells did not exhibit caspase-3 activity during EV release, indicating that apoptosis is not involved in EV generation. Pro-necrotic cancer cells also exhibited an increase in cancer EV release. This was accompanied by cell volume reduction and a decrease in cancer cell extravasation and metastatic colony formation rates. Moreover, inhibition of necroptosis significantly reduced EV release, improving extravasation and metastatic colony formation rates.

Overall, our findings suggest that a reduction in cell volume by EV release facilitates extravasation but excessive release is counterproductive. Additionally, our findings on the inhibition of necroptosis and the pro-necrotic process implicate that necroptosis is a more critical regulator of cancer metastasis.

Distinct ECM proteins of breast cancer metastatic niches in multiple organs.

J.D. Hebert¹, S.A. Myers², A. Naba¹, K.R. Clauser³, S.A. Carr², R.O. Hynes¹;
¹Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA,
²Proteomics Platform, Broad Institute of MIT and Harvard, Cambridge, MA

Metastasis remains the cause of the vast majority of cancer-related deaths, and one of the most insidious aspects of metastatic cancer is the incredible adaptability of cells from a single primary tumor to survive in multiple, vastly different secondary sites. Nevertheless, how cells from the same primary tumor are able to adapt to all these environments is not fully understood. At each secondary site of metastasis, tumor cells create a metastatic niche, a microenvironment conducive to their survival and proliferation. A critical component of each niche is the extracellular matrix (ECM), which provides structural support, migration control, and growth and survival signals. However, a comprehensive comparison of the ECM components of metastatic niches at various secondary tumor sites has not yet been conducted. We isolated metastases from the bone marrow, brain, liver and lung, which were all derived from a common population of MDA-MB-231 breast cancer cells. We then enriched these tumor samples for ECM proteins and used quantitative mass spectrometry to analyze their ECM composition. Across all samples, 247 ECM and ECM-associated proteins were identified, of which 44 were exclusively produced by the human tumor cells and 142 were made solely by the murine stroma. Strikingly, both the tumor-derived and the induced stroma-derived ECM and ECM-associated proteins differ at each site; that is, the niches created are distinct. By abundance, most of the proteins produced only by tumor cells were secreted factors, while the proteins made only by stromal cells were mostly ECM glycoproteins. The set of proteins produced by both the tumor and stromal cells consisted mainly of collagens. Overall, greater than 90% of the total ECM protein abundance within metastases originated from stromal cells. Using these data, protein abundance was compared across all metastatic sites in order to determine which ECM proteins were most significantly elevated in each particular tissue relative to the others. By comparing all metastatic to all normal samples, proteins that were broadly elevated across all metastatic tissues were also identified. Following this analysis, ongoing work is focused on a set of ECM proteins produced by tumor cells specifically in metastases to the brain, testing whether the metastasis of MDA-MB-231 cells to the brain is dependent on the expression of these proteins by injecting knockdown cells into circulation and observing their resulting metastatic growth and tropism. This investigation will
provide insight into the fundamental biology of metastatic niches, as well as provide potential markers of metastatic breast cancer at various sites for imaging and therapy.

Liver metastasis is facilitated by the adherence of circulating tumor cells to vascular fibronectin deposits.
J. Barbazan1,2, L. Alonso-Alconada3, N. Elkhatif3, S. Geraldo3, B. Gurchenkov3, A. Glentis2, G. van Nie1, R. Palmulli1, B. Fernandez3, P. Viaño4, T. Garcia-Caballero5, R. Lopez-Lopez1, M. Abal1, D. Matic Vignjevic2; 1Translational Medical Oncology, Health Research Institute of Santiago (IDIS), Santiago de Compostela, Spain, 2UMR144, Institut Curie, Paris, France, 3Department of Pathology, Complexo Hospitalario Universitario de Santiago de Compostela/SERGAS, Santiago de Compostela, Spain, 4CHUS, Health Research Institute of Santiago (IDIS), Santiago de Compostela, Spain, 5Department of Morphological Sciences, University of Santiago de Compostela, Santiago de Compostela, Spain

The interaction between circulating tumor cells (CTC) and endothelial cells during extravasation is a critical process during metastatic colonization, but its mechanisms remain poorly characterized. Here we report that the luminal side of liver blood vessels contains fibronectin deposits that are enriched in mice bearing primary tumors and are also present in vessels from human livers affected with metastases. Cancer cells attached to endothelial fibronectin deposits via talin1, a major component of focal adhesions. Talin1 depletion impaired cancer cell adhesion to the endothelium and transendothelial migration, resulting in reduced liver metastasis formation in vivo. Talin1 expression levels in patient CTC’s correlated with prognosis and therapy response. Together, our findings uncover a new mechanism for liver metastasis formation involving an active contribution of hepatic vascular fibronectin and talin1 in cancer cells.

3D collagen fiber architecture regulates cell migration phenotypes by modulating MMP activity.
D. Ortiz Velez1, S.I. Fraley1,2; 1Bioengineering, University of California San Diego, La Jolla, CA, 2Moore's Cancer Center, University of California San Diego, La Jolla, CA

Cancer cells interact closely with the extracellular matrix (ECM), and defined collagen ECM architectures have been correlated with metastatic potential in vivo. However, the role of local ECM structure on the regulation of metastatic motility phenotypes is not completely understood. In previous studies, we identified a confining collagen architecture characterized by short, thin fibers and small pores that triggers a conserved metastatic migration phenotype and transcriptional response independently of matrix stiffness and density. To further explore the role of this confining architecture on the development of an invasive motility phenotype, we sought to characterize the coordination of the four key biophysical processes used by cells to migrate through 3D environments: cell adhesion, actomyosin cytoskeleton polymerization and contraction, and protease mediated degradation of the surrounding ECM. These processes were quantified in HT-1080 fibrosarcoma cells using: i) fluorescence recovery after photobleaching (FRAP) to study actin polymerization dynamics in cellular protrusions labeled with LifeAct, ii) traction force microscopy (TFM) of matrix-embedded beads to study cell adhesion and contractility, and iii) fluorescent dye quenched (DQ) collagen degradation to study MMP activity. We observed that cells embedded in matrices with small pores and short fibers, produce smaller and shorter
lived protrusions as compared to cells embedded in a matrix with longer and thicker fibers. Actin FRAP studies revealed that this difference in protrusion lifetime was not caused by differences in actin polymerization rates. TFM and protrusion-ECM displacement correlation showed that in confining architectures, cells fail to properly bind and pull on the surrounding matrix. Rather, they displayed a chaotic probing phenotype, that suggests early breaking or degradation of the small fibers composing the matrix. Interestingly, DQ collagen degradation assays showed that cells in the confining architecture degrade the surrounding collagen significantly more than cells in the porous architecture. Preliminary results suggest that this increase in collagen degradation is accompanied by increased collagen internalization. Moreover, gene expression analysis using RNA sequencing showed that cells in the confining architectures upregulate uPARAP (MRC2), a mannose receptor protein implicated in the internalization of degraded collagen fragments. Taken together, our results suggest that the short fibers associated with confining 3D collagen architectures promote the upregulation of a collagen degradation and internalization pathway that could trigger downstream intracellular signaling cascades.

Role of Laminin Matrikines in Phenotypic Switching of Motile Cancer Cells.
L. Perrin¹, B. Gligorijevic¹;
¹Bioengineering, Temple University, Philadelphia, PA

Dissemination to distant organs and formation of metastatic outgrowth are the leading causes of cancer-related death. The metastatic process heavily relies on cancer cell motility and much effort has been made to decipher the physiologic mechanisms governing cell movement. Recently, increasing evidence has shown that different cues present in the tumor microenvironment may modify cell behavior. Homotypic interactions between cancer cells themselves, but also heterotypic interactions between cancer cells and stromal cells have been described in the context of cell fate. However, the dynamic role of the extracellular matrix on cancer cell decision-making came into the spotlight only recently. Studies show that the extracellular matrix continuously exchanges both mechanical and chemical signals with cancer cells. For instance, cancer cells pull on the extracellular matrix and use it as a structural support for migration. In addition, cancer cells remodel the extracellular matrix via degradation in order to invade into the healthy tissues, and intravasate into the blood vessels or nerves. Our previous work demonstrated that motile cancer cells which are entering perivascular niche within the primary tumor, switch their phenotype from migration to extracellular matrix degradation by invadopodia. Such degradation subsequently leads to intravasation and metastasis. In contrast, invadopodia inhibition prevents future metastasis.

Our working hypothesis is that the matrikines created by invadopodia have the capability of regulating the level of further degradation by acting as a phenotype switching triggers. Our preliminary data shows that soluble beta 1 laminin fragments, released by degradation of perivascular basement membrane, can inhibit further degradation by invadopodia. We are interested in mapping matrikines that may modulate cancer cell plasticity in each step of the metastatic cascade. Further, we believe that understanding their effects on the cancer cell behavior will be a powerful tool to develop new therapeutic treatments and prevent early metastasis.

Collective epithelial intravasation in breast cancer metastasis.
V.L. Silvestri¹, A. Wong³, P. Sears³, A.J. Ewald¹,²,⁴
¹Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Materials Science and Engineering, Johns Hopkins University, Baltimore, MD, ³Institute for Nanobiotechnology (INBT), Johns Hopkins University, Baltimore, MD, ⁴Sidney Kimmel Comprehensive Cancer Center, Johns Hopkins University, Baltimore, MD, ⁵Oncology, Johns Hopkins University School of Medicine, Baltimore, MD, ⁶Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD

A key goal in cancer research is to understand the underlying mechanisms of the metastatic process, by which cancer cells spread from a primary tumor to other sites and form secondary tumors. Indeed, metastasis is responsible for around 90% of cancer patient mortality. Despite its clinical importance, metastatic dissemination is an inefficient process. In experimental animal models, less than 0.02% of the single tumor cells leaving the primary tumor ultimately develop into metastatic lesions. Our lab has found that cells from primary tumors sometimes escape as clusters and that cell clusters are more efficient in forming lung metastases than single cancer cells.

We now focus on a key step of the metastatic process: intravasation. This process is facilitated by molecular changes that promote the ability of cancer cells to cross endothelial cell barriers that form the walls of microvessels. Previous studies have shown that tumor cell clusters are able to travel through pulmonary circulation in vivo. However, the mechanism by which tumor clusters gain access to the systemic circulation is still unknown. Our lack of understanding of this mechanism is due to the difficulties in establishing tumor models in which tumor-vessel interactions can be visualized and characterized. To overcome this barrier, we use a microfluidic approach with a physiologically and morphologically realistic vasculature along with 3D organotypic culture of mammary gland tumor organoids embedded in collagen-I gels. This approach allows us real-time and quantitative assessment of tumor-vessel interactions under in vivo like conditions. Preliminary evidence shows tumor organoids pushing through the tumor-vessel boundary resulting in the disruption of the vessel structure and function. We observed in real-time an intravasation event that preceded the disruption of a vessel. Our current work focuses on imaging optically cleared primary tumors to correlate the tumor-vessel structures observed in vivo with those observed in vitro. We anticipate that deeper understanding of the mechanisms of tumor cell cluster intravasation will provide new insights for targeted anti-metastatic treatments.

Cell-density dependent migration in pancreatic ductal adenocarcinoma.
M. Karl¹, H. Jayatilaka¹, D. Wirtz¹,²,³
¹Department of Chemical and Biomolecular Engineering, The Johns Hopkins University, Baltimore, MD, ²Johns Hopkins Physical Sciences - Oncology Center, The Johns Hopkins University, Baltimore, MD, ³Departments of Pathology and Oncology and Sydney Kimmel Comprehensive Cancer Center, The Johns Hopkins School of Medicine, Baltimore, MD

Pancreatic cancer is the 4th most common cause of cancer-related death in the United States with only 9% of patients diagnosed with pancreatic ductal adenocarcinoma (PDAC) living to the 5-year mark. Despite this, relatively few improvements have been made to the treatment of PDAC. Gemcitabine, a drug approved in 1996, is now being used in combination with nab-paclitaxel, a therapy that is one of
two standard first-line treatment options despite only having increased overall survival by two months. My objective is to dramatically improve overall survival and ultimately impact the current 5-year survival statistic by providing a novel combination therapy designed to treat both the solid tumor and inhibit the migration of cancer cells in patients with PDAC. Our lab has recently proven that cells display a migratory phenotype which only occurs when a high number of tumorigenic, metastatic cells are in a localized environment, such as would be found near a growing tumor. The cause behind this was determined to be paracrine signaling via a precise ratio of secreted interleukin 6 (IL-6) and interleukin 8 (IL-8). Cells exposed to these cytokines display enhanced invasion in comparison to cells that are not in an interleukin-rich environment or cells whose IL-6 and IL-8 receptors have been blocked. While this was shown in breast cancer, preliminary findings lead us to believe that this is also true in pancreatic cancer models. An in vitro 3D migration assay conducted with various metastatic PDAC cell lines seeded in collagen I shows that there is an increase in the mean square distance (MSD) of cells embedded in a high-cell-density environment when compared to low density. This migratory phenotype can be prevented with treatment of a combination therapy of Tocilizumab and Reparixin. Based on these results, we designed an in vivo experiment utilizing a patient-derived xenograft mouse model. The mice were randomly assigned to one of four treatment arms; saline (control), Gemcitabine, Tocilizumab + Reparixin, or Gemcitabine + Tocilizumab + Reparixin. We anticipate the results from the tumor volume and the analysis of the excised lung, liver and lymph nodes will show that the combination of Gemcitabine, Tocilizumab, and Reparixin has a synergistic effect on preventing tumor growth, as well as providing the best protection against metastases. In conclusion, because metastases are generally considered to be the cause of death in most PDAC patients, utilizing this novel combination therapy which targets both the growth and invasion of cancer cells has the potential to revolutionize treatment efficacy for PDAC patients.

**NHE1 overexpression disrupts organization of epithelial cell monolayers and accelerates collective cell migration.**

H.H. Jensen¹², G.A. Pedersen¹, J.J. Morgen¹², M. Parsons³, S.F. Pedersen⁴, L.N. Nejsum¹;
¹Department of Clinical Medicine, Aarhus University, Aarhus, Denmark, ²Department of Molecular Biology and Genetics, Aarhus University, Aarhus, Denmark, ³Randall Division of Cell and Molecular Biophysics, King’s College London, London, United Kingdom, ⁴Department of Biology, University of Copenhagen, Copenhagen, Denmark

Metastasis is the main cause of cancer patient mortality and substantially complicates treatment strategies. The Na⁺/H⁺ Exchanger 1 (NHE1) is upregulated in many cancers and plays a major role in cancer cell motility and thus metastasis. NHE1-mediated acid extrusion levered the increased intracellular acid production in cancer cells and contributes to the acidification of cancer tissue. Moreover, NHE1 recruitment to the front of migrating single cells promotes cell movement, in part by regulating intracellular and extracellular pH (pHᵢ, pHₓ). A number of studies have shown that collective cell migration is common in epithelial cancers, but how NHE1 affects organization and morphology of migrating epithelial cell collectives has not been investigated. To test this, NHE1-GFP was overexpressed in normal epithelial MDCK cells. NHE1 overexpression increased the steady state pHᵢ of MDCK cells from 7.17 to 7.41 and the H⁺ transport capacity after an acid load by 49%. During collective cell migration, NHE1-GFP localized in the leading edge of leader cells as well as migrating cells further back in the cell sheets. Overexpression of NHE1 alone significantly increased collective cell migration by 17%, and this effect was potentiated by stimulation with EGF and low serum concentrations. Within the migrating sheets, NHE1 overexpressing
cells were less organized, formed more migration fingers, and the cell spacing was increased. Combined NHE1 overexpression and EGF stimulation further decreased organization of cell monolayers and migration fingers. This difference was not reflected in detectably altered pH of migrating cells, underlining the importance of intracellular signaling for NHE1 in migration. In summary, we found that overexpression of NHE1 alone is sufficient to accelerate collective epithelial cell migration and disturb the organization of mammalian epithelial cells in migrating sheets. Live tracking of migrating MDCK cells overexpressing NHE1 can identify whether NHE1 can interfere with cell-cell coordination and regulation of directionality during migration.

Loss of MTSS1 results in increased metastatic potential in pancreatic cancer.
A.E. Zeleniak1,2, W. Huang2,3, M.K. Brinkman2,3, R. Hill2,3;
1Integrated Biomedical Sciences, University of Notre Dame, South Bend, IN, 2Harper Cancer Research Institute, South Bend, IN, 3Biological Sciences, University of Notre Dame, South Bend, IN

Pancreatic ductal adenocarcinoma (PDAC) has a 5-year survival rate of 7%. This dismal outlook is largely due to the inability to diagnose the disease before metastasis occurs. 53% of patients afflicted with pancreatic cancer are diagnosed at the metastatic stage. Thus, there is a critical need to better understand what causes early tumor cell dissemination and metastatic progression in this disease. One of the hallmarks of early stages of PDAC is inflammation. It is well known that patients with chronic pancreatitis have a much higher chance to develop PDAC. While many studies have focused on elucidating the mechanisms by which this inflammation drives PDAC progression, few have focused on the role inflammation plays in metastasis. Using a novel inflammation-driven mouse model of PDAC, we were able to uncover a subset of genes that were not only regulated by increased inflammation, but also correlated with poor PDAC patient prognosis. Here, we functionally test the role of one of the genes found in this subset that is involved in metastatic progression, namely, metastasis suppressor protein 1 (MTSS1). We show that loss of MTSS1 leads to increased invasion and migration in PDAC cell lines. Moreover, PDAC cells treated with cancer-associated fibroblast-conditioned media also have increased metastatic potential, which is augmented by loss of MTSS1. Additionally, overexpression of MTSS1 in PDAC cell lines leads to a loss of migratory potential in vitro and an increase in overall survival in vivo. Furthermore, we present a novel regulatory mechanism for the stabilization of MTSS1 via the tumor suppressor protein, phosphatase and tensin homolog (PTEN). Our data show that PTEN loss in PDAC cells results in both increased metastatic potential in vitro, and in a decrease in MTSS1 expression. Furthermore, we show that ectopic MTSS1 expression rescues this effect. Additionally, we demonstrate that PTEN forms a complex with MTSS1 in order to stabilize it from proteosomal degradation. Finally, we show that the inflammatory tumor microenvironment, which makes up over 90% of PDAC tumor bulk, is capable of downregulating PTEN expression, potentially uncovering a novel extrinsic, upstream mechanism of MTSS1 regulation. Collectively, these data offer new insight into not only the role and regulation of MTSS1 in suppressing tumor cell invasion and migration, but also a different glimpse as to what molecular mechanisms could be leading to early cell dissemination in PDAC.

CCL18 from tumor-associated macrophages promotes breast cancer metastasis via ACAP4-ARF6 signaling cascade.
X. Liu1, X. Yuan1, M. Mullen2, H. Green2, X. Ding1, X. Yao1,2;
1Cellular Dynamics, Anhui Key Laboratory for Cellular Dynamics Chemical Biology, Hefei, China, 2Keck Center for Molecular Imaging, Morehouse School of Medicine, Atlanta, GA

Tumor-associated macrophages influence cancer progression and metastasis. Our study showed that cytokine CCL18 derived from breast tumor-associated macrophages promotes breast cancer metastasis via PITPNM3 (Chen et al., 2011. Cancer Cell). However, the signaling cascade underlying CCL18-elicted breast cancer metastasis remains elusive. Here we show that CCL18 stimulates acetylation of ACAP4 which liberates ACAP4 from plasma membrane and release into the cytosol. Surprisingly, this acetylation tunes ACAP4 effector binding for elevation of ARF6 GTPase activity. Importantly, acetylation of ACAP4 promotes the invasion and metastasis of breast cancer xenografts, whereas suppressing PCAF abrogates these CCL18-elicted, ACAP4-mediated effects. These findings indicate that ACAP4 acetylation plays a critical role in CCL18-elicted breast cancer metastasis. Currently, we are studying CCL18-elicted cellular dynamics using a combination of human breast cancer organoids with spectral imaging.

Cellular localization of ER chaperones may predict cancer patient prognosis.
1Lawrence J. Ellison Institute for Transformative Medicine, University of Southern California, Los Angeles, CA, 2Radiology, Keck School of Medicine, University of Southern California, Los Angeles, CA, 3Radiology, Stanford University, Stanford, CA

Background: Anterior Gradient 2 (AGR2) is a member of the Protein Disulfide Isomerase (PDI) family which regulate protein homeostasis and the unfolded protein response (UPR) pathway. AGR2 has also been characterized as a proto-oncogene and a potential biomarker when secreted. We investigated the interplay between AGR2’s activity as an endoplasmic reticulum (ER) chaperone versus its role as a secreted protein in the context of cancer progression and response to therapy. Materials and Methods: In order to characterize the role of the ER resident versus secreted protein, we performed a comprehensive protein-protein interaction screen (BioID and AP-MS/MS) on distinct cellular compartments. Ingenuity Pathway Analysis (IPA) of the interaction screen was used to identify novel signaling axis. These findings were confirmed in vitro, in vivo, and with clinical cohorts from The Cancer Genome Atlas (TCGA). The prognostic significance of AGR2 expression and cellular localization on response to chemotherapy was assessed on metastatic prostate cancer tissue and circulating tumor cells (CTCs) Results: We identified over 800 proteins across three different cancer cell lines (FDR <0.01). Enrichment of pathways associated with the ER versus secreted AGR2 interactome highlighted differences in several cancer related pathways (angiogenesis, PI3/AKT, HIPPO). A combination of in vivo and in vitro assays confirmed that localization of AGR2 can either promote or inhibit pathway activity (e.g. Hippo pathway). For example, cancer cell spheroid formation was accelerated by dosing with recombinant AGR2 while overexpression of ER AGR2 inhibited this phenotype. The distinction between ER versus secreted AGR2 was most pronounced in various in vivo models that collectively confirmed the metastasis promoting phenotype of secreted AGR2. Importantly, TCGA and CTC expression data suggest
that increased ER AGR2 sensitizes cancer cells to chemotherapy while secreted AGR2 promoted resistance.

Conclusion: Taken together, our results identified opposing biological phenotypes predicated on AGR2 localization. The PDI activity of AGR2 seems to be most pronounced in the ER. Our findings also raise an interesting possibility for screening of secreted AGR2 as a means to guide therapy options.

Myoepithelial cells are a dynamic barrier to epithelial dissemination.
K. Sirka¹, E.R. Shamir¹, A.J. Ewald¹;
¹Cell Biology, Johns Hopkins University, Baltimore, MD

The normal mammary gland forms a branching ductal network, arranged in a bilayer: an inner luminal epithelial and an outer myoepithelial layer of cells. Most breast cancers arise in luminal cells and such luminal-derived tumors can generate life-threatening metastases. The first step of breast metastasis is tumor invasion past the myoepithelial layer; however, the role of myoepithelium during tumor progression and metastasis remains poorly understood. Hence, it is important to understand if myoepithelial cells play a functional role during cell invasion. To investigate behaviors at the single-cell level and in real-time, we used 3D culture of mouse mammary epithelial clusters, termed organoids. We have previously demonstrated that constitutive expression of the prometastatic transcription factor Twist1 in the murine mammary gland leads to cell dissemination. In the current study, we characterized the dissemination potential of specific mammary epithelial cell populations. Using time-lapse confocal microscopy, we observed that in the ubiquitous-Twist1 organoids, myoepithelial cells could actively limit the escape of luminal epithelial cells. To further study this potential role of myoepithelium in regulating cell dissemination, we generated mouse models in which myoepithelial or luminal cell-specific promoters drove Twist1 expression, while the remaining cells were Twist1-negative. In organoids with myoepithelial-specific Twist1 expression, there was cell-autonomous myoepithelial cell dissemination. Remarkably, in the organoids with luminal-specific Twist1 expression, we observed a major reduction in dissemination when compared to control organoids expressing Twist1 in both luminal and myoepithelial cell types (5 fold decrease in dissemination). To test the functional role of myoepithelial cells in controlling luminal cell dissemination, we combined Twist1+ luminal cells with varying numbers of normal Twist1- myoepithelial cells. The results showed that an increasing number of normal myoepithelial cells added to Twist1+ luminal cells acted to decrease dissemination. To elucidate the molecular mechanisms for this myoepithelial barrier function, we used lentivirally-delivered shRNA in luminal-specific Twist1+ organoids to knockdown expression of myoepithelial-specific contractility genes. Our results reveal that knockdown of α-smooth muscle actin in the luminal-Twist1 model markedly enhanced dissemination (3 fold increase). Collectively, our data showed that the normal myoepithelium acts as an active suppressor of luminal cell dissemination, and myoepithelial contraction is required for this function.

Emerin regulation of nuclear structure in cancer cell invasion.
P.G. White¹, K. Nee¹, J. Ellis¹, J.M. Holaska¹;
¹Pharmaceutical Sciences, University of the Sciences, Philadelphia, PA

Breast cancer accounts for approximately 20-25% of cancer diagnoses each year. Metastasis is the spread of cancer from the site of the original tumor to another site in the body and responsible for most of the deaths. Metastasis requires cancer cells to enter and exit the blood vessels through incredibly small gaps; without this, metastatic tumors cannot form. The cell’s nucleus is much larger than these gaps and thus must be ‘squished’ to 10% of its original diameter for the cell to squeeze through these small gaps. The nucleus is very rigid in normal cells and resists the compressive forces required to contort the nuclei to fit through these gaps. However, metastatic cancer cell nuclei are more compliant and compress more easily. The molecular changes underlying this increased compliance remain poorly understood. Our studies focused on emerin, an integral membrane protein of the nuclear envelope, because of its well established roles in nuclear structure and function. The nuclear area of emerin-null myoblasts was measured to directly test if emerin expression was important for nuclear size. 400-600 wildtype myoblasts or emerin-null myoblasts from three biological replicates were used for this analysis. Nuclear area was measured using the NII Plugin in ImageJ software (NIH). The NII Plugin measures aspect, area, radius ratio and roundness of selected nuclei. The area of wildtype nuclei was 44% larger than emerin-null nuclei. Wildtype emerin was expressed in emerin-null myogenic progenitors to test if increased emerin expression rescued nuclear size and structure. Emerin expression increased nuclear size by 49% in emerin-null cells, comparable to the differences seen between wildtype and emerin-null cells. Previous studies showed the MDA-231 invasive breast cancer cells had decreased nuclear size and abnormal nuclear structure. Emerin protein expression was measured in invasive breast cancer cells (MDA-231, Hs578t and MDA-157), control breast fibroblasts (MCF10A) and primary fibroblasts (normal). Emerin protein levels were decreased 1.4- to 1.8-fold in the invasive breast cancer cell lines, compared to control cells. There was no statistical difference between emerin levels in MCF10A cells and primary fibroblasts (p=0.47; Figure 5). Thus decreased nuclear size in breast cancer cell lines correlated with decreased emerin expression. Our future studies will continue to test the hypothesis that emerin plays a critical role in regulating nuclear size and stiffness and that disruption of emerin expression contributes to the increased invasiveness of breast cancer cells by reducing nuclear size and stiffness. We anticipate our studies will yield a more complete understanding of cell invasion and migration and uncover novel therapeutic targets for metastasis.

Leader cells are defined by DNA hypermethylation and aberrant gene expression during collective lung cancer invasion.
E.R. Summerbell¹, J. Bell¹, J. Konen¹, J. Kowalski⁵, P.M. Vertino⁴, A.I. Marcus¹;
¹Department of Hematology and Medical Oncology, Emory University, Atlanta, GA, ²Graduate Program in Cancer Biology, Emory University, Atlanta, GA, ³Graduate Program in Genetics and Molecular Biology, Emory University, Atlanta, GA, ⁴Department of Radiation Oncology, Emory University, Atlanta, GA, ⁵Department of Biostatistics and Bioinformatics, Emory University, Atlanta, GA

Collective cancer cell invasion, wherein packs of cancer cells invade together, is present in patient samples of most solid tumor types and contributes to cancer metastasis. Within these collective invasion
packs, highly-invasive leader cells pioneer migration and invasion while highly-proliferative follower cells travel behind them. Our lab previously developed an image-guided genomics technique to isolate and culture individual leader and follower cells, termed Spatiotemporal Genomic and Cellular Analysis (SaGA). Since epigenetic mechanisms, such as DNA methylation, regulate phenotypic plasticity and cell differentiation in many cellular contexts, we hypothesize that leader and follower cell phenotypes can emerge through epigenetic reprogramming of lung cancer cells. We performed DNA methylation profiling using a DNA methylation array wherein leader cells showed significant global DNA hypermethylation compared to both follower cells and the H1299 lung adenocarcinoma parental population. Furthermore, integrating DNA methylation analysis with RNAseq analysis identified gene expression patterns unique to leader cells that correlate with these changes in DNA methylation. Differentially methylated CpG islands overlapping promoters correlated with significant gene silencing or overexpression of 57 genes in leader cells, including multiple putative tumor suppressors and oncogenes. In addition, leader cells showed differential methylation at FANTOM5 enhancers correlated with many gene ontology pathways critical for collective cancer invasion, including VEGF signaling, which we have previously shown to be critical for collective pack formation. In addition, inhibition of DNA methylation using 5-aza-2'-deoxycytidine (DAC) significantly abrogated collective invasion of 3-D spheroids of H1299 parental cells and even more significantly in spheroids of purified leader cells. DAC treatment also rescued expression of genes in leader cells that had little to no gene expression and high promoter DNA methylation compared to parental and follower cells. Our data suggest a mechanism wherein global DNA hypermethylation can drive the leader cell phenotype and wherein DNA methylation regulates gene expression critical for leader cell behavior. Subsequent validation of differentially methylated target genes may determine functionally-relevant genes driving leader cell-dependent collective cancer invasion.

Migration through micron-size constrictions has been seen to rupture the nucleus, release nuclear-localized GFP, and cause localized accumulations of ectopic 53BP1 – a DNA repair protein. Here, constricted migration of two human cancer cell types and primary mesenchymal stem cells (MSC) increases DNA breaks throughout the nucleoplasm as assessed by endogenous damage markers and by electrophoretic ‘comet’ measurements. Migration also causes multiple DNA repair proteins to segregate away from DNA, with cytoplasmic mis-localization sustained for many hours as is relevant to DNA repair times. Partial knockdown of repair factors that are known to also regulate chromosome copy numbers is seen to increase DNA breaks in U2OS osteosarcoma cells, with nucleoplasmic patterns similar to migration, and knockdown likewise increases aberrant levels of DNA without affecting migration. Migration-induced nuclear damage is nonetheless reversible for wild-type and sub-cloned U2OS lines, whereas DNA arrays and sequencing reveal lasting genomic differences. Gains and losses of hundreds of megabases in many chromosomes are typical of the changes and heterogeneity in bone cancer. Phenotypic differences that arise from constricted migration of U2OS cells are further illustrated by a clone with a highly elongated and stable MSC-like shape that depends on microtubule assembly.
downstream of the transcription factor GATA4. Such changes seem consistent with reversion to a more stem-like state upstream of cancerous osteoblastic cells. Migration-induced genomic instability can thus associate with heritable changes. Next, we tested such migration-induced genomic aberrations in vivo, by using a metastatic mouse model followed by genomic comparisons between the cells derived from primary and metastatic sites.

**Metastasis by tumor epithelial clusters requires E-cadherin expression.**

V. Padmanaban¹, A.J. Ewald³;

¹Departments of Cell Biology and Oncology, Center for Cell Dynamics, Johns Hopkins University School of Medicine, Baltimore, MD

**Introduction**: Metastasis is the major driver for cancer related deaths. The genetic/ epigenetic loss of E-cadherin (E-cad) is linked to increased invasion of cancer cell lines and therefore, has been inferred to promote metastasis. Consistent with this concept, invasive lobular breast cancer cells lack E-cad expression and commonly metastasize. However, contrary to this concept, more than 80% of breast cancers are invasive ductal and these tumors retain their E-cad expression in both the primary tumor and distant metastases. We recently demonstrated that cancer cell clusters expressing E-cad contribute to >95% of metastases arising from these tumors. The current study aims to dissect the direct functional contribution of E-cad towards metastasis.

**Results**: To address this question, we used MMTV-PyMT mice, a frequently used metastatic model of invasive ductal carcinoma. We bred these mice to also include additional transgenes that allow for a Cre-inducible, GFP reported deletion of E-cad. Primary tumor organoids isolated from these mice were infected with Adeno-Cre recombinase to delete E-cad. We observe that loss of E-cad expression results in increased invasion and dissemination in 3D organotypic culture. Disseminated cells typically lack E-cad, but retain expression of other epithelial markers such as cytokeratins. To test the requirement of E-cad expression for metastasis, we transplanted E-cad deficient tumor organoids into immunocompromised host mice. Tumors in these mice grow slower but have a more invasive front compared to tumors with intact E-cad expression. Interestingly, however, cancer cells that have lost E-cad do not contribute to any observable metastases. From *in-vivo* tail vein assays, we concluded that E-cad null cancer cells are defective at seeding distant organs. To then test if E-cad expression promotes survival of cancer cells, we performed colony formation assays using flow sorted cancer cells. E-cad null cancer cells show a 7-fold decrease in colony forming potential. We are currently investigating molecular signaling alterations downstream of E-cad deletion that confer a decreased metastatic potential.

**Conclusions**: Consistent with previous reports, loss of E-cad increases tumor invasion and dissemination. However, our results reveal that E-cad loss in cancer cells can inhibit metastatic colonization. Interestingly, we observe an uncoupling of the relative efficiency of local invasion/ dissemination and distant metastatic outcome. **We propose an alternate route of collective epithelial metastasis in which cancer cells need to maintain gene expression consistent with their epithelial origin to efficiently metastasize.**

ZEB1 becomes a transcriptional activator upon interacting with YAP.
W. Lehmann1, R.L. Eccles1, J. Kleemann1, D. Mossmann1,2, C. Meisinger1, V. Mahadevan3, S. Brabletz1, M. Stemmler1, T. Brabletz1;
1Experimental Medicine I, Friedrich Alexander University, Erlangen-Nuremberg, Germany, 2Biozentrum, University of Basel, Basel, Switzerland, 3Institute of Bioinformatics and Applied Biotechnology (IBAB), Bangalore, India

Early dissemination, metastasis and therapy resistance are central hallmarks of aggressive cancer types and the leading cause of cancer-associated deaths. Dissemination of tumour cells is enabled by an aberrant activation of the epithelial to mesenchymal transition (EMT) program. The EMT-inducing transcription factor ZEB1 is a crucial stimulator of these processes, particularly by coupling the activation of cellular motility with stemness and survival properties. The potent effects of ZEB1 cannot be solely explained by its well-established role as a transcriptional repressor of epithelial genes. We analysed in which context ZEB1 can act as a transcriptional activator and discovered a functional link between ZEB1 and YAP, the key downstream effector of the Hippo pathway. We found ZEB1 to be an activator of a set of classical YAP target genes in breast cancer cell lines, and that ZEB1 and YAP synergistically co-regulate this common ZEB1/YAP gene set. We could further demonstrate that ZEB1 and YAP directly interact. Intriguingly ZEB1 was not found to interact with TAZ, the YAP paralogue, indicating functional differences between YAP and TAZ. We are currently modelling the ZEB1/YAP interface in silico, in order to further dissect the binding determinants and determine how this interaction is regulated upstream. The ZEB1/YAP common target gene set is a predictor of poor survival, therapy resistance and metastasis formation in breast cancer, proving clinical relevance of our findings. The identification of this ZEB1/YAP crosstalk directly links two cancer promoting pathways and provides insight into how ZEB1 switches to a transcriptional activator in order to drive tumour progression beyond EMT.

Constricted migration suppresses cell cycle progression.
C.R. Pfeifer1,2,3, V.M. Morales Garcia4, L.M. Santiago Millan5, B. Niese6, J. Irianto5,2, D.E. Discher1,2,3;
1Physical Sciences Oncology Center at Penn, University of Pennsylvania, Philadelphia, PA, 2Molecular Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA, 3Graduate Group, Department of Physics Astronomy, University of Pennsylvania, Philadelphia, PA, 4Industrial Biotechnology, University of Puerto Rico at Mayagüez, Mayagüez, PR, 5Biology, University of Puerto Rico at Humacao, Humacao, PR, 6Engineering Physics, Ohio University, Athens, OH

As a cancer cell invades adjacent tissue, penetrates a basement membrane barrier, or squeezes into the smallest blood capillaries, its nucleus can be highly constricted. Such nuclear stress has recently been shown to enhance DNA damage and genome variation. However, little is known about the interaction between constriction-induced damage and cell cycle/DNA replication, even though the latter is increasingly being appreciated as a major source of cancerous mutations. Here, U2OS osteosarcoma cells, U251 glioblastoma cells, and A549 lung carcinoma cells were seeded at three different densities (low, medium, high) on 2D plastic and were also migrated through rigid 3 μm and 8 μm pores. In each case, cell cycle analysis was performed using total DNA content combined with EdU incorporation, as measured by fluorescence microscopy. For all three cell types, G2 was found to be suppressed most in 2D by high density, indicating possible contact inhibition. In 3D, G2 was suppressed most among cells.
that migrated through 3 μm pores, even though this was the lowest density condition. These findings suggest that constricted migration inhibits cell cycle progression, perhaps due to checkpoint activation by constriction-induced DNA damage.

Leptomycin B sensitizes ovarian and endometrial cancer cells to TRAIL and cisplatin induced apoptosis through synergistic modulation of crucial apoptosis regulators.

F. Fabi\(^1\), P. Adam\(^1\), K. Vincent\(^1\), F. Demontigny\(^1\), S. Parent\(^1\), E. Asselin\(^1\);

\(^1\)Medical Biology, Université du Québec à Trois-Rivières, Trois-Rivières, QC

The vast majority of malignant tumors found in human can be fought through the use of chemotherapeutic drugs. However, chemoresistance is a major hurdle in the treatment of cancer, especially in the case of ovarian cancer (OC) as well as in endometrial cancer (EC). Both of these cancers display high mortality rates due to the establishment of chemoresistance. It is thus of utmost importance that we develop novel approaches to overcome this problem and restore chemosensitivity in cancer cells. Nuclear transport has been shown to be crucial in cell fate dynamics. CRM1, also known as XPO1, is a nuclear export receptor that recognizes proteins bearing NES domains. Substantial CRM1 enrichment is indicative of highly invasive and resistant tumors and is generally suggestive of reduced patient survival. Our hypothesis is that CRM1-driven nuclear exclusion of Par-4, p53 and FoxO1 could be an acquired resistance mechanism in cancer cells and interference with this mechanism could be an interesting therapeutical approach.

To explore this hypothesis, we first treated various OC and EC cell types with Leptomycin B (LMB), cisplatin and TRAIL, either singly or in combination, in order to observe whether Par-4, p53 and FoxO1 would accumulate to the nucleus; immunofluorescence revealed a drastic enrichment of p53 and FoxO1 in the nuclei of cells following LMB treatments as well as combination of LMB and TRAIL. We then treated multiple OC and EC cell lines with the aforementioned drugs to determine whether the tumor suppressors nuclear enrichment induced by CRM-1 inhibition could sensitize tumor cells to apoptosis induction; to this end, we assessed caspase-8 cleavage, as well as MCL-1, XIAP, cFLIP, caspase-3 cleavage and TRAIL decoy receptors expression. We then confirmed the results pertaining to cell death by flow cytometry (Annexin V/PI). The obtained results suggested that the combination of LMB and TRAIL largely increased cell death and apoptosis when compared to their respective single use; this effect is enabled through the synergistic downregulation of apoptosis inhibitors with the concomitant upregulation of apoptotic inducers. Namely, we observed the downregulation of DcR2, XIAP, MCL1 and c-FLIP as well as the upregulation of DR4, DR5, cleaved PARP, cleaved caspase 3 and caspase 8.

Taken together, these results suggest that CRM1 controls the export of various tumor suppressors which contributes to the acquired chemoresistance seen in both OC and EC. The use of CRM1 inhibitors in combination to chemotherapeutic drug regimen could be an attractive strategy to reduce chemoresistance in the context of gynecological cancer therapy.

Imaging effect of cellular heterogeneity on anti-cancer drug responses in breast cancer.
P. Wu1, C. Tseng1, J.S. Lee2, D. Wirtz3;
1Department of Chemical and Biomolecular Engineering, The Johns Hopkins University, Baltimore, MD, 2Center for Strategic Scientific Initiatives, National Cancer Institute, National Institute of Health, Bethesda, MD

Cell-to-cell variations are ubiquitous in any cell population and the evolution and ramification of this variability is less well understood. In cancers, the heterogeneity of cancer cells introduces significant challenges in designing effective treatment strategies. In this work, we study the cellular heterogeneity of breast cancer cells MDA-MB-231 cells in their response to drugs. We found that single-cell progenies derived from parental MDA-MB-231 cells exhibiting distinct progeny-to-progeny morphologies and gene expression patterns. These progenies show distinct growth inhibition response to several common anticancer drugs suggesting that treating tumor with chemotherapy can induce the changes of cancer subpopulation. To directly observe the change of subpopulation in progeny mixture system in response to drug, we fluorescently labeled three functionally distinct progenies by different colors and established high throughput microscopy analysis system to measure the population composition of the progenies under a broad spectrum of treatments and dosages. Our results showed that progenies subpopulation can significantly change under different treatments and dosage such as Taxol for more than 50%. Since these progenies exhibit different in vivo function, our results suggested that different chemotherapies can change tumor behaviors as result of changing cell subpopulations compositions. Together, our study highlights that evaluating cancer subpopulations responses to anticancer treatments is critical in identification of optimal personalized cancer treatments.

Kravis Center for Molecular Oncology, Memorial Sloan Kettering Cancer Center, New York, NY, 9Radiology, Memorial Sloan Kettering Cancer Center, New York, NY, 10Department of Pharmacology, Weill Cornell Medical College, New York, NY

Primary central nervous system lymphoma (PCNSL) is an aggressive tumor, of which almost all are diffuse large B cell lymphoma (DLBCL) by immunophenotype. Targeted cancer gene resequencing (586 genes) in 177 PCNSL patient biopsies identified recurrent somatic mutations in several genes that mediate B cell receptor (BCR) signaling. The most highly mutated genes were myeloid differentiation primary response gene 88 (MYD88) and cluster of differentiation 79B (CD79B), with frequencies of 58% and 41%, respectively. Since Bruton Tyrosine Kinase (BTK) is a central node in the BCR pathway, we
examined the activity of the BTK inhibitor in patients with relapsed or refractory primary CNS lymphoma. We observed a response rate of 77% (10/13 patients), including five complete responses. None of the complete responders, but the majority of tumors with partial ibrutinib response, harbored a CD79B mutation. RNA expression profiling and gene set enrichment analysis of human PCNSL biopsies showed an enrichment of mammalian target of rapamycin (mTOR)-related gene sets in CD79B mutant tumors. In a novel PCNSL cell line derived from a newly diagnosed PCNSL patient carrying a CD79B hotspot mutation, ibrutinib synergized with both PI3K and mTOR inhibitors to induce cell death. In summary, our results suggest a role of mutant CD79B in mitigating ibrutinib response in PCNSL, at least in part through PI3K/mTOR pathway. Drug combinations targeting both the PI3K/mTOR and BCR pathways may be more efficacious than single agent therapies for PCNSL patients harboring the CD79B hotspot mutation.

Development of a Cocktail Therapy against Human Malignant Melanoma by Combining Autophagy Inhibitors and Vemurafenib.
G. Wang¹, H. Qian¹, Y. Yang²;
¹Biological Sciences, Emporia State University, Emporia, KS

Metastatic melanoma, a malignancy originating from pigment-producing melanocytes, is the most aggressive form of skin cancer. Most patients with metastasized melanoma harbor the activating mutation gene, BRAF V600E. Vemurafenib (PLX4032), a BRAF inhibitor (BRAFi), develops drug resistance in the patients. Autophagy is a self-salvaging mechanism for cells to deal with different stresses and promotes cancer cell survival and growth. However, the role autophagy contributes to resistance to anti-tumor drugs is not well studied. In this research, we determine the effects of autophagy inhibitors, as well as a combination of autophagy inhibitors and Vemurafenib, on cell viability and cell migration. Autophagy inhibitors significantly reduced cell viability and inhibited cell migration of human malignant melanoma cells and displayed an additive cytotoxicity with PLX4032 in both Vemurafenib sensitive and resistant melanoma cells. Moreover, autophagy inhibitors alone, or combined with Vemurafenib, induced apoptosis in both Vemurafenib sensitive and resistant melanoma cells. We further examined the signaling pathways that autophagy inhibitors may employ to exert cytotoxic effect and overcome BRAFi resistance. Autophagy inhibitors alone activated Erk and worked synergistically with BRAFi to inhibit autophagy by reducing the expression of Atg12. In conclusion, our results suggest that a combination of autophagy inhibitors and BRAFi would be a potential therapeutic strategy to treat melanoma and to overcome the drug resistance in the melanoma cells.

Introduction: Metastatic breast cancer exhibits diverse and rapidly evolving intra- and inter-tumor heterogeneity. Patients with similar clinical presentations often display distinct tumor responses to standard of care (SOC) therapies. Genome landscape studies indicate that EGFR/HER2/RAS pathway activation is highly prevalent in malignant breast cancers. The identification of therapy-responsive and prognostic biomarkers is paramount important to stratify patients and guide therapies in clinical oncology and personalized medicine.

Methods: In this study, we analyzed matched pairs of tumor specimens collected from 182 patients who received neoadjuvant systemic therapies (NST). Statistical analyses were conducted to determine whether EGFR/HER2/RAS pathway biomarkers and clinicopathological predictors, alone and in combination, are prognostic in breast cancer.

Findings: SIAH and EGFR outperform ER, PR, HER2 and Ki67 as two logical, sensitive and prognostic biomarkers in metastatic breast cancer. We found that increased SIAH and EGFR expression correlated with advanced pathological stage and aggressive molecular subtypes. Both SIAH expression post-NST and NST-induced changes in EGFR expression in invasive mammary tumors are associated with tumor regression and increased survival, whereas ER, PR, and HER2 were not. These results suggest that SIAH and EGFR are two prognostic biomarkers in breast cancer with lymph node metastases.

Interpretations: The discovery of incorporating tumor heterogeneity-independent and growth-sensitive RAS pathway biomarkers, SIAH and EGFR, whose altered expression can be used to estimate therapeutic efficacy, detect emergence of resistant clones, forecast tumor regression, differentiate among partial responders, and predict patient survival in the neoadjuvant setting, has a clear clinical implication in personalizing breast cancer therapy.

Analysis of the Nature of Paclitaxel Resistance in APC Knockdown Breast Cancer Cells. B.J. Berkeley1,2,3,4, A.H. Arnason2,3, J.R. Prosperi1,2,3;
1Biochemistry and Molecular Biology, Indiana University School of Medicine, South Bend, IN, 2Biological Sciences, University of Notre Dame, South Bend, IN, 3Harper Cancer Research Institute, South Bend, IN, 4Smurfit Institute of Genetics, Trinity College Dublin, Dublin, Republic of Ireland

Adenomatous Polyposis Coli (APC) is a multi-domain tumor suppressor protein that binds to proteins including β-catenin, axin, and microtubules (MTs). APC is lost in many epithelial cancers and up to 70% of sporadic breast cancers, with a tendency towards triple negative breast cancers (TNBCs). In a mouse breast cancer model of APC loss, MMTV-PyMT;ApcMin/+; our laboratory previously demonstrated that APC loss resulted in metaplastic-like tumors, a subtype of TNBCs that often develops resistance to chemotherapy. Using the human breast cancer cell line, MDA-MB-157, we created APC knockdown cells (APCKD) using lentiviral mediated shRNA knockdown of APC, which demonstrated resistance to the Taxane family chemotherapeutic agent, Paclitaxel. This APCKD model has an increased proportion of tumor initiating cells (TICs), a subpopulation of highly tumorigenic cells found in most cancers that are resistant to traditional chemotherapeutic agents. Given that Taxanes and APC both alter MT dynamics, we sought to understand the molecular mechanisms of APC-mediated resistance. Based on RNA-seq data, we hypothesized that genes involved in the G2/M transition or those co-identified in PTX treated APCKD cells and a TIC signature list would be responsible for PTX resistance. We used three approaches to examine the molecular architecture and cell cycle phase pattern of Paclitaxel resistant APCKD cells: Western blots, RT-qPCR and flow cytometry. Four genes were identified as being selectively regulated by PTX in the APCKD cells and overlapping with the TIC signature (PLEKHG2, GPR37, MLF1, and IGSF3). RT-
qPCR confirmed the RNA-seq data, and future studies will investigate the effect of manipulating expression of these genes. Western blot analysis of the checkpoint proteins CDK1 (Thr14, Thr161, Tyr15) and Cyclin B1 showed no significant difference in expression between the parent MDA-MB-157 and APCKD cells after PTX treatment. Finally, cell cycle analysis demonstrated that PTX treatment of APCKD cells resulting in G2/M arrest similar to the parent cells. Combined, this suggests that the PTX resistance of APCKD cells is not mediated by the G2/M checkpoint but by an alternative mechanism. We propose that APCKD cells evade apoptosis induced by cell cycle arrest in G2/M by utilizing mutant proteins, such as kinases or phosphatases, which interact with checkpoint proteins directly. As the functionality of checkpoint proteins hinges on their phosphorylation profile, an examination of this in APCKD cells and parent cells may explore this as a potential PTX resistance mechanism. By understanding the molecular nature of PTX resistance in APCKD cells, a prospective therapeutic target may be identified to work towards a targeted treatment for some TNBC types.

Mapping mechanisms of drug sensitivity and resistance: genetics and environment.
P. Patel1, Z. Kianfard2, S.A. Sabatinos3;
1Chemistry and Biology, Ryerson University, Toronto, ON

Gemcitabine is a powerful chemotherapeutic that targets DNA replication, killing proliferating cells. Generally, it is a last-line of defense in high-fatality cancers and is one of relatively few options used to treat pancreatic cancer. The window of opportunity is short because gemcitabine treatment tends to develop resistance. However, it is largely unknown which patients are candidates for successful gemcitabine therapy, and which will not respond. This decreases the window of opportunity to treat the tumor, and exposes patients to gemcitabine’s side effects without its tumor-cell killing benefit. We use defined mutations in fission yeast (Schizosaccharomyces pombe) to profile gemcitabine sensitivity and its relationship with environmental stress. Our transgenic yeast pipeline aims to categorize loss-of-function mutations that promote sensitivity or resistance in individual cells. We report that loss of the replication checkpoint is an important predictor of gemcitabine sensitivity, but that dose-sensitivity varies even between mutants of the same class. This correlates with enhanced resistance during later drug exposures. Yet, not all mutants that survive gemcitabine are resistant, suggesting that population-wide heterogeneity is a critical consideration when defining outcome. We have found that transient environmental stress has a profound effect upon checkpoint mutant survival, defining the conditions of cell death in different drug classes. In this way, we define conditions that allow checkpoint mutants to survive gemcitabine, and the changes in cells that survive drug. Long-term, genetic profiling for chemotherapy drugs may help to suggest which cells are more likely to respond, and whether targeted synthetic lethality strategies may enhance patient- and cancer-specific treatment.

Chronic lymphocytic leukemia (CLL) is a common B-cell malignancy which covers 40% of all leukemia cases in the Western world. The disease shows high biological and clinical heterogeneity, and it has become a priority to understand the underlying abnormalities in order to provide tailored treatment. Here, cell signaling aberrations which may serve as biological indicators for suitable therapy were characterized. Phospho-specific flow cytometry was applied to map basal and induced phosphorylation levels of 20 phospho-epitopes on proteins relevant to B-cell signaling in B cells from 22 CLL patients and 25 normal controls. CLL cells displayed similar or lower basal phosphorylation levels than normal B cells, with the exception of STAT3 (pY705) which was elevated. Importantly, STAT3 inhibitors normalized the STAT3 (pY705) level and reduced cell viability in CLL cells. After BCR stimulation, CLL cells showed significantly impaired phosphorylation levels for several of the analyzed phospho-proteins. However, the level of Akt (pS473) was more effectively increased in IgHV unmutated CLL (UM-CLL) patient samples and was significantly higher than in M-CLL cells. Notably, the PI3Kdelta inhibitor idelalisib potently reduced Akt (pS473). Moreover, the signaling impacts of the cytostatic drugs fludarabine, doxorubicin and vincristine were also investigated, but only minor effects were observed. In conclusion, signaling aberrations could be identified by phosphoflow cytometry and were normalized by small molecule drugs. This approach can thus be applied to identify relevant drug targets as well as drug effects in the individual patient.

Pyrrolidine dithiocarbamate reverses Bcl-xL-mediated apoptotic resistance to doxorubicin by inducing paraptosis.

S. Park1,2, D. Lee2,3, E. Ju1, E. Ko1, S. Jeong1, K. Choi2,3, E. Choi4;

1Asan Institute for Life Sciences, Center for Advancing Cancer Therapeutics, Asan Medical Center, Seoul, South Korea, 2Department of Biochemistry, Department of Biomedical Sciences, Ajou University School of Medicine, Suwon, South Korea, 3Genomic Instability Center, Ajou University School of Medicine, Suwon, South Korea, 4Center for Advancing Cancer Therapeutics, Department of Radiation Oncology, Asan Medical Center, University of Ulsan College of Medicine, Seoul, South Korea

Elevated Bcl-xL expression in cancer cells contributes to doxorubicin resistance, leading to failure in chemotherapy. In addition, the clinical use of high-dose doxorubicin in cancer therapy has been limited by issues with cardiotoxicity and hepatotoxicity. Here, we show that co-treatment with pyrrolidine dithiocarbamate (PDTC) attenuates doxorubicin-induced apoptosis in Chang-L liver cells and human hepatocytes, but overcomes doxorubicin resistance in Bcl-xL-overexpressing Chang-L cells and several
hepatocellular carcinoma (HCC) cell lines with high Bcl-xL expression. Additionally, combined treatment with PDTC and doxorubicin markedly retarded tumor growth in a Huh-7 HCC cell xenograft tumor model, compared to either mono-treatment. These results suggest that PDTC/doxorubicin co-treatment may provide a safe and effective therapeutic strategy against malignant hepatoma cells with Bcl-xL-mediated apoptotic defects. We also found that induction of paraptosis, a cell death mode that is accompanied by dilation of the endoplasmic reticulum and mitochondria, is involved in this anti-cancer effect of PDTC/doxorubicin. The intracellular glutathione levels were reduced in Bcl-xL-overexpressing Chang-L cells treated with PDTC/doxorubicin, and PDTC/doxorubicin-induced paraptosis was effectively blocked by pretreatment with thiol-antioxidants, but not by non-thiol antioxidants. Collectively, our results suggest that disruption of thiol homeostasis may critically contribute to PDTC/doxorubicin-induced paraptosis in Bcl-xL-overexpressing cells.

Many chemotherapeutic agents act in a nondiscriminatory fashion, targeting both cancerous and noncancerous cells in S phase and M phase. One approach to reduce the toxic side effects in normal tissue is to exploit the differences in p53 functionality between cancerous and noncancerous cells. For example, activating p53 signaling by nongenotoxic means can transiently arrest noncancerous p53 positive cells in G1 phase and protect them from the cytotoxic effects of chemotherapeutic drugs. However, since most cancerous cells have faulty p53 signaling, they will proceed to cycle, and continue to be affected by the drug. In this study we asked if this G1-phase arrest and cytoprotection can be achieved by targeting ribosome biogenesis. Through the expression of a dominant negative mutant ribosome assembly factor Bop1, we were able to transiently inhibit rRNA maturation. Using this genetic model, we have shown that inhibition of rRNA maturation protects 3T3 cells from chemotherapeutic agents camptothecin and methotrexate. This cytoprotection is associated with a transient arrest of cells in G1 phase, and is p53 dependent. We have also shown that the depletion of ribosomal protein Rps19 via shRNA arrests cells in G1 phase and protects them from camptothecin. However, this G1 arrest and cytoprotection was not achieved in shRNA-mediated depletion of several other tested ribosomal proteins, indicating distinct cellular responses to different targets in ribosome biogenesis. Using a mixed population of isogenic p53 positive and p53 negative cell lines, we have further shown that camptothecin in combination with the inhibition of ribosome biogenesis selectively kills p53 negative cells. We propose that the inhibition of select post-transcriptional ribosome assembly steps can enhance the efficiency of existing chemotherapeutic treatments.

Most high-risk neuroblastoma patients succumb to lethal therapy resistant disease, selected for during the course of intensive multimodality treatment. Therapy resistance is largely attributed to insensitivity to drug-induced apoptosis, however the exact mechanisms remain unknown. Apart from integrating death signals, mitochondria (mito) interact with the endoplasmic reticulum (ER) at close contact sites known as mitochondria associated membranes (MAM) of the ER to regulate calcium and lipid transfer and apoptotic sensitivity, a process often derailed in therapy resistant cancers. ER-mito contact sites are enriched in tethering and mitochondrial remodeling proteins including MFN2, PACS2 and DRP1. Pathologic deregulation of these contact sites has been implicated in the genesis of neurodegenerative and metabolic disorders. Here, we show that disruption of bona fide ER-mito proteins in therapy sensitive neuroblastomas induces apoptotic insensitivity and a shift towards a resistant phenotype. Isolated mitochondria from matched isogenic tumor pairs obtained from the same patient at diagnosis (DX; therapy sensitive) and relapse (REL; therapy resistant) were assessed for their apoptotic response downstream of therapeutic stressors tBid and Bim by measuring cytochrome C release by ELISA (BH3 profiling). Electron microscopy (EM) image analyses of ER-mito contact sites revealed that REL tumors contain up to 70% fewer ER-mito interactions than their matched DX tumors, as confirmed by IB for organelle-specific proteins. shRNA gene silencing of MFN2 or PACS2 in DX cells revealed a resistance-like phenotype as confirmed by BH3 profiling and chemotherapeutic drug response in vitro. A 60% decrease in MFN2 protein in DX cells partially phenocopied the resistance profile of isogenic REL cells. The degree of apoptotic resistance correlated with the extent of protein knockdown for MFN2. Treatment of shMFN2 and shPACS2 DX cells with ABT-737, a BH3 mimetic, or carboplatin, increased their IC50s multiple-fold compared to control cells, paralleling their blunted mitochondrial apoptotic response. In DX cells, chemical disruption of ER-mito communication by targeting DRP-1 inhibition with mitochondrial division inhibitor 1 (Mdivi-1) lead to decreased cytochrome C release. Likewise, blockage of the opening of the mitochondrial permeability transition pore by treatment of DX cells with cyclosporine A also resulted in lower cytochrome C release and apoptotic attenuation. Our data implicate ER-mito contact sites as positive regulators of apoptosis, whose disruption is associated with apoptotic attenuation and therapy resistance. We present a potential mechanism for broad therapy resistance arising under therapeutic stress that selects for reduced communication of ER with mitochondria.

Sunday-197
Cancer resistance to aggressive therapeutic regimens is one of the major setbacks in cancer treatment and recovery. It is thus critical to identify the molecular players and pathways that promote tumor resistance and recurrence. Sodium-4-phenyl butyrate (PBA) is a commonly used histone deacetylase inhibitor (HDAC). HDAC inhibitors are a new class of antineoplastic agents currently being tested in clinical trials. In this study, we sought to evaluate the anticancer effects of PBA in various cancer cell lines and determine the underlying mechanisms of action. Our results show that PBA inhibits cell migration and tumor progression both in vitro and in vivo. We also demonstrate that the expression levels of the oncogene DJ-1 increase after treatment with BPA indicating a protective pro-tumor role for DJ-1. Knock down of DJ-1 with siRNA decreased cell motility by inhibiting the tumor suppressor PTEN and activation of the PI3K pathway further confirming the neoplastic role of DJ-1. We therefore conclude that PBA is a potential therapeutic agent for controlling cancer metastasis and that DJ-1 protein expression levels can be used as an indicator to predict resistance to PBA therapy.

1Centro de Envejecimiento y Regeneración (CARE), Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile, 2Centro de Biología Celular y Biomedicina, Facultad de Ciencia, Universidad San Sebastian, Santiago, Chile, 3Departamento de Hematología y Oncología, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile, 4Departamento de Patología, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile, 5Centro de Biología Celular y Biomedicina, Facultad de Medicina, Universidad San Sebastián, Santiago, Chile

Endocytic trafficking regulates EGFR function and can be targeted to counteract cancer malignancy. A recent approach resulting in harmful effects upon tumoral cells has been to induce EGFR endocytosis and inaccessibility to ligand stimulation through the inhibition of phosphatidic acid (PA) hydrolysis with D-propranolol (Shaughnessy-FEBS J-2014). This pathway involves PA-mediated activation of type 4 phosphodiesterases (PDE4), which reduces cAMP levels and PKA activity. As in other conditions that decrease basal PKA activity, the EGFR becomes accumulated in recycling endosomes due to both increased internalization and reduced recycling. Indeed, this pathway has to be tested in cancerous cells bearing different malignant contexts. Here we first studied gallbladder G-415 cancer cells that are highly aggressive and resistant to the chemotherapy drug gemcitabine. In G-415 cells, D-propranolol induced EGFR endocytosis and sorting to recycling endosomes through the PA/PDE4/PKA pathway, accompanied by inhibition of cell proliferation, migration and invasion. Interestingly, sequence analysis revealed a p53 point mutation (R282W), one of the five most abundant p53 missense mutations in human cancers, not previously described in G-415 cells. Other p53 mutants (R175H or R273H) have been shown to enhance recycling of β1-integrins and EGFR providing high migration/invasion capabilities. Therefore, we compared the effects of D-propranolol in H1299-p53 null cells with transfected H1299 cells expressing either p53 R175H or p53 R273H. In all these cells, D-propranolol induced EGFR accumulation in recycling endosomes, indicating inhibition of EGFR recycling and thus a counteraction of the p53 mutant influence. Our results suggest that D-Propranolol could be effective against gallbladder cancer cells and other cancerous cells carrying gain-of-function p53 point mutations. (Financed by CONICYT Doctoral Scholarship to JBC, CONICYT Basal Grant PFB12/2007 and Fondecyt #1141127 to AG).
Mitotic slippage is the major outcome for cells treated with microtubule inhibitors.

S.R. Bekbayev\textsuperscript{1}, M. Suleimenov\textsuperscript{1}, A. Kakpenova\textsuperscript{1,2,3}, S. Kauanova\textsuperscript{1,2,3}, I.A. Vorobjev\textsuperscript{1,3,4};
\textsuperscript{1}School of Science and Technology, Nazarbayev University, Astana, Kazakhstan, \textsuperscript{2}School of Engineering, Nazarbayev University, Astana, Kazakhstan, \textsuperscript{3}National Laboratory Astana, Nazarbayev University, Astana, Kazakhstan, \textsuperscript{4}A.N. Belozersky Institute of Physico-Chemical Biology, M.V. Lomonosov Moscow State University, Moscow, Russia

The response of cancer (HT1080, A549, U118) and immortalized normal (HaCaT, 3T3) cells to microtubule inhibitors (Nocodazole, Taxol, Vinorelbine) was analysed by time-lapse microscopy. The cells had entered mitosis were tracked for 72 hours under the drug treatment in the dose range from 0.03 nM to 3000 nM, or after preliminary incubation in the drug-containing media for 72h. All types of cells display same dose-dependent fates for each drug used. With increase in dose mitotic cells underwent the following fates: normal division, delayed bi-polar division, abnormal (asymmetric and/or incomplete) division, mitotic slippage, and death of mitotic cell without or after exit into interphase. The exact doses where each fate was dominating depended on cell line and drug. The duration of mitotic arrest of the cells finely divided, regardless the type of division and behavior of daughter cells did not exceed 10 hours.

Above a threshold concentration after which cells were arrested for a long time in mitotic stage several outcomes were observed: abnormal division, mitotic slippage with survival, death after mitotic slippage, or death in mitosis. The duration of mitotic arrest for the last three outcomes was similar (10-30 hours) irrespective to drug type and cell line.

Mitotic slippage, the most commonly observed behavior in the wide range of concentrations (Nocodazole: 100-1000 nM; Taxol: 10-1000 nM; Vinorelbine: 3-1000 nM) of the drugs, occurred always after prolonged mitotic arrest and resulted in formation of multinucleated cells. Similarly multinucleated cells were also formed after abnormal division with incomplete cytokinesis. The cells undergoing mitotic slippage after Nocodazole treatment acquired on average 2-5 medium-to-large sized nuclei; Taxol treatment resulted in the formation of 5-16 micronuclei; and Vinorelbine treatment gave 2-7 small-to-medium nuclei. Occasionally, at high concentrations of all drugs, cells after mitotic slippage formed one large nucleus. The majority of cells after mitotic slippage at moderate concentrations remained alive for >72 h. At highest concentrations tested (1-3 \textmu M) prolonged survival, death after mitotic slippage, and death in mitosis could be observed at reasonable frequency.

To conclude, cultured cells after irreversible mitotic arrest with different microtubule inhibitors mainly escape into interphase, form multinucleated cells and survive for prolonged time. Mitotic cell fate only partially depends on the drug type and drug concentration.

This work was supported by Grant # 0472/GF4 from MES (Republic of Kazakhstan).

Label free proteomics profiling of MCF7 and K562 cancer cells treated with mitomycin C and dicarbamoyl mitomycin C identifies main cellular networks leading to inhibition of tumor cell proliferation.
C.C. Clement¹,², S.Y. Cheng³, M. Dzieciatkowska ⁴, W. Aguilar³, E. Champeil³;
¹Pathology, Albert Einstein College of Medicine Inc, Bronx, NY, ²Chemistry, Lehman College CUNY, Bronx, NY, ³Department of Sciences, John Jay College of Criminal Justice CUNY, New York, NY, ⁴Biological Mass Spectrometry Core Facility, University of Colorado Denver, Aurora, CO

Mitomycin C (MC), a frequently used anticancer drug, induces DNA damage via DNA alkylation and inter-strand mediated cross-links (ICLs). Decarbamoyl mitomycin C (DMC), a mitomycin derivative which lacks the carbamate at C10, generates similar ICLs lesions thought to be the main mechanism responsible for MC cytotoxicity, and DMC. A higher toxicity of DMC for human cancer cells with or without a functioning p53 has been investigated by independent research groups. This finding was the basis for the hypothesis that the opposite stereochemistry of the ICLs generated by MC (trans) and DMC (cis) was responsible for an enhanced DMC mediated p53-independent cell-death (Cheng, SY et al., Int J Oncol. 2016 Nov; 49(5)). To better understand the mechanisms underlying DMC vs MC toxicity we employed global and label free quantitative proteomics assays for profiling the changes in the proteomes associated with the cellular signaling networks modulated by the two drugs in MCF7 (p53-proficient), and K562 (p53-deficient) in comparison with control, untreated cells. The proteomics platform employed the nanoLC-ESI MS/MS sequencing of tryptic/Glu-C/Lys-C generated peptides from total cell lysates, as well as a Q-Exactive quadrupole orbitrap mass spectrometer coupled with the label free quantification (LFQ) method for data analysis. The global proteomics analysis retrieved 1380-1400 proteins (FDR <1.0% for proteins and <0.8% for peptides) for each treated and untreated sample. The biochemical and cellular pathways were quantitatively investigated using the ingenuity pathway analysis (IPA; Ingenuity Systems), and the protein ratios extracted from LFQ analyses. The bioinformatics analysis predicted that MC and DMC can significantly increase cell death of tumor MCF7 and K562 cells. This was projected to be most likely accomplished by coordinated inhibition of cell proliferation; activation of apoptosis; and downregulation of proteins involved in the DNA repair machinery. Remarkably, biomarkers of the DNA damage repair machinery showed at least a two-fold down-regulation (p<0.05) in the MC and DMC treated samples compared with untreated control: e.g., proteins from the double strand (ds) break repair nuclease family (MREII); MUTS (MSH2) mismatch repair system; apurinic/apyrimidinic endodeoxynuclease (APEX1); PARP1, PCNA and X-Ray repair cross complementing 1 (XXCR1) family (BER pathways, and ds DNA breaks repair pathways). The label free proteomics approach utilized in this research confirmed that integrative cellular and “omics” assays are valuable tools for providing a deeper understanding of the structure-activity relationship of MC and DMC in p53-proficient and p53-deficient cancer cells.

Acute changes in leukocyte populations following focal irradiation of the intestine.
B.I. Bell\(^1\), S. Koduri\(^2\), I.I. Verginadis\(^1\), C. Koumenis\(^3\);
\(^1\)Department of Radiation Oncology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Radiotherapy is indicated for the treatment of half of all cancer patients. However, incidental irradiation of the bowel results in dose-limiting side effects in the majority of patients receiving abdominal or pelvic radiation treatment. The major late stage complication in the irradiated bowel is connective tissue fibrosis. In the intestine, this process is likely driven by the immune response in the acute phase following focal irradiation. We recently developed a mouse model which involves surgically implanting a radiopaque marker onto the surface of the intestine in order to replicate highly focal clinical radiotherapy. Mice were then imaged with cone beam computed tomography to locate the marker, and irradiated with 18 Gy of 5x5 mm collimated x-rays onto the marked intestine using the Small Animal Radiation Research Platform (SARRP). Irradiated mice exhibited 100% survival with minimal weight loss after irradiation when compared to mock-irradiated controls. Irradiation significantly impaired crypt regeneration as assessed by a 5-ethylcytosine-2'-deoxyuridine (EdU) cell proliferation assay one day post-irradiation. Furthermore, a TdT dUTP nick end labeling (TUNEL) assay indicated a localized increase in crypt apoptosis in the irradiated area, suggesting the marked intestine was successfully irradiated. Beginning 3.5 days after irradiation, there was significant ablation of intestinal structure with very few proliferating cells in the irradiated area. The intestinal barrier was maintained in the acute phase by markedly hyperplastic crypts on the edges of the irradiated area. Furthermore, a severe innate immune response was observed in the irradiated intestine 3.5, 7, and 14 days post-irradiation as evidenced by increased neutrophil and macrophage infiltration. This inflammatory process induced a systemic leukocytosis which was driven by an increase in neutrophils in the peripheral blood. Two months post-irradiation, fibrosis was observed in the irradiated area by Masson’s trichrome stain. Our results suggest that a major inflammatory reaction in the acute phase precedes fibrosis.

Repurposing Verteporfin for chemotherapeutic treatment of endometrial cancer.
R.P. Gogo\(^1\), L. Bang\(^2\), J.E. Miller\(^2\), D. Kim\(^2,3\), V. Dasari\(^1\);
\(^1\)Molecular and Functional Genomics, Weis Center for Research, Geisinger Clinic, Danville, PA, \(^2\)Biomedical and Translational Informatics Institute, Danville, PA, \(^3\)Huck Institute of the Life Sciences, Pennsylvania State University, University Park, PA

Endometrial cancer (EMCA) is the most prevalent gynecologic cancer in women in the United States. The majority of women diagnosed with EMCA are surgically cured with a hysterectomy; however, a considerable subset of patients shows persistent or recurrent tumors that are refractory to current chemotherapies. For these women, who are diagnosed with advanced stage disease, unfavorable histologic subtypes, and disease recurrence, survival is poor as there are no adjuvant therapies proven to be effective. Chemotherapy has a critical role for these patients with poor prognosis as well as for patients with increased risk of recurrence or persistent disease after surgery. Platinum-based chemotherapy is the standard first-line chemotherapy with carboplatin plus paclitaxel being the most commonly used regimen. However, response rates to first-line chemotherapy are low, with even lower responses for recurrent diseases. Hence, it is of utmost importance that novel chemotherapeutic agents
are identified to increase or restore chemo-sensitization to platinum-based chemotherapy. Verteporfin (VP, Visudyne™) is a benzoporphyrin derivative used in the treatment of adult macular degeneration. We investigated the therapeutic efficacy of Verteporfin (VP) alone or in combination with Cisplatin or Paclitaxel on Type 1 (HEC-1-B) and Type 2 (ARK-1) EMCA cell lines. Our results show that migration and invasion capabilities of EMCA cells were inhibited by VP treatment. In patient-derived organoids, VP is able to induce caspase-3 mediated apoptosis. Cytotoxicity assays were performed with VP, Cisplatin, Paclitaxel alone or in combination. VP and Cisplatin or VP and Paclitaxel exhibited synergetic effects when inducing cytotoxicity in EMCA cells. In order to determine the efficacy of VP in changing cellular transcriptome, we performed RNASeq of EMCA cells after treatment with VP. Analysis of RNA-seq data with MultiQC and DESeq shows that in both cell lines, 547 common genes were downregulated, whereas 452 genes were upregulated. To test the efficacy of VP under in vivo conditions, we developed an orthotopic mouse model of EMCA using HEC-1-B-GFP cells and administered VP (100 mg/kg body weight of mouse) by IP injection. We observed both responders as well as non-responders to VP treatment. Taken together, our results suggest that VP is a promising chemotherapeutic agent for the treatment of endometrial cancer.

1LGCP, National Cancer Institute, Bethesda, MD, 2Pathology, Beth Israel Deaconess Medical Center, Boston, MA

We are performing a correlative genomic and molecular pathology study to an ongoing clinical trial (NCT02430480), in which patients with locally advanced prostate cancer receive 6 months of GnRH agonist plus enzalutamide as intense neoadjuvant androgen deprivation therapy (ADT). Each patient receives multiparametric magnetic resonance imaging (mpMRI) at baseline and prior to radical prostatectomy (RP). The underlying biology and associated molecular features of tumor from patients who respond or fail to respond remain unknown. We are drawing associations between pre-treatment mpMRI, somatic alterations in pre-treatment mpMRI-targeted biopsies, ROIs in post-treatment mpMRI, tumor histology, and the molecular features of residual tumor in RP specimens. Imaging and anatomical landmarks on pre- and post-treatment mpMRI were used to match targeted biopsies to RPs. A series of IHC stains, including AR, GR, PTEN, SYP, ERG, and PIN-4, were performed to guide laser capture microdissection (LCM) and characterization of residual disease. RNA and DNA were simultaneously extracted from LCM biopsy and RP tissues. Paired-end RNA-seq and gene expression analysis, and whole exome sequencing with somatic mutation calling and copy number analysis, were subsequently performed. For the first patient analyzed, we have discovered two adjacent tumor clones, distinguished by distinct somatic copy number alterations and mutations in the diagnostic biopsies. Alignment of these biopsies to pre- and post-treatment mpMRI revealed that one clone corresponded to the imaging responder, while the other aligned with the imaging nonresponder. Pathologic examination of matched RP sections revealed residual tumor for both ROIs, and bioinformatic analysis indicated that both clones persisted after treatment with minimal genomic divergence from the biopsy, suggesting intrinsic resistance. All foci were PTEN intact, AR-V7 negative, and < 1% positive for Ki-67. Common to all tumor foci (pre- and post-treatment) were single-copy losses of chromosome 16q overlapping with ZFHX3, although the breakpoints of the 16q loss were different for both clones. The mpMRI-nonresponding
clone also harbored single copy losses to chromosomes 6q, 8p, and 12p, while the mpMRI-responding clone showed losses to 13q (encompassing BRCA2 and RB1), 15q and 18q, and was positive for microsatellite instability. The major genomic events were shared between biopsy and RP tissue from each clone. These data demonstrate feasibility in comparing mpMRI response, pathologic treatment response, and the underlying genomic features that drive tumor development versus treatment resistance, to ultimately evaluate the clonal evolution of resistant tumor and associate molecular features of primary disease with resistance or response.

Models of Ovarian Cancer Cell Resistance to Doxorubicin and Cisplatin.

P. Caffrey\(^1\), L. Gasper\(^2\);

\(^1\)Biological and Environ Sci, California University of PA, California, PA

Resistence to chemotherapy is a major cause of treatment failure in ovarian cancer. In contrast to the reversal of pre-existing resistance, the prevention of its development requires the use of models in which resistance occurs rapidly and predictably. We have utilized our previous model of cisplatin resistant ovarian cancer to identify potential resistance preventatives. The aim of the current study is to design a model of resistance to the chemotherapy drug, Doxorubicin (Dox). Replicate culture wells of A2780 ovarian cancer cells were pretreated in sub-toxic Dox doses ranging from 2 uM to 8 uM for 24-48 hours. Replicate wells were exposed to PBS to serve as controls. At the end of this pretreatment period, the medium was replaced with either control medium or a higher, acute dose of Dox (10 uM). To test for cross-resistance to cisplatin (CP), additional culture wells were pre-treated with subtoxic doses of CP or Dox prior to treatment with a higher, toxic dose of either drug. To track the response of cells over time, the cells were counted daily, and the means and standard deviations were calculated and compared to the mean starting cell counts. Drug resistance was identified as an increase in cell number following treatment with the high dose. Of the pretreatment doses and intervals tested, two different models resulted in Dox resistance within five days. This was determined by cell counts recorded after 24 hour exposure to high dose drug: there was an increase in pre-treated cell count of 8-22%, as compared to the decrease in control cell cultures ranging from 11-31%. Cross-resistance to both Dox and CP was also observed. Studies are underway to characterize mechanisms involved in Dox resistance and cross-resistance, and to use these models to test potential preventatives.

Epigallocatechin-3-gallate has antitumor effects due to induction of differentiation and apoptosis in a model of acute promyelocytic leukemia mice.

F.I. Della Vía\(^1\), C.O. Torello\(^1\), F.M. Roversi\(^1,2\), R.N. Shiraishi\(^3\), M.C. Alvarez De Prax\(^4\), E.M. Rego\(^3\), S.T. Saad\(^1\);

\(^1\)Hematology and Transfusion Medicine Center, University of Campinas (Hemocentro/Unicamp), Campinas, São Paulo, Brazil, \(^2\)Universidade São Francisco (USF), Bragança Paulista, Brazil, \(^3\)Department of Internal Medicine, University of São Paulo (USP), Ribeirão Preto, Brazil

Clinical studies show that there is no consensus regarding therapy for older patients with acute leukemia, who are susceptible to aggressive chemotherapy and ineligible to bone marrow (BM) transplantation. Thus, the search for effective compounds with less adverse effects is required.
Catechins are a major compound that has been standing out over the last years and is distributed in many teas. Epigallocatechin-3-gallate (EGCG), the major polyphenol present in green tea, has been shown to inhibit tumor formation and growth in different animal models for human cancer. In this context, the aim of this study was to investigate the effects of EGCG using acute promyelocytic leukemia (APL) as a model. For the APL model, NOD/SCID received 2 Gy irradiation followed by transplantation with intravenously injection in caudal vein with leukemia cells obtained from hCG-PML-RARα transgenic mice. After 12 days, the establishment of the disease was confirmed by leukocytosis (>30x10^3/µL), anemia (<10g/dL), thrombocytopenia (<500x10^3/µL) and the presence of 1% of blast at the peripheral blood (PB). The mice were randomly selected to receive EGCG (25mg/Kg/day) or vehicle (saline), intraperitoneally. The mice were then sacrificed after 5 days treatment and PB, BM and spleens were collected for hematological and flow cytometry analyses. Hematological analysis revealed that the treatment with EGCG reduced leukocyte number (p=0.0153; n=10), and increased platelets number (p=0.0015; n=10) and hemoglobin level (p=0.019; n=10). A reduced number of undifferentiated cells (blast cells) (p=0.0021; n=9) and an increase of neutrophils (p=0.0194; n=9) were also detected in PB. EGCG treatment significantly increase the APL mice survival (medium survival 13 vs 15 days, p=0.0017). Notably, EGCG also reduced the expression of CD117+ in the BM cells while increasing Gr-1+/Mac-1+ expression possibly related to a myeloid differentiation (p=0.0161; n=4). Apoptosis however, was not detected in the BM cells, despite the fact that EGCG treatment induces apoptosis of total spleen cells (p=0.0197; n=10) measured by Annexin/PI. This apoptotic effect was confirmed by activation of caspase-3 and -9. In addition, a significant increase in reactive oxygen species (ROS) production was detected in CD117+ (p=0.0255; n=10) and Gr-1+ (p=0.0062; n=10) BM cell populations. ROS induces apoptosis through the loss of mitochondrial transmembranopotentials and activation of caspase-3 and -9. Moreover, excess of ROS might also induce differentiation of myeloid leukemic cells to mature cells. Taken together, our results demonstrate that EGCG has anti-leukemic effects on APL model by inducing apoptosis and cell differentiation, and suggest that this could be an interesting compound for leukemia treatment.

Ganoderma lucidum derivative fraction effects in triple-negative breast cancer.
G. Ortiz-Soto1, C.L. Santiago Negron2, I. Suarez Arroyo3, T. Ling4, F. Rivas3, M.M. Martinez-Montemayor1; 1Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR; 2Biotechnology Department, University of Puerto Rico Bayamon, Bayamon, PR; 3Chemical Biology Therapeutics, St. Jude Children’s Research Hospital, Memphis, TN

Breast cancer (BC) is known as the leading cause of cancer among women in the United States and Puerto Rico. Moreover, triple-negative breast cancer (TNBC) is characterized by the absence of estrogen and progesterone receptors as well as lacking the presence of the epidermal growth factor receptor 2 (HER2). Since there are no targeted therapies available, currently, there are very few options of treatments for TNBC. Thus, the development of novel strategies is necessary to combat this deadly disease. The objective of this study is to identify the effects of fractions derived from Ganoderma lucidum extract (GLE) and test their efficacy in TNBC cells. Pulverized GLE (10.0g) was dissolved in 150mL of isopropanol and refluxed for 24h. The resultant extract was filtered, and the solvent evaporated. The crude oil was fractionated via silica gel column chromatography. Based on MS and NMR analysis, 8 fractions were prepared for biological evaluation. Further purification via preparatory HPLC and structure elucidation of active fractions is currently under investigation. Additional GLE (10.0g) was extracted with isopropanol for 24h, and the crude compound was purified by silica gel column chromatography (hexane/ethyl acetate, 1:9) to generate 14 fractions. Further assessment of the
fractions resulted in similar chemical composition so they were combined into 8 unique fractions based on MS, where F3 proved to have the greatest efficacy. TNBC cells (MDA-MB-231 & SUM-149) were then treated with increasing concentrations of F3 ranging from 0 to 0.3 mM for 72h. Our results show that F3 significantly decreased MDA-MB-231 and SUM-149 cell viability. The IC50 for F3 in MDA-MB-231 cells was 12.7 μM compared to 0.3 mg/mL of GLE. The IC50 for F3 in SUM-149 cells was 14.7 μM compared to 0.2 mg/mL of GLE. Thus, our data suggests that the GLE F3 fraction is a potential compound against TNBC. This work was supported by NIH NIGMS #GM111171 (MMM), SGRP 2017-00143 (MMM and GOS), NIMHD #MD007583 (MMM), GM103475 (UPR MMM) and Title-V-PPOHA #P031M105050 and Title-V-Cooperative #P031S130068 from the U.S. Dept. of Education.

Board Number: B324
The cytotoxic effects of purified *Ganoderma lucidum* compounds on triple negative breast cancer.

R. Vallejo Calzada1, I. Suarez Arroyo1, C.L. Santiago Negron2, T. Ling3, F. Rivas3, M.M. Martinez-Montemayor2;
1Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR, 2Biology Department, University of Puerto Rico Bayamon, Bayamon, PR, 3Chemical Biology Therapeutics, St. Jude Children's Research Hospital, Memphis, TN

Successful breast cancer therapies involve a systemic approach combining chemotherapy, surgery, and other options including targeted therapies. Triple negative breast cancer (TNBC) patients are diagnosed with a form of cancer that lack hormone (ER & PR) and growth factor (HER2) receptors targeted during therapy. TNBC's aggressive nature and the lack of approved targeted therapies often leave patients distressed about the prognosis of their disease. The objective of this study is to examine the effects of purified compounds extracted from *Ganoderma lucidum* (GLE) in TNBC cells and compare its effects to those observed with similar steroidal clinical therapeutic agents. Pulverized GLE (10.0g) was dissolved in 150mL isopropanol and refluxed for 48h. The resultant extract was filtered, and the solvent evaporated. The crude oil was fractionated via silica gel column chromatography to provide 8 fractions (10%EtOAc-5%MeOH). Based on TLC, MS and NMR analysis, 8 fractions were prepared for biological evaluation and two fractions were further purified based on biological activity. These fractions were purification via preparatory HPLC and structure elucidation provided GA and an isoform LZ, which are currently being elucidated. MDA-MB-231 & SUM149 TNBC cells, and non-cancerous MCF-10A cells were seeded and treated for 72h with increasing concentrations ranging from 0 to 64μM of GA, LZ, or eight clinical candidates (SJ-1010, 1030, 5692, 7272, 7380, 7493, 7420, or 8468) with similar chemical core scaffold were used to evaluate potential biological target(s). Cell viability was determined by fluorescence detection. Finally, we assessed apoptotic activity using Annexin V staining in SUM149 cells treated with GA. Results demonstrate that GA causes a dose-dependent decrease in TNBC viability, with an IC50 of 23.0 and 40.3μM, in 231 and SUM149 cells respectively. LZ did not appear to confer any significant cytotoxic effect on TNBC cells, suggesting that its mode of action is different to that of GA. Treatments with two clinical candidates showed some degree of cytotoxicity, suggesting that stereochemical alterations of GA affect its effectiveness. None of the compounds were cytotoxic to non-cancerous cells at the concentrations tested. GA has potential therapeutic properties against TNBC. Our findings indicate that either synergetic mechanisms are present when cells are treated with the pure extract or we have yet to isolate the compound responsible for the observed activity of the pure extract. This work was supported by NIH GM111171 (MMM), MD007583 (MMM), SGRP 2017-00143 (MMM), MD008149

Sunday-205
Cancer cell metastasis, the process by which cancer cells migrate and form new tumors elsewhere in the body, accounts for approximately 90% of cancer-related deaths. Consequently, finding new ways to hinder cancer cell metastasis is crucial for the effective treatment of late-stage cancer patients. For the last thirty years, the majority of anticancer drugs have originated in some form from natural compounds. These compounds continue to be the main source of disease treatment. Naturally occurring flavonoids have been found to have anticancer effects on various cancer cell lines. However, the effects of flavonoids have not been extensively studied on breast cancer cells. In this project, we tested the effects of acacetin and pinostrobin on MDA-MB-231 invasive breast cancer cells. Using scratch and transwell assays, both acacetin and pinostrobin inhibited MDA-MB-231 cell migration in a dose-dependent manner. However, neither of the drugs had any effect on cell proliferation when tested over a wide range of drug concentrations. In addition, both acacetin and pinostrobin produced approximately a 58% and 40% inhibition on cell adhesion, respectively. Interestingly, while both acacetin and pinostrobin inhibited cell adhesion, there was no measureable difference in focal adhesion formation, compared to the control, when treated with various concentrations of either acacetin or pinostrobin. These results suggest that both acacetin and pinostrobin mediate their effects on motility by preventing breast epithelial cell adhesion. However, additional studies are necessary to better understand how acacetin and pinostrobin alter cell adhesion dynamics to influence MDA-MB-231 cell migration.

Triale negative breast cancer (TNBC) represents approximately 20% of all breast cancer cases worldwide. Prognosis for this subtype of cancer is especially dire due to the absence of Estrogen (ER), Progesterone and Human Epidermal Growth Factor receptors, usually targeted by neoadjuvant therapies like Tamoxifen. *Myrothamnus flabellifolius* (MF), a well-studied South African medicinal herb, has shown significant potency against TNBC with minimal effect on normal cells. In this study, we use miRNA profiling, Ingenuity Pathway Analysis (Qiagen), MTT, immunoblots and immunofluorescence to characterize the targeted cytotoxic mechanism of MF in TNBC. We found deregulation in the expression of several oncogenic and anti-cancer miRNAs in TNBC post MF treatment. Using Ingenuity Pathway Analysis to analyze the miRNA expression profiles of the treated cells, we determined Estrogen Signaling as a pathway significantly affected by MF in TNBC. Immunoblots confirmed increase of the ERa/ERß ratio
in TNBC, a well-studied marker for Tamoxifen-therapy sensitivity in TNBC. MTT cell viability assay and Annexin V staining confirmed increased sensitivity to Tamoxifen post treatment with low doses of MF, with up to 70% cell death at half the IC\textsubscript{50} of Tamoxifen in TNBC. This study establishes a potential non-toxic therapeutic to supplement Estrogen-receptor targeting therapies in TNBC by increasing the ER\textsubscript{a}/ER\textsubscript{ß} ratio. The data also evaluates the ER\textsubscript{a}/ER\textsubscript{ß} ratio as a potential target for combination therapies in TNBC.

\textit{Ganoderma lucidum} in combination with carboplatin inhibits the DNA damage response in triple negative breast cancer cells.

I. Suarez Arroyo\textsuperscript{1}, M.M. Martinez-Montemayor\textsuperscript{1};

\textsuperscript{1}Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR

Management of triple negative breast cancer (TNBC) is challenging because of a lack of targeted therapy, aggressive behavior and poor prognosis. Interest in using platinum agents, such as carboplatin as a line of treatment in these patients emerged from data suggesting frequent DNA repair defects. However, carboplatin resistance may occur as a result of multiple factors including increased activation of DNA repair mechanisms. Studies show that \textit{Ganoderma lucidum} extract (GLE) sensitizes cancer cells to different anti-cancer therapies. Thus, we aim to investigate the effects of GLE in combination with carboplatin and to elucidate its effects in DNA Damage Response (DDR) signaling. Our hypothesis is that GLE sensitizes breast cancer cells to carboplatin therapy decreasing DDR. SUM-149 and MDA-MB-231 triple negative breast cancer cell lines were treated with several concentrations of carboplatin, GLE, or both treatments simultaneously for 72h. Our results demonstrate that when carboplatin and GLE are used in combination, their IC\textsubscript{50}s decreased in both breast cancer cell lines when compared to each treatment alone. Our data revealed that GLE and/or the combination decreases the expression of 53BP1, p-CHK2, p-CHK1, p-ATR, p-ATM and p-BRCA1 in SUM-149 and/or in MDA-MB-231 cells. In addition, the phosphorylation of the pro-apoptotic protein p53 was upregulated by the combination. Immunofluorescence studies on DNA repair proteins 53BP1 and phosphorylated \textit{\gamma}H2AX performed to detect DNA double strand breaks suggest that GLE and their combination impair DDR. Taken together, our results provide evidence of GLE’s potential in chemosensitizing TNBC cells to carboplatin therapy affecting the DDR. These results highlight GLE’s anti-breast cancer therapeutic potential. THE EFFECT OF RESVERATROL ON CELL VIABILITY IN THE BURKITT'S LYMPHOMA CELL LINE RAMOS.
A.H. Zambrano¹,², P. Jara², J. Spies², C. Cárcamo², G. Vargas², C.L. Otth¹,³, M. Salas²;
¹³Center for Interdisciplinary Studies on the Nervous System (CISNe), Universidad Austral de Chile, Valdivia, Chile, ²Instituto de Bioquímica y Microbiología, Universidad Austral de Chile, Valdivia, Chile, ³Instituto de Microbiología Clínica, Universidad Austral de Chile, Valdivia, Chile

Resveratrol is a polyphenolic natural compound produced by a variety of crops. Currently, resveratrol is considerer a multi-target anti-cancer agent with pleitropic activity, including the ability to prevent the proliferation of malignant cells by inhibiting angiogenesis and curtailing invasive and metastatic factors in many cancer models. However, the molecular mechanisms mediating resveratrol specific effects on lymphoma cells remain unknown. To begin tackling this question, we treated the Burkitt’s lymphoma cell line Ramos with resveratrol and assessed cell survival and gene expression. Ours results suggest that resveratrol shows a significant anti-proliferative and pro-apoptotic activity on Ramos cells, inducing the DNA damage response and modulating the expression of several genes that regulate the apoptotic process and their proliferative activity. This work was supported by grants FONDECYT REGULAR 1141067, and DID UACH S-2016-48.

Purification and characterization of natural chemopreventative compounds for the treatment of prostate adenocarcinoma.
O.H. Richmond III¹, Z. Wang¹;
¹Biological Sciences, Clark Atlanta University, Atlanta, GA

Metastatic prostate adenocarcinoma is the leading cause of morbidity and the second-leading cause of mortality among American men. The development of prostate cancer is propagated by a plethora of genetic and proteomic abnormalities. Yet, the specific biology underpinning the initiation and promotion of tumor development remains to be elucidated. The protein arginine methyltransferase (PRMTs) family of proteins regulates epigenetic and post-translational modifications within protein signaling pathways. Under abnormal conditions, these proteins can function to constitutively drive the growth and/or proliferation of dysregulated cells. It has been reported that protein arginine methyltransferase 5 (PRMT5) is over-expressed and/or upregulated in numerous cancer types, including breast, colorectal, leukemia, lung and melanoma cancers. Previously, we have demonstrated that PRMT5 is upregulated in prostate cancer and correlates with disease progression. More specifically, we have demonstrated that PRMT5 localized to the cytoplasm, functions to drive both growth and proliferation of prostatic tumors. A growing body of literature reports antitumor activity from the Dendrobium genus of orchid plants. We have extracted, purified and begun to characterize natural PRMT5 inhibitory compounds from the orchid plant, Dendrobium denneanum. Additional preliminary studies using crude extracts on LNCaP and PC3 prostate cancer cell models have revealed halted growth through G2 cell cycle arrest. A compound purified from Dendrobium elicited a cell cycle G1-growth arrest, in addition to inhibition of proliferation of both cell models at a low-micromolar concentration. We hypothesize that purified phytochemical compounds obtained from the orchid plant may exhibit an inhibitory effect of PRMT5 activity on the progression of metastatic prostate cancer. In order to accomplish this objective, we will: (i) elucidate the molecular structure of the purified compound, (ii) identify the selectivity to other methyltransferases
and determine the global effects of inhibition on cell cycle regulatory gene targets and (iii) test the purified compound for prostate cancer prevention in the transgenic adenocarcinoma of the mouse prostate (TRAMP) model. Targeting of PRMT5 for inhibition potentiates novel therapeutic opportunities for better understanding the aberrant molecular regulation of prostate cancer growth and proliferation as well as possible therapeutics for mitigation of the disease.

Rosehip (Rosa canina) Extracts Decrease Human Breast Cancer Cell Migration and Invasion.
P.M. Martin¹, P.D. Cagle²
¹Biology, North Carolina AT State University, Greensboro, NC

Triple Negative Breast Cancer (TNBC) is an aggressive form of breast cancer, characterized by the characteristic lack of receptors such as human epidermal growth factor receptor-2 (HER-2), the estrogen receptor (ER), and the progesterone receptor (PR) which is normally targeted in adjuvant therapy in effective therapies. Major concern for side effects of commercial drugs and the emergence of drug-resistant cancer cells, has created interest in the use of naturally occurring substances that possess chemo-preventive and chemotherapeutic properties in cancer treatment. Rosehip (Rosa canina) extracts which have traditionally been used as dietary supplements to relieve symptoms associated with diarrhea, gastritis, and rheumatoid arthritis, have also been shown to prevent cancer cell growth and migration in various cancers. Specifically, we have previously demonstrated rosehip extracts can prevent brain tumor cell growth, induce a G0/G1 cell cycle arrest and stall cell migration. This study investigated the efficacy of rosehip extracts in preventing cell migration and invasion in triple negative (HCC1806 and HCC70) breast cancer cells. Treatment with rosehip extracts (1 mg/ml, 250 µg/ml, 25 µg/ml, and 25 ng/ml) caused a decrease in cell migration in each of the breast cancer cell lines tested. Additionally, pretreatment of these cell lines with rosehip extracts decreased the level of AKT, MAPK, and NF-κB phosphorylation, suggesting that these extracts prevent TNBC cell migration by blocking these signaling mechanisms. Anti-invasion effects were also observed after exposure to rosehip extracts (1 mg/mL and 25 µg/ml). The observed decrease in cell invasion correlated with decreases in MMP expression. These data suggest rosehip extracts are capable of decreasing cell invasion by down-regulating MMP expression. Rosehip extracts also had a synergistic effect with Doxorubicin (20µM), a chemotherapeutic agent currently used to treat breast cancer, to deplete triple negative breast cancer cell migration. Taking together these data demonstrate rosehip extracts are capable of decreasing cell migration and invasion in triple negative breast cancer cells by attenuating MAPK, AKT, and NF-κB signaling mechanisms. Additionally, these data demonstrate the enhanced effect of Doxorubicin with rosehip in preventing breast cancer cell migration and invasion. Additionally, these results demonstrate rosehip extracts may serve as an alternative or compliment to current chemotherapeutic treatments for triple negative breast cancer.

Involvement of HIF-1α signaling in leukemia model by polyphenols of green tea.

C.O. Torello1, R.N. Shiraishi1, F.I. Della Via1, T.C. L. Castro1, F. Martins1, M.C. Alvarez De Prax1, M.L. Queiroz2, E.M. Rego2, S.T. Saad1;

1Hematology and Transfusion Medicine Center, University of Campinas, Campinas, Brazil, 2Department of Internal Medicine, University of São Paulo, Ribeirão Preto, Brazil

Green tea (GT) is chemically characterized by the presence of large amounts of polyphenols, which are known as the most effective substances with the ability to inhibit tumorigenesis. Acute myeloid leukemia is an aggressive hematologic malignancy and there is no sufficient evidence that supports a protective role of GT intake on its development. Our previous findings showed that GT administration to leukemia mice reduced leukocytosis and blasts in the peripheral blood (PB), bone marrow (BM) and spleen (SP), and increased mature cells in the BM. We also observed that GT induced apoptosis; reduced the number of CD34+ and CD117+ neoplastic clones; and increased ROS production on Gr1+ cells but reduced on CD34+ and CD117+ cells from the BM. Studies have shown that reactive oxygen species (ROS) increase the expression of CXCR4 in cancer cells through nuclear translocation of HIF-1. We then studied CXCR4 expression and localization of HIF-1α on CD34+ and CD117+ cells of acute promyelocytic leukemia mice. After 2 Gy irradiation, leukemia cells from hCG-PML-RARα transgenic mice were injected in the tail vein of NOD SCID mice. Hematologic counts were monitored and the following criteria was used for the diagnosis of leukemia: presence of at least 1% of blast in PB associated with leukocytosis above 30 000 cells/L, hemoglobin levels below 10 g/dL, and thrombocytopenia below 500×103 cells/L. Twelve days after transplantation, mice were then submitted to daily oral treatment (gavage) with 250 mg/kg GT or vehicle only (water) for 5 consecutive days and were sacrificed. Our results show that GT decreased the expression of CXCR4 in the surface of CD34+ (197±8 vs untreated 142±20) and CD117+ cells (9028±1367 vs untreated 4196±970), detected by flow cytometry. Reduction of HIF-1α activation was also observed, demonstrated by the lower co-localization of HIF-1α with the nuclei, using ImageStream imaging flow. Literature data have shown that GT polyphenols can inhibit the activation of HIF in cancer cells. Besides, a tumor microenvironment that is rich in ROS may influence CXCR4-mediated expression and functions, encouraging tumor development. Expression of CXCR4 can induce leukemia cell trafficking and homing to the marrow niche, where SDF-1, its ligand, retains leukemia cells in close contact with stromal cells that provide growth and drug resistance signals. Therefore, it is possible that GT could affect ROS levels on neoplastic cells, which may impair HIF-1α activation, ultimately reducing CXCR4 expression and cell survival. The impairment of SDF-1/CXCR4 axis induced by GT could cause loss of adhesion of leukemia cells in the BM, leading to mobilization out of their niche and becoming these cells more susceptible to chemotherapy drugs.

The Antitumorigenic Effects of Natural Compounds, Conessine and Cardamonin, on MDA-MB-231 Breast Epithelial Cells.

M.B. Kinder1, S.R. Gehler1;

1Biology, Augustana College, Rock Island, IL

In addition to their potential of reducing tumor growth, natural compounds, such as cardamonin and conessine, may be able to stifle cancer cell migration and invasion in order to hinder tumor cell metastasize. Conessine and cardamonin are natural compounds that have been shown to have
antitumorigenic properties on some forms of cancer cells, but little has been researched on the effects of these compounds on breast epithelial cells. Conessine inhibited MDA-MB-231 cell proliferation in a dose-dependent manner, while increasing concentrations of cardamonin increased cell proliferation. However, MDA-MB-231 cell migration decreased when treated with either conessine or cardamonin using both scratch assays and transwell assays. Furthermore, conessine inhibited cell adhesion at varying concentrations with an approximately 39% reduction in cell adhesion when treated with 40uM conessine. However, cardamonin had no effect on cell adhesion. In addition, there was a 20-29% reduction in focal adhesion area, as assessed using an anti-FAK397 antibody, when treated with either conessine or cardamonin. These results suggest both conessine and cardamonin inhibits MDA-MB-231 breast epithelial cell migration and adhesion. However, additional experiments are necessary to further elucidate the mechanisms by which these natural compounds mediate their effects.

Suppression of breast cancer cell proliferation by combinations of the phytochemicals fisetin, luteolin and hesperetin.
T. Beaumont1, M. Castanon1, H. Sabol1, K.M. Baker1;
1Biology, University of Indianapolis, Indianapolis, IN

Epidemiological studies suggest that a diet rich in plant flavonoids may prevent cancer. Fisetin, luteolin, and hesperetin, dietary flavonoids found in a variety of fruits and vegetables, have been shown to exhibit anticancer activity in vitro. In this study, we evaluated the antiproliferative effects of fisetin, luteolin, and hesperetin, individually and in combination, using MCF-7 breast cancer cells. We found that fisetin, luteolin, and hesperetin each inhibited MCF-7 cell proliferation in a dose dependent manner. Furthermore, we found that co-administration of lower doses of fisetin and luteolin or hesperetin and luteolin led to a greater inhibition of cell proliferation than either agent alone at the same dose and indicate an additive effect. These results suggest that combinatorial treatments using fisetin, luteolin, and hesperetin may be an effective chemotherapeutic strategy against breast cancer. Additionally, these findings support the hypothesis that consumption of flavonoids may play an important role in breast cancer chemoprevention.

Ganoderma lucidum extract (GLE) decreases stemness properties via STAT3 regulation in Triple Negative Breast Cancer models.
T.J. Rios1, P. Lopez2, V. Rivera-Amill2, Y. Yamamura2, M.M. Martinez-Montemayor1;
1Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR, 2Basic Sciences, Ponce Health Sciences University, Ponce, PR

Triple-negative breast cancer (TNBC) accounts for approximately 15-20% of all breast cancer (BC) cases worldwide. TNBC is an aggressive breast cancer subtype with poor clinical outcome, increased mortality rate, high risk of early recurrence, and the lack of effective therapies. This aggressive nature may be explained by the presence of breast cancer stem cells (BCSCs), which are involved in tumor initiation, progression, metastasis, recurrence, and therapy resistance. With rising evidence that cancer stem cells (CSCs) are present within the tumor, it is vital to understand the molecular mechanisms that regulate self-renewal, differentiation, and maintenance of stem cell properties. Interestingly, the signal transducer and activator of transcription 3 (STAT3) participates in the development and progression of
BCSCs, but its role in TNBC remains unclear. Moreover, BCSCs are defined by the CD44+/CD24-phenotype, which correlates with a worse prognosis in TNBC patients. Furthermore, the transcription factors Nanog, Sox2, and Oct4A, are essential in maintaining CSCs phenotype, where activation of STAT3 leads to enhanced Oct4 and Sox2 expression. Importantly, it has become a major challenge developing non-toxic targeted therapies to improve the outcome of TNBC patients. In this regard, our laboratory investigates the role of *Ganoderma lucidum* extract (GLE), a medicinal mushroom used in complementary medicine. We hypothesize that STAT3 regulation by GLE will decrease stem cell properties in our TNBC cell line, MDA-MB-231 cells. Our in vitro results demonstrates at 24hr GLE significantly decreases total JAK2 and STAT3 and their phosphorylation, ALDH, and Nanog expression in MDA-MB-231 cells. In addition, at 72hr GLE significantly decreases total and the phosphorylation of JAK2 and STAT3, ALDH, and the three transcription factors (Sox2, Nanog, and Oct4A). Furthermore, our flow cytometry results at 24hr and 72hr show that GLE significantly decreases the CD44+/CD24- population in MDA-MB-231 cells. Additionally, our in vivo studies demonstrate that GLE significantly decreases tumor volume of mice injected with CD44+/CD24- cells, and tumor weight of GLE treated mice was marginally significantly lower (p=0.053) compared to controls. We can conclude that STAT3 regulation by GLE decreases stemness of TNBC. **Epigallocatechin gallate-induced magnetic nanoparticle uptake by glioma cells: Mechanism via nitric oxide/cGMP signaling.**

N. Wu¹,², S. Hsu¹, Y. Lu², Y. Ma²;

¹Graduate Institute of Biomedical Sciences, Chang Gung University, Taoyuan City, Taiwan, ²Department of Physiology Pharmacology, Chang Gung University, Taoyuan City, Taiwan, ³Department of Biomedical Sciences, Chang Gung University, Taoyuan City, Taiwan

Magnetic nanoparticles (MNP) can be potentially used as carriers in a drug delivery system with magnetic targeting; MNP interaction with tumor cells may be crucial in achieving therapeutic efficacy. Epigallocatechin gallate (EGCG), a polyphenolic component in green tea, enhances MNP uptake by glioma cells (Lu et al., Nanoscale 6:10297, 2014), but the mechanism remains unclear. Since EGCG has been demonstrated to interact with a 67 kDa laminin receptor (67LR) and activate nitric oxide/cGMP pathway to induce apoptosis, we asked whether EGCG-induced MNP uptake is mediated by nitric oxide/cGMP signaling. Uptake of MNPs coated with carboxymethyl-dextran (200 nm) by LN229 glioma cells was determined by measurement of cell-associated MNPs (MNPcell) using potassium thiocyanate colorimetric method. EGCG at micromolar range increased MNPcell in a concentration-dependent manner, and the effects of EGCG were synergistically enhanced by magnetic field. Inhibition of nitric oxide synthase using N⁵-O⁴-Nitro-L-arginine methyl ester hydrochloride (L-NAME) significantly attenuated EGCG-induced MNPcell increase in a concentration-dependent manner in the absence, but not presence of the magnet. In addition, heparin, a 67LR-binding glycosaminoglycan, significantly attenuated EGCG-induced MNPcell increase in the absence, but not presence of the magnet. Pretreatment with MLuC5, an antibody against 67LR, and NSC47924, a 67LR inhibitor, attenuated EGCG-induced MNPcell increase by up to 35% and 22%, respectively. In addition, Bay 63-2521, an activator of soluble guanylate cyclase, and
zaprinast, a phosphodiesterase inhibitor, significantly increased MNP<sub>cell</sub>. These results indicate that cGMP level in glioma cells is positively associated with levels of MNP<sub>cell</sub>. Although EGCG may also interact with epidermal growth factor receptor (EGFR) and modulate EGFR signaling, C225, an antibody against EGFR, exerted no effect on EGCG-induced MNP<sub>cell</sub> increase. In conclusion, EGCG-induced nitric oxide/cGMP signaling, probably via interaction with 67LR, may mediate the enhancing effects of EGCG on MNP uptake by glioma cells.

The place of Phytobiological Compounds in Colorectal Cancer: An in vitro study.
M. Francis<sup>1,2</sup>, A. Geagea Jurju<sup>1,3</sup>, S. Al Kattar<sup>1</sup>, K. Cehovin<sup>1</sup>, M. Diab Assaf<sup>2</sup>, S. Harakeh<sup>4</sup>, A. Eid<sup>1</sup>, A.R. Jurju<sup>1</sup>;
<sup>1</sup>Anatomy, Cell Biology and Physiology, Amrican University of Beirut, Beirut, Lebanon, <sup>2</sup>Doctrol School of Science and Technology, Lebanese University, Beirut, Lebanon, <sup>3</sup>University of Palermo, Palermo, Italy, <sup>4</sup>King Fahd Center for Medical Research, Jeddah, Saudi Arabia

Introduction: Colorectal cancer is a leading cause of cancer death worldwide with progressive appearance of resistance towards permitted chemotherapies. Novel complementary treatments using antioxidants were reported to have beneficial effects in its management. Aim: The aim of this study is to assess the effect of a combination of antioxidants (Curcumin, quercetin, cruciferex, green tea extract and resveratrol) on colorectal cancer cells and delineate the possible mechanism of action. Materials and methods: Two CRC cell lines HCT116 (P53/-), and HT29(P53+/+) were used, in addition to a human leukemic monocyte cell line THP1, cultured and treated with increased concentrations of the phytobiological (PB) mixture ranging from 5 to 150 μg/ml for different time periods. Two methods were used to determine the anti-proliferative and cytotoxic activity: The Trypan Blue Exclusion Assay and the 3-(4,5-dimethythiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) assay. In addition, Annexin V-FITC Apoptosis Assay was used. Results: PB had a dose related cytotoxic effect at 24, 48 and 72h against HCT116, HT29.On the other hand, the effect was not significant on THP1.At 48H, the IC50’s were 50.73±50 μg/ml for HCT116, 46.94 ± 150 μg/ml for HT29 and 72.45±150 μg/ml for THP1. Annexin data is in progress. Conclusion: PB was found to have a promising anti-proliferative effect for both types of cancer cells. Concerning the Annexin V-FITC Apoptosis Assay to identify the underlying mechanism of action of PB against colorectal and leukemic cancer cell lines, the results are still preliminary.

Cytotoxic activity of a new lectin from Rhizoctonia solani in vitro.
R. Muhammediev<sup>1</sup>, T. Salikhova<sup>1</sup>, R. Muhammediev<sup>1</sup>, T. Bagaeva<sup>1</sup>;
<sup>1</sup>Institute of Fundamental medicine and biology, Kazan (Volga Region) Federal University, Kazan, Russia

Lectins are specific carbohydrate-binding proteins, which hold great potential for cancer therapy<sup>1</sup>. Micromycetes are promising and insufficiently explored resource of lectins with different structures and activities. A new lectin preparation from mycelium of <i>Rhizoctonia solani</i> was previously isolated and characterized<sup>2</sup>. This lectin is a galactose-specific, Ca/Mg-dependent protein with dimeric structure and molecular weight of about 36 kDa.

In this study, cytotoxic activity of the lectin preparation was evaluated on different human cells, including mammary cancer (MCF-7), prostatic carcinoma (PC-3), cervical carcinoma (HeLa), embryonic kidney (HEK-293) cells as well as human skin fibroblasts (HSF). According to MTT proliferative assay, the
lectin preparation possessed noticeable toxicity towards the cancer cells with its half-maximum inhibitory concentration ($IC_{50}$) varied from 3 to 10 μg/ml, which are comparable to those for some plant lectins. Relatively low activity of the lectin was observed for HEK-293 cells and HSF, indicating preferable cytotoxic effect of the lectin towards cancer cells.

The variation in $IC_{50}$ values for cancer cells versus untransformed cells as well as between cancer cell lines can be attributed to differences in composition of the plasma membrane of mammalian cells, e.g. structure of the carbohydrate component on their surface. The specific membrane-bound carbohydrates in the cancer cells seem to assist their interaction with the lectin and promote lectin-induced cytotoxicity7.

Our results show a potential of the lectin isolated from R. solani in selective killing of cancer cells. The molecular structure and mechanism of cytotoxicity of this lectin preparation will be studied elsewhere.

**Title:** Epigallocatechin-3-gallate regulates BRCA1 expression in triple negative breast cancer.

Authors: Fernando J. Garzon, Lisset A. Duran and Lissette Delgado-Cruzata

Breast cancer is a hostile disease that is responsible for tens of thousands of deaths of mostly women every year. Diet is considered an important factor in breast cancer prevention. Some studies suggest that green tea consumption has the potential to reduce breast cancer risk. Specifically catechins, a group of green tea polyphenols, have been shown to have anti-tumor effects. One of the catechins, epigallocatechin-3-gallate (EGCG), has been shown to suppress proliferation, to inhibit migration and invasion, as well as to induce apoptosis in ER+ and ER- breast cancer. Studies suggest epigenetic mechanisms underlie these effects in ER-positive breast cancer cell lines, by modulating DNA methylation through the inhibition of DNA methyltransferase (DNMT1). However less is known about the epigenetic effects of EGCG in ER- and triple negative breast cancer and whether its effects are mediated by changes in miRNA expression levels. The aim of this study is to investigate the effects of EGCG in triple negative MDA-MB-468 breast cancer cells. Specifically how EGCG affects BRCA1 expression levels and BRCA1 targeting microRNA. We treated MDA-MB-468 with 25μM and 50μM of EGCG for 48 hours and use Taqman assays to determine expression levels. We found a statistically significant decrease in BRCA1 gene expression with higher EGCG treatment concentrations (BRCA125μM= 29.96%+6.05% (p=0.009); BRCA150μM=16.20%+2.49% (p=0.006) when compared to untreated). We also found that while not statistically significant the levels miRNA 182, which has been identified as a miRNA that regulates BRCA1, were higher with increasing concentrations of EGCG (miR-18225μM= 108.62%+0.72% (p=0.381); miR-18250μM= 112.71%+0.08% (p=0.302) when compared to
untreated). Our results suggest that BRCA1 expression can be modulated by treatment with EGCG, and that is possible that miRNAs have a partial role in regulating the expression of this gene as a response to treatment.

THE FLAVONOID QUERCETIN MODULATES NRF2 EXPRESSION AND INDUCES APOPTOSIS IN XENOGRAFT MODELS AND LEUKEMIA CELLS LINES.

M.C. Alvarez De Prax¹, C.O. Torello¹, S.T. Saad¹;
¹HEMATOLOGY AND HEMOTHERAPY CENTER, UNICAMP, CAMPINAS, Brazil

Nuclear factor-erythroid 2 related factor (NRF2) is persistently activated in many human tumors, including acute myelogenous leukemia, in this way inhibition of nrf2 activity may be a promising target in leukemia therapy. In the present study, we evaluated the effect of Qu, a natural polyphenolic flavonoid compound, as a modulator of NRF2. This study was performed in vivo in human xenograft acute myeloid leukemia (AML) models, and in vitro using leukemia cells lines. Qu treatment induced apoptosis and resulted in an increased cell arrest in G1 phase of the cell cycle. Reduced tumor growth, up regulated BCL2L11 and BAX at message levels and downregulated NRF2 at protein and message levels (p<0.05). In our previous work (Alvarez, 2016) we found that Qu treatment up-regulated the expression profile of 63% (n=17) and 24% (n=4) (in vitro and in vivo, respectively) of the 84 miRNAs evaluated. Of these, 42% (n=7) and 100% (n=4) corresponding exclusively to miRNAs that target anti-apoptotic genes and to miRNAs that have been demonstrated to have pro-apoptotic functions. Further, expression levels of miR-1, miR- 206 and miR-133a and b were validated in xenograft model samples, resulting in a significant up-regulation of the expression levels in treated animals compared to controls (p<0.05). The up regulation of miR-1 and mir206 are related to decreased levels of NRF2 as these miRs levels were described as being regulated by NRF2, as a gain of NRF2 function in cancer cells attenuated expression of them. Therefore, Qu acting as an inhibitor of NRF2 might be a promising compound that may have application in AML treatment, however, the mechanism by which Qu decrease NRF2 expression remains to be investigated.

The Supernatant of RAW 264.7 cells M1 Polarized with Phellinus linteus Prevents the Migration and Invasion in Prostate Cancer Cells by Inhibiting the Epithelial-mesenchymal Transition Pathway.

H. An¹, S. Yu¹, H. Kim¹, S. Ahn¹;
¹Department of Microbiology Immunology, Pusan National University School of Medicine, Yangsan, South Korea

Most deaths from prostate cancer are due to treatment-resistant metastasis. *Phellinus linteus* has been used for centuries to prevent and treat several diseases in East Asia. Unlike cancer chemotherapy, radiotherapy and anticancer drugs, natural products that have been used from centuries can safely be given antitumor treatment without serious side effects. Once activated by interferon gamma or lipopolysaccharide (LPS), macrophages can kill cancer cells directly or by secreting the factor that kills the cancer cells indirectly. Epithelial-mesenchymal transition (EMT) is associated with stem cell markers of prostate cancer cells. By acquiring the characteristics of stem cells, resistance to apoptosis is increased, aging is reduced, immune response escapes, and ultimately resistance to treatment is
Achieved. EMT is considered an important step in cancer metastasis. The new components that target these EMT molecules can effectively block the interaction between cancer cells and other tissues. Phellinus linteus hot water extract (PL-HWE) was treated into mouse macrophage RAW264.7 cells to observe NO release that is an indicator of macrophages polarization into M1 type. iNOS, IL-1β, IL-6, TNF-α, COX2 and PSG2 were detected at the mRNA level by real-time PCR to confirm that the RAW 264.7 cells were polarized into M1 type. The supernatant of RAW 264.7, which was identified as the M1 type, was treated into prostate cancer cells at volume ratio of 5%, 10%, and 20% for 48h. As a result, mRNA and protein involved in EMT pathway were determined. Real-time PCR at the mRNA level, western blot at the protein level, and wound healing assay were performed to confirm. Based on this research, it can be a new way of preventing cancer metastasis through immunomodulation.

Colorectal cancer (CRC) is ranked as the third most common cancer and cancer-related mortality worldwide. Although the treatment outcome is very much improved for early stages of disease, however long-term survival rate is relatively poor for patients with an advanced stages due to the development of metastasis. Therefore, searching for anti-metastatic agent for CRC is urgently needed. Cleistanthin A (CA) is phytochemical derived from Phyllanthus taxodiifolius Beille (Euphorbiaceae family). In this study we investigated the anticancer activities as well as their underlying mechanisms of CA and its analogue (MUC535) in CRC cell lines, HCT-116 and SW480. By MTT assay, CA and MUC535 induced cytotoxic effects against HCT-116 and SW480 cell lines in concentration- and time-dependent manner. IC50 values of CA at 72 h in HCT-116 and SW480 cells were 0.63+0.25 micromolar and 1.26+0.29 micromolar, respectively. Moreover, IC50 values of MUC535 at 72 h in HCT-116 and SW480 cells were 0.079+0.019 micromolar and 0.59+0.198 micromolar, respectively. The cytotoxic activities of both compounds were not observed at 24 h. Treatment with CA and MUC535 for 24 h significantly reduced migration and invasion of HCT-116 and SW480 cells in dose-dependent manner. Treatment with 10 micromolar of CA suppressed CRC cell migration and invasion approximately by 60% and 40% for HCT-116; 60% and 70% for SW480 cells, respectively. Moreover, treatment with 10 micromolar of MUC535 suppressed CRC cell migration and invasion approximately by 30% and 35% for HCT-116; 50% and 35% for SW480 cells, respectively. Mechanistically, treatment of CA and MUC535 decreased focal adhesion kinase (FAK) Y397 phosphorylation in both CRC cell lines. Collectively, our results indicate that CA and its analogue (MUC535) suppress CRC cell migration and invasion partly through FAK-related signaling pathway. Therefore, CA and MUC535 have potential to be developed as anti-metastatic agents for CRC.
Colorectal cancer (CRC) is the third most common type of cancer in the world and the second leading cause of death among people (Siegel, Desantis, & Jemal, 2014). Rumex crispus extracts, a source of anticancer compounds, have demonstrated induction of apoptosis in colorectal cancer cells (DLD-1). Bhandari (2015) extracted water soluble compounds from the roots and leaves of Rumex crispus and screened those extracts for compounds that induced apoptosis in DLD-1 cells. A compound referred to as L19 was isolated and has been studied in more detail in this project. In this research, specific genes involved in apoptosis induction as a result of treatment of the DLD-1 cells with L19 are identified.

Accelerated solvent extraction (ASE) followed by high performance liquid chromatography (HPLC) was utilized to obtain larger amounts of L19. GC-Mass spectrometry was used to identify the compound L19. Apoptosis was measured by detecting the levels of caspase 3, 6 and 7 using the APO-one assay (Promega, Corp.) after treating the DLD-1 cells with varying concentrations of L19. Furthermore, the mechanism of apoptosis was determined using qRT-PCR and gene specific primers for caspase 8,10 (extrinsic pathway), 9 (intrinsic), 4, 5 and 12 (ER stress). RT2 Profiler™ PCR Array for human apoptosis genes was used to explore additional effects on genes involved in apoptosis. Microarray analysis using the Human OneArray® Microarray from Phalanx Biotech Group (California, USA) to determine which genes of other key cellular pathways are affected by the compound. A time course at 8, 12, and 24 hours exposure of the cells to L19 followed by qRT-PCR showed that caspases 1, 3, 6, 8, 9, 10, and 12 exhibits up regulation by 12 hours. RT² Profiler™ PCR Array using 12 hour cDNA showed a down regulation for BCL2 which was the inhibitor for intrinsic pathways (Favaloro et al., 2012). CASP 9, 3, Apaf-1, Bax and P53 genes, which are key factors for the intrinsic pathways in apoptosis, are shown to be up regulated. CASP 12 and BH3 proteins which are involved in the ER stress pathways had up regulation as well (Puthalakath, 2007). FAS, FASLG, CASP 10, 8, 7, 6, and 3 which are involved in the extrinsic pathway had the largest up regulation.

Colorectal cancer (CRC) is one of the most common type of cancer worldwide. To improve treatment outcome, new chemotherapeutic drugs are required. Aberrant activation of Wnt/β-catenin signaling pathway has extensively been reported to play an important role in colorectal cancer progression. Previously, the anticancer property of cleistanthin A (CA), a plant-derived compound from Phyllanthus taxodifolius Beille, has been demonstrated. However, the detailed molecular mechanisms have not been investigated. Therefore, we aimed to investigate the anticancer activity of CA on Wnt/β-catenin signaling pathway in human colorectal cancer cell lines, SW480 and HCT-116. We found that CA...
exhibited dose- and time-dependent cytotoxic activity against both CRC cell lines. CA enhanced DNA damage and suppressed the expression of survivin, an anti-apoptotic protein leading to CRC apoptosis cell death. In addition, CA suppressed the canonical Wnt signaling pathway as illustrated by reduction of β-catenin protein expression and β-catenin-mediated transcriptional activity. To further confirm the inhibitory effect on Wnt signaling pathway, the effect of CA on the expression of Wnt target genes was examined by real-time PCR. We found that the expression levels of Wnt target genes including Axin2, cyclin D1 and survivin were significantly reduced. The inhibitory effect on Wnt signaling pathway-mediated by CA was GSK-3β-independent since the transcriptional activity-mediated by GSK-3β insensitive β-catenin was still able to suppress by CA. Taken together, our results demonstrate for the first time that CA induces CRC cell apoptosis partly through induction of DNA damage and inhibition of Wnt/β-catenin signaling pathway. Therefore, CA has the potential for further development as a novel anticancer agent for colorectal cancer.

Characterization of monoclonal antibodies from mice immunized with phycocyanin as a medicinal substance.

1 Health Science, Nihon Institute of Medical Science, Moroyama, Japan; 2 Physiology, Saitama Medical University, Moroyama, Japan; 3 Biomedical Research Center, Saitama Medical University, Moroyama, Japan; 4 Health and Nutrition, Kagawa Nutrition University, Sakado, Japan

Background: Spirulina platensis is a blue-green algae. Phycocyanin (PC) is a light-harvesting, pigment-binding protein isolated from S. platensis (N. T. Eriksen, 2008). PCs isolated from blue-green and red algae are classified as crude PC (C-PC) and R-PC, respectively (A. N. Glazer, 1984; C. M. Hilditch, et al., 1991). C-PC has been reported to have various medicinal properties, including antioxidant, inflammatory, and antitumor effects. However, the molecular mechanisms underlying these properties remain poorly understood. Therefore, to reveal these molecular mechanisms, we investigated the function of PC, particularly regarding the anti-tumor effect, and then determined making monoclonal antibodies (mabs) against the PC.

Materials and Methods: C-PC derived from S. platensis was kindly provided by Dainippon Ink Corporation (Ichihara, Chiba, Japan). Phycocyanobilin were purchased from Santa Cruz Biotechnology (Santa Cruz, CA, USA). Other materials were from Wako and Sigma-Aldrich.

Female Balb/c mice were immunized with C-PC and Freund’s complete or incomplete adjuvant multiple times over several months. We obtained several mabs in accordance with previously reported methods (K. Yoshimura et al., 1996). Two established mabs (S5C2 and T1) were characterized with immunocytochemistry (ICC), Western blotting, enzyme-linked immunosorbent assay (ELISA), and mab isotyping. Results and discussion: ICC revealed that S5C2 and T1 recognized intact cyanobacteria, S. platensis, which forms spiral-shaped, multicellular filamentous cyanobacteria. Interestingly, these mabs appear to recognize different constituents in osteosarcoma U2OS cells. Western blotting of C-PC with these mabs also suggested that both mabs bind these constituents, revealing a few bands corresponding to the major components of PC. ELISA indicated that both mabs reacted with the entire PC fraction, whereas those almost did not bind phycocyanobilin. A mouse isotyping antibody kit showed that the isotypes of both mabs are IgM and kappa. In the present study, we indicate the characterization of those two mabs from mice immunized with C-PC and discuss the possible applications.
Curcumin is a natural product extracted from C. longa plant with remarkable anti-cancer activity and low toxicity. However, the extensive preclinical and clinical studies have shown that curcumin exhibit poor bioavailability and fast metabolism. The product of metabolic destruction of curcumine, dehydrozingerone (DZG), is stable under physiological conditions and possesses expressed antitumor properties. Several studies demonstrated promising pharmacological potential of DZG and its synthetic modifications. In this work we explored several bioisosteric analogs of DZG based on pyridoxine (vitamin B6) scaffold. Specifically, we synthesized a series of DZG bioisosteres, in which the aromatic part was replaced by substituted pyridoxine rings, and studied their biological properties. The obtained compounds were screened for cytotoxicity against several tumor cell lines (mammary gland, lung adenocarcinoma, glioblastoma, colorectal carcinoma, and melanoma cells) in comparison with DZG and doxorubicin (DOX). Most of the studied compounds demonstrated high cytotoxic activity against the tumor cells with IC_{50} in the range of 0.5-6.6 µM, which is comparable to cytotoxic activity of DOX and 6-20 times higher than cytotoxicity of DZG. At the same time, the cytotoxicity of the leading compounds against the normal HEK293 cells was lower than that of DOX though higher than that of DZG. As a result, several compounds had high selectivity indexes (SI from 6 to 57) as compared to DZG and DOX. According to flow cytometry data, the leading compounds arrest the cell-cycle in G2/M phase and inhibit further transition of cells to G0/G1 phase. Similar action is typical of DZG and some commercial antineoplastic agents such as paclitaxel. Interestingly, our DZG analogs show only slight influence on the membrane potential of mitochondria and probably cannot serve as apoptosis inducers. By analogy to DZG, they also demonstrate expressed antioxidant properties and reduce the level of reactive oxygen species in tumor cells. Our compounds also significantly suppress the migration activity and invasiveness of tumor cells in vitro. The leading compound also shows excellent safety in in vivo acute toxicity experiment (LD_{50} > 2000 mg/kg of weight, mice, p.o.). The obtained results demonstrate that the new pyridoxine-based bioisosteres of DZG are promising antineoplastic agents which can be recommended for further in vivo studies on human tumor xenograft models.

The WAVE3-YB1 interaction regulates cancer stem cells activity in breast cancer.
K. Sossey-Alaoui\textsuperscript{1}, K. Bledzka\textsuperscript{1}, W.P. Schiemann\textsuperscript{1}, B. Schiemann\textsuperscript{3}, E.F. PLo\textsuperscript{1};
\textsuperscript{1}Molecular Cardiology, Cleveland Clinic Lerner Research Institute, Cleveland, OH, \textsuperscript{2}Case Compherensive Cancer Center, Cleveland, OH

Resistance to therapy is the main cause of tumor recurrence and metastasis, and cancer stem cells (CSCs) play a crucial role in this process, especially in triple-negative breast cancers (TNBCs), for which chemotherapy is the main course of treatment. Unfortunately, no FDA-approved treatment is currently available for this subtype of BC, which explains the high rate of mortality in patients with TNBC tumors. WAVE3, a member of the WASP/WAVE actin-cytoskeleton remodeling family of protein, has been established a major driver of tumor progression and metastasis of several solid tumors, including those originating in the breast. Recent studies found WAVE3 to mediate the process of chemoresistance in TNBCs. The molecular mechanisms whereby WAVE3 regulates chemoresistance in TNBC tumors remains largely unknown, as does the role of WAVE3 in CSC maintenance. Here we show that WAVE3 mediates chemoresistance by promoting CSC self-renewal and transcription of CSC-specific genes. Our data show that WAVE3 is enriched in the CSC-subpopulation of TNBC cell lines. Knockout of WAVE3 via CRISPR/Cas9 significantly depletes CSC-subpopulation and inhibits transcription of CSC transcription factors. Mechanistically, we established a link between WAVE3 and the Y-box binding protein 1 (YB1), a transcription factor and CSC-maintenance gene. Indeed, the interaction of WAVE3 with YB1 is required for the translocation of YB1 to the nucleus of cancer cells, and the subsequent activation of transcription of CSC-specific genes. Collectively, our findings identify a new WAVE3/YB1 signaling axis that regulates the CSC-mediated resistance to therapy and opens a new therapeutic window for the treatment of TNBCs.

Cancer stem cells play an important role during metastatic progression of breast cancer. However, the phenotypes specific to breast cancer stem cells have not been evaluated at single cell resolution in vivo. Here, we employ high-resolution intravital two-photon microscopy in orthotopic xenograft tumors, formed from human breast cancer cell lines expressing a previously characterized SOX2/OCT4 transcription-based fluorescent stem cell biosensor (SORE6) (Tang et al 2015). Using this high resolution imaging technology we found that SORE6+ stem cells: (a) constitute a minority population of the primary mammary tumors, (b) move approximately ten times slower than non-stem breast cancer cells.
(0.1 vs 1.1 μm/min, respectively), (c) are migratory toward blood vessels and, (d) compared to non-stem cells, they are enriched for ECM degrading invasive cellular protrusions called invadopodia. All these phenotypes are specifically associated with the disseminating population of tumor cells in the primary tumor site (Gligorijevic et al 2014) and, in addition, invadopodia are required for transendothelial migration during intravasation (Roh-Johnson et al 2013). We examined the mechanism of cancer stemness initiation and using live cell imaging found that stemness in cancer cells is induced upon physical contact with a macrophage. Interestingly, previous work has shown Mena\textsuperscript{INV} upregulation in cancer cells upon physical contact with a macrophage and Mena\textsuperscript{INV}—dependent transendothelial migration during intravasation. Intravital imaging in mice confirmed that stem cells have a three-fold higher incidence of direct contact with a macrophage compared to non-stem cells. We also checked the relationship of stem cells with the three cell complex called TMEM, composed of a macrophage, Mena\textsuperscript{Hi} tumor cell and endothelial cell, all in direct contact. TMEM was previously shown to be the doorway for intravasation of tumor cells in primary mammary tumors (Harney et al 2015) and is validated as a prognostic of metastasis in human breast cancer patients (Rohan et al 2014; Robinson et al 2009). Intravital imaging confirmed the presence of cancer stem cells in TMEM. Distance histograms of stem cells relative to TMEM sites showed that stem cells are accumulated close to TMEM. Interestingly, Mena\textsuperscript{INV} expressing cancer cells were similarly seen to accumulate close to TMEM, consistent with the observations that Mena\textsuperscript{INV} expression and stemness are both induced by macrophage contact. We conclude that stemness, as well as Mena\textsuperscript{INV} expression, is induced in breast cancer cells by direct contact of cancer cells with macrophages, and that these stem cells utilize Mena\textsuperscript{INV}—dependent invadopodia to invade into surrounding stroma and reach TMEM sites to intravasate into blood vessels.

Suppression of the growth of cancer stem cells developed from iPSCs by soluble form of human Cripto-1.
M.J. ALAM\textsuperscript{1}, A. Mizutani\textsuperscript{1}, H. Murakami\textsuperscript{1}, A.K. Oo\textsuperscript{1}, D.S. Salomon\textsuperscript{2}, M. Seno\textsuperscript{1};
\textsuperscript{1}Department of Medical Bioengineering, Okayama University, Okayama, Japan, \textsuperscript{2}Mouse Cancer Genetics Program, Center for Cancer Research, National Cancer Institute, Frederick, MD

Cripto-1 (CR-1) is a GPI-anchored signaling protein of epidermal growth factor (EGF)-cripto-1-FRL-1-cryptic (CFC) family and plays a significant role in early developmental stages and in the different types of cancer cells, epithelial to mesenchymal transition and tumor angiogenesis. Previously, we developed cancer stem cells (miPS-LLCcm) from mouse IPS cells cultured in the conditioned medium of Lewis lung carcinoma cells for 4 weeks. We found the expression of CR-1 during the conversion. To investigate the biological role of CR-1 in cancer stem cells, we have prepared a C-terminally truncated recombinant human CR-1 protein (rhCR-1) in E. coli, in which GPI (glycosphatidylinositol) anchored part has been removed by insertion stop codon through PCR based site-directed mutagenesis. This soluble form of CR-1 was designed in the plasmid pBO1801 to be expressed under the control of T7 promoter with His-tag. The soluble form of rhCR-1 protein was produced as inclusion bodies in E. coli BL21 (DE3) harboring plasmids pLysS. The protein was denatured and solubilized in the presence of 8M urea and purified by nickel column and CM650M cation-exchange column chromatography. Then the recombinant protein was refolded in a redox buffer and subsequently dialyzed against 1xPBS. The soluble form of rhCR-1 effectively suppressed the growth of miPS-LLCcm cells in a dose dependent manner. Further biological effect of rhCR-1 is under investigation.

Investigating the role of YAP and TAZ in medulloblastoma cancer stem cell formation and asymmetric cell division.
B. Araujo Cortez1,2, L. Carvalho Price1, M. Dias3, N.J. Ganem2, O. Okamoto1;
1Department of Genetics and Evolutionary Biology, Institute of Biosciences, University of Sao Paulo, Sao Paulo, Brazil, 2Department of Pharmacology Experimental Therapeutics, Boston University School of Medicine, Boston, MA, 3Laboratório Especial de ToxinoLogia Aplicada, Instituto Butantan, Sao Paulo, Brazil

Medulloblastoma is the most common malignant brain tumor of childhood. It is very aggressive and few effective treatments are available. The presence of cancer stem cells (CSC) correlates with medulloblastoma aggressiveness, and efforts have been done to identify signaling pathways that control CSC maintenance and proliferation. Researchers have described in others brain tumors that, similarly to normal stem cells, CSC are able to undergo asymmetric cell division (ACD). This kind of mitosis ensures the formation of one stem cell and one cell committed to differentiation. In tumors, low rates of ACD might be related to increased proliferation and aggressiveness, since the occurrence of symmetric divisions will increase the pool of CSC. Recently, some elements of Hippo pathway (a pathway related to the control of organ size, tumorigenesis and stem cell phenotype) were related to ACD in flies. In this context, the aim of this project is to investigate the contribution of the effectors of Hippo pathway (the transcription factors YAP and TAZ) to medulloblastoma stem cells formation and their ability to undergo ACD. For that, we generated YAP, TAZ and YAP/TAZ knockout cells from two different medulloblastoma cell lines (DAOY and USPMed13) using CRISPR technology. To evaluate the formation of CSC and to culture these cells for different experiments, tumorspheres were formed in low attachment plates in a defined culture medium. After tumorspheres culture for 7 days, when the expression levels of RNAm and protein of pluripotency genes were increased, spheres were dissociated and cell proliferation and the rates of ACD were analyzed in different culture conditions. The rates of ACD were analyzed based on NuMA and Numb location in mitotic cells using confocal microscopy. The rates of ACD could be modulated according to the culture: in culture medium that stimulates cell differentiation, the rates of ACD were increased when compared to culture conditions that stimulates proliferation. No difference in cell proliferation was observed in YAP knockout cells when culture in monolayers. However, fewer tumorspheres were formed from these cells when compared to controls, and their morphology was altered in both cell lines. Regarding ACD, YAP knockout cells showed decreased rates of ACD when cultured in the medium that stimulates cell differentiation. However, in YAP knockout cells the expression of TAZ was increased, what could overcome the absence of YAP. Now the same experiments are being performed with TAZ and YAP/TAZ knockout cells. Taken together, the results indicate that medulloblastoma CSC are able to undergo ACD, and that YAP and TAZ are important for CSC formation and ACD cell division occurrence in medulloblastoma cells.

The Snail/Let-7 axis induces stemness in ovarian, breast, and pancreatic cancer cells.
H. Wang1, M. Lombere1, E. Chirshev1, N. Hojo1, A. Hill1, J.J. Unternaehrer-Hamm1;
1Basic Sciences, Loma Linda University, Loma Linda, CA

One big challenge in cancer therapies is to find effective treatments to relapses and metastases. They are caused by a high-stemness subpopulation within tumors. The increase of stemness in cancer cells is
associated with the loss of miRNA let-7. The mechanisms of let-7 in cancer cells are not known. However, evidence from reprogramming studies is consistent with a role for the epithelial-mesenchymal transition (EMT) factor Snail in let-7 repression. EMT is a process by which epithelial cells gain migratory properties to become mesenchymal cells. EMT in cancer cells results in metastases and chemoresistance. In other words, after EMT, cancer cells have gained stemness. This leads us to believe, just like in reprogramming, Snail is repressing Let-7 directly in cancer cells. The goal of our study is to investigate the interaction between Snail and let-7 and its role in regulating cancer cells’ differentiation status. Hence, we hypothesize that Snail directly represses let-7, leading to increased stemness in cancer cells. To approach this, we treated breast (MCF-7), pancreatic (PANC-1), and ovarian cancer cells (OVCAR8, OVSAHO) with TGFβ or EGF; both growth factors are known to induce EMT. We also overexpressed Snail by using an estrogen-receptor fusion protein. Using qPCR, we detected the expression levels of mRNAs including EMT and stemness markers as well as miRNA let-7. These results were further confirmed by immunofluorescence. Luciferase assay and Chromatin immunoprecipitation (CHIP) were used to test the repressing action and the direct binding of Snail on let-7. After either EMT induction or Snail overexpression, an increase in pluripotency markers, as well as a decrease in let-7, was observed, indicating the negative association between Snail and let-7. CHIP data shows that overexpression of Snail increases the level of binding at let-7 family members’ promoter regions, demonstrating that let-7 is a direct target of Snail. In conclusion, our study has shown that Snail directly represses let-7 transcription and causes an increase in stemness in cancer cells.

O-GlcNAc transferase regulates breast cancer tumor-initiating cells.
N. Akella¹, D. Mukhopadhyay¹, A. Mukherjee², Z. Bacigalupa³, M.J. Reginato⁴;
¹Biochemistry, Drexel University, Philadelphia, PA

Tumors are heterogeneous with a sub-population of quiescent stem-like cells that when isolated can regenerate the whole tumor. Chemotherapy targets rapidly dividing cells and may not readily target these tumor-initiating cells (TIC) contributing to resistance and relapse. TICs, like cancer cells, rewire metabolism to meet demands of increased growth and biosynthesis. The hexosamine biosynthetic pathway utilizes glucose to generate UDP-GlcNAc. O-GlcNAc Transferase enzyme (OGT) uses UDP-GlcNAc as a substrate for adding O-GlcNAc moieties to nuclear and cytoplasmic proteins, akin to phosphorylation. Our lab has shown that OGT/O-GlcNAc levels are elevated in multiple cancers and reducing OGT in breast cancer cells blocks growth in-vitro and in-vivo. Since OGT directly modifies proteins associated with pluripotency in embryonic stem cells, we hypothesized that OGT may regulate breast cancer TICs. Here, we show that breast cancer cells enriched in tumor initiating activity in mammosphere cultures contain elevated levels of OGT/O-GlcNAcylation. Inhibition of OGT genetically or pharmacologically reduces mammospheres forming efficiency and reduces the CD44H/CD24L and Nanog-expressing TIC population. Conversely, over-expressing OGT increases mammospheres formation and preliminary evidence shows an increase of tumor initiation in-vivo. Analysis of potential mechanism revealed that OGT overexpression increased mRNA expression of transcription factor c-Myc, protein expression of cancer stem cell markers CD44, Snail and epithelial to mesenchymal transition markers including Vimentin and Fibronectin. These results suggest that OGT plays a key role in regulation of breast cancer tumor initiating cells in-vitro and in-vivo.

Expression of ALDH Isoforms in Colon Tumorigenesis.  
R. Kowash1, G. Masters3, B.M. Boman3, L.M. Opdenaker3,4, S.R. Modarai3;  
1Biology, Dickinson College, Carlisle, PA, 2Biology, Hamilton College, Clinton, NY, 3CTCR, Christiana Care Health Services Inc., Newark, DE, 4Biological Sciences, University of Delaware, Newark, DE

**Background:** Tumorigenesis is driven by stem cell (SC) overpopulation. Aldehyde dehydrogenase (ALDH) is a marker for SCs in several tissues, and there are 19 known isoforms of ALDH that each have specific roles and are cell and tissue-type dependent. Although a handful of ALDH isoforms have been implicated in various cancers, the remaining isoforms still remain to be investigated, especially in colorectal cancer (CRC). **Hypothesis:** There is a unique ALDH isoform signature in normal colonic SCs and that unique expression pattern changes during CRC initiation and progression. By identifying the phenotype of the normal colonic SC and comparing it to the colonic cancer SC, we can identify what role these isoforms play in colon cancer biology. **Methods:** We analyzed matched normal colon epithelium and colorectal tumor tissues to see ALDH isoform mRNA expression and verified protein expression of select isoforms by Western blot. ALDH1A1 protein was knocked down by siRNA, and its effect on cell proliferation was analyzed. **Results:** Select ALDH isoforms were expressed in the normal colon epithelium and aberrantly expressed in the matched tumor tissues. ALDH1A1, ALDH1A3, ALDH1B1, ALDH2, ALDH4A1, and ALDH7A1 were identified as important isoforms. Knockdown of ALDH1A1 protein was validated and revealed that it is important for the regulation of cell proliferation. **Conclusions:** The ALDH1A1 knockdown was successful; however other functional tests of the ALDH1A1 knockdown have yet to be completed, as well as the knockdown of the other ALDH isoforms. **Implications:** Ultimately, the major contribution of targeting colonic CSCs, via ALDH isoform expression, will lead to new, more effective treatments for colorectal cancer to limit CSC growth and inhibit tumor recurrence.

Hypoxia and cancer stem cell activity are linked during tumor cell dissemination and metastasis in breast tumors.  
E. Xue1, V.P. Sharma1,2, D. Entenberg1,2,3, Y. Wang1,2,3, B. Tang4, L. Wakefield4, M.H. Oktay1,2,3,5, J.S. Condeelis1,2,3;  
1Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 2Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, 3Integrated Imaging Program, Albert Einstein College of Medicine, Bronx, NY, 4Laboratory of Cancer Biology and Genetics, National Cancer Institute, Bethesda, MD, 5Department of Pathology, Albert Einstein College of Medicine, Bronx, NY

**Hypoxia,** an established hallmark of cancer, is responsible for many pro-metastatic changes that occur within aggressive tumors, including increased angiongenesis, tumor cell invasion, dormancy, and dissemination. Hypoxia may be associated with the induction of cancer stem cells, a rare population thought to be responsible for progression, metastasis, recurrence and drug resistance. Here, we describe the creation of a double-reporter MDA-MB-231 cell line for the visualization of hypoxic and cancer stem cells in real time in vivo. The double-reporter cell line contains both our previously published novel optical reporters; for hypoxia (based upon a genetically encodable fluorescent protein, mCherry, and expressed only under hypoxic conditions) (Wang et al 2016), and for cancer stem cells (SORE6-Dscp-GFP) (Tang et al 2015). Using multiphoton microscopy, hypoxic tumor cells were found to
postgraduate students exhibit a more persistent slow migration phenotype, associated with blood vessels, and had increased invadopodium-associated collagen degradation and intravasation activity, all as compared to normoxic cells in the same tissue location in vivo. In addition, hypoxic tumor cells migrated toward human epithelial growth factor gradients in vivo and were present in the CTC population supporting hypoxia involvement in blood vessel directed streaming migration (Leong et al 2016) and intravasation (Wang et al 2016). Since these are characteristics of dissemination and metastasis competent breast tumor cells (Gligorijevic et al 2014), we determined if hypoxic tumor cells with these phenotypes expressed the cancer stem cell reporter (SORE6-DsCop-GFP). We found that the SORE6+ cancer stem cells exhibited the hypoxic tumor cell phenotypes including slower migration than non-stem breast cancer cells (0.1 vs 1.1 \( \mu m/min \), respectively), migration toward blood vessels, and enrichment for ECM degrading invasive cellular protrusions called invadopodia. Furthermore, in the primary tumor, we observed that stem cells were co-labeled with the hypoxia reporter when in association with blood vessels. Finally, we found, in spontaneous metastases in the lung, that the majority of tumor cells were SORE6+ cancer stem cells during early arrival from the primary tumor. Our results show, for the first time by intravital imaging of live tumor cells in both primary and metastatic breast tumors, that hypoxia and stemness are linked within the same migratory and disseminating population of tumors cells leading to the dissemination of tumor initiating cancer stem cells to the lung.

CD82 expression affects acute myeloid leukemia chemosensitivity.
M. Floren\(^1\), K.M. Alvarez\(^1\), C.M. Termini\(^1\), K.D. Marjon\(^1\), J.M. Gillette\(^1\);
\(^1\)Pathology, University of New Mexico, Albuquerque, NM

Acute myeloid leukemia (AML), the most common acute leukemia, is a myeloid lineage cancer that accumulates in the blood and bone marrow, interfering with the normal production of blood and immune cells. Relapse and resistance to therapeutics are among the most challenging obstacles in the management of AML. Recent studies suggest that disease relapse is predominantly due to a population of leukemia stems cells that seek shelter in the bone marrow, resulting in increased cell survival and resistance to chemotherapeutics. Therefore, the interactions between AML cells and the bone marrow microenvironment are critical for AML disease progression and relapse. Recently, our lab identified the tetraspanin CD82 as critical regulator of AML cell bone marrow adhesion and homing. More specifically, we find that AML cells from primary patient samples with increased CD82 expression display enhanced bone marrow homing in preclinical animal models. In the current study, we test the hypothesis that CD82 overexpression in AML cells promotes chemoresistance. We investigated the role of CD82 expression on AML chemosensitivity using the conventional therapeutic, daunorubicin. Flow cytometry analysis of active caspase 3, 7 expression indicates that overexpression of CD82 promotes chemoresistance in AML cells. Additionally, we find increased resistance in AML cells when the N-linked glycosylation sites on CD82 are disrupted. In contrast, we detect an increase in chemosensitivity when CD82 is knocked down. CD82 overexpressing AML cells also have increased IL-8 gene expression and cytokine production following daunorubicin treatment, indicative of a chemoresistance phenotype. Next, we investigated the mechanism by which CD82 modulates AML chemosensitivity, specifically focusing on the WNT-signaling pathway. Our data suggest that CD82 overexpressing AML cells become more chemosensitive to daunorubicin after treatment with a \( \beta \)-catenin inhibitor. RT-PCR and western blotting analysis show an increase in \( \beta \)-catenin gene and protein expression in CD82 overexpressing AML cells treated with daunorubicin. In combination, these results suggest that differential expression of CD82 modulates chemosensitivity in AML cells. Moreover, our data suggest the possible role of \( \beta \)-
catenin signaling in chemosensitivity downstream of CD82. Future studies will be directed at elucidating CD82-mediated chemoresistance and AML relapse in animal models.

Histone demethylase inhibitor JIB-04 blocks the self-renewal of human colon cancer stem cells. H. Cho1,2, M. Kim1,2, Y. Jang1,2;
1Department of Systems Biology, College of Life Science and Biotechnology, Yonsei university, Seoul, South Korea, 2Initiative for Biological Function Systems, Yonsei university, Seoul, South Korea

Cancer stem cell (CSC) exists as a minor population of tumor mass, which shares similar properties associated with normal stem cells like pluripotency and self-renewal. Since CSCs possess resistance for drug-, radio therapy, untouched CSCs after conventional therapy lead to develop recurrent disease and induce metastasis by promoting epithelial-mesenchymal transition (EMT). Therefore, understanding the mechanism by which cancer stem cells maintain self-renewal and discovery of novel compound selectively targeting CSCs are important to annihilate cancer. Although JIB-04, a small molecule inhibitor of the jumonji family of histone demethylase, was reported to have selective anticancer effects in lung cancer and prostate cancer cell lines and reduce cell growth and proliferation of drug-resistant cancer cell in brain and lung cancer, effects of JIB-04 on CSCs were not elucidated yet. In this study, we investigated the function of JIB-04 on CSCs and its underlying mechanism. Our data showed that JIB-04 decreased cancer stem cell properties like expression of CD133, CSC surface marker, self-renewal ability and tumor initiating ability in three colorectal cancer cells. Furthermore, we found that JIB-04 down-regulated the expression of Wnt signaling target genes associated with colorectal CSC progression. Collectively, our results suggest that JIB-04 may be a novel therapeutic agent for colorectal cancer.

Gene Regulation and Genome Structure

Gene Annotation of Contig17 Within Dot Chromosome of Drosophila eugracilis. A.M. Herken1, T. Sadikot1;
1Biology, Washburn University, Topeka, KS

With the use of many open-source computational genomic tools for sequence alignment, prediction models, the Drosophila genome browser, and model checker contig17 of Drosophila eugracilis, located within the dot chromosome was studied for gene features both genes and pseudogenes. The goal of the study was to annotate and identify all genes located within this contig sequence. To do this the Drosophila melanogaster sequence was used as a reference for conservation-based analysis. Various gene predictions show there are three potential genes in the contig. These genes are apolpp, actbeta, and sv. Each gene contained a varying number of isoforms. Analysis of this contig showed all of the predicted genes to be present within the contig. The genes are conserved between D. melanogaster and D. eugracilis. A non-canonical donor site, GC instead of GT, was found in one of the introns of many isoforms of sv. This non-canonical donor site is conserved between D. melanogaster and D. eugracilis.

Annotation of contig40 of the Drosophila eugracilis dot chromosome.
R.P. Powell1, T. Sadikot1;
1Biology, Washburn University, Topeka, KS

The genome of Drosophila melanogaster was completed in 2000 and it has since become one of the most studied species in biology. D. melanogaster serves as a model organism for studying many developmental and cellular processes common to higher eukaryotes, and is also used as a reference species for computational analysis and annotation. The Genomics Education Partnership (GEP), sponsored by Washington University, Saint Louis, is a collaborative effort designed to incorporate undergraduate students in genomics research involving various Drosophila species. Students are tasked with certain steps in taking raw sequence data to a high-quality finished sequence; the completed data is used to answer questions in genomics. For this project, the DNA sequence of contig40 of Drosophila eugracilis dot chromosome was analyzed and compared to D. melanogaster for the presence of protein coding genes and other genomic features. Sequence analysis and data collection were carried out using several open-source computational genomic tools for sequence alignment, gene-prediction and Drosophila genome browsing. The data files and resources for this project were made available through the GEP. Based on BLAST analysis using the D. melanogaster genome as a reference and other gene prediction models, there appeared to be strong support for the presence of two genes, zinc finger homeodomain 2 (zfh2) and Asator, and weak support for a third gene, discs overgrown (dco). Data analysis revealed that resource information supporting the presence of zfh2 and Asator was consistent, and that the support for dco contained incongruences that indicate its absence in the contig. The annotated model produced in this research project was submitted to the GEP for their data repository.

P1351
Board Number: B359
Annotation of contig 20 of dot chromosome in Drosophila eugracilis by comparison to Drosophila melanogaster genome using bioinformatics techniques.
M. Radford1, T. Sadikot1;
1Biology, Washburn University, Topeka, KS

The genome of Drosophila melanogaster was completed in 2000 and it has since become one of the most studied species in biology. D. melanogaster serves as a model organism for studying many developmental and cellular processes common to higher eukaryotes, and can also be used as a reference for identifying genes and other genomic elements in other Drosophila species. The goal of this project was to analyze and annotate a contig sequence of chromosome 4 from the D. eugracilis genome. Sequence analysis and data collection was carried out using a number of open-source computational genomic tools for sequence alignment, gene-prediction and Drosophila genome browsing. The data files and resources for this project were available through the Genomics Education Partnership (GEP) sponsored by Washington University, Saint Louis. Data analysis and interpretation required careful screening of the DNA sequence of interest, identification of gene markers and comparison of the predicted gene features to a reference D. melanogaster DNA sequence. Four genes were predicted to be in the contig: PlexA, ATPsynbeta, PlexB, and ATPsynbetaL. It was determined that the PlexA and ATPsynbeta genes existed in the contig as predicted by the D. melanogaster reference model and that the PlexB and ATPsynbetaL are falsely predicted to be in this regions. It was also determined that the toy
gene exists in the contig despite the ortholog not being marked as such by the *D. melanogaster* alignment.

Annotation and cross-species comparison of *Drosophila* genes.

J. Hobson¹, M. Van Stry¹, W. Leung², S.C. Elgin²; ¹Biology, Lane College, Jackson, TN, ²Biology, Washington University in St. Louis, St. Louis, MO

*Drosophila melanogaster* has a small fourth chromosome (3.5% of the genome * )*, that has very large heterochromatin domains which are rich in HP1. Our goal for this project is to understand the mechanisms of gene expression in this heterochromatic environment. In the Genomics Education Partnership Project, we are using comparative genomics to identify conserved DNA regulatory sequences, by comparing the *D. melanogaster* Muller F element to those of other fly species that deivered from *D. melanogaster* ~10 million years ago, aiming to find regions of homology surrounding the transcription start sites. I have annotated the genes on a 40,000 base-pair piece from the *Drosophila eugracilis* chromosome four. Sequence comparisons using BLASTX, gene predictors like Gene Scans, and RNA sequence data were used to annotate coding genes in this region. I identified two genes: *myo* (3 isoforms) and *ey* (4 isoforms) and annotated protein coding exons and splice sites for each isoform. The *myo* amino acid sequence is identical for each isoform in *D. eugracilis*, with 70.3% amino acid identity compared to the *D. melanogaster* *myo* protein. The *D. eugracilis ey* isoforms are also similar to the *D. melanogaster ey* protein sequences, with a range from 73% to 78% identity to their corresponding *D. melanogaster* isoform. Putative Transcription Start Sites for each gene were investigated, including a search for known transcription factor binding sites. By pooling results, GEP students are annotating several megabases of DNA, and contributing to an understanding of heterochromatic genes.

Influence by ecdysone and transcription on developmentally regulated DNA re-replication in Sciar* DNA puffs.

J.M. Urban¹, L. Kadota¹, J. Leung¹, A. Lee¹, Y. Yamamoto¹, E. Gustafson¹, M.S. Foulk¹, J. Bliss¹, S.A. Gerbi¹; ¹BioMed Division, Dept of Molecular and Cell Biology and Biochemistry, Brown University, Providence, RI

The polytene chromosome DNA puffs of the fly Sciar* bypass cell cycle regulation during development: (1) mitosis is skipped and the polytene cells alternate between G and S phase, reaching 4096C in larval salivary glands; (2) re-replication occurs at the DNA puff loci in late larval salivary glands. To investigate how these rogue replication origins override the normal controls that ensure that an origin fires no more than once per S phase, we have sequenced the Sciar* genome (using Illumina, PacBio, MinION and BioNano Irys sequencing) and identified 14 DNA puff sequences based on their increased read copy number, with validation by qPCR. The amplification levels range from 32-fold (DNA puff II/9A), to 16-fold (DNA puff II/2B) and 8-fold or less (the remaining DNA puffs). The width of the amplicons was 267-607 kb. FISH allowed correlations between the DNA puff sequences and polytene chromosome map positions.

To investigate the interplay between transcription and re-replication, and whether transcription helps to open the chromatin for re-replication, we have sequenced the transcriptome of Sciar* salivary glands before, during and after DNA puff amplification. Most DNA puff loci do not begin transcription until after re-replication, where the amplified DNA can serve as abundant template for massive transcription...
required to build the larval cocoon at the next stage of development. Intriguingly, we found a microRNA that is present during re-replication and is complementary to one strand of the DNA puff II/9A origin. We are extending this observation to explore its presence at the other DNA puff loci and its possible role in re-replication.

We found by qPCR that re-replication was prematurely induced in the 14 DNA puffs by injection of the steroid hormone ecdysone into young larvae prior to the developmental stage when DNA amplification would normally occur. A match to the ecdysone receptor binding site (EcRE) occurs at DNA puff II/9A adjacent to the ORC binding site where we previously mapped the start site of DNA synthesis. This EcRE has been maintained during evolution and is present in a polymorphic strain of Sciara. Using methodology we have developed for genome editing in Sciara, we are investigating by mutational analysis if the DNA puff II/9A origin EcRE is required for DNA puff amplification. This would suggest that the ecdysone receptor functions as a re-replication factor in addition to its well-studied function as a transcription factor.

A function of the inverted repeat sequences located in the upstream of the mouse Oct3/4 gene.

Y. Yamamoto, O. Miura, S. Umekita, T. Ohyama;

1Biology, Waseda University, Tokyo, Japan

A DNA sequence that reads the same from 5’ to 3’ in either strand is known as an inverted repeat (IR) or a palindrome. A vast many studies have been heretofore performed to understand the biological significance of IRs. However, it is still elusive. We found a cluster of 6 IRs in the ~1.5 ~ ~2 kb upstream of the mouse Oct3/4 gene that is known as a key gene for pluripotency. Here, we suggest that this cluster plays some important role in the expression of the gene. The expression of the Oct3/4 is regulated by the proximal promoter (PP), the proximal enhancer (PE) and the distal enhancer (DE), which is flanked by the IR cluster. In order to know whether this cluster is implicated in the Oct3/4 expression, the CRISPR/Cas9-based genome editing was performed using mouse ES cells, by which this cluster was replaced with mirror repeat sequences that retain the sequences of the repeat units in the respective IRs. In the resulting cells, the level of the Oct3/4 expression was found reduced. Since the IR cluster is located in the downstream vicinity of the DE, the cluster seems to have some important role to make the enhancer function efficiently. In the meeting, we will also show the resulting effect on the phenotype of the ES cells.

The histone methyltransferases Set1 and Set5 promote subtelomeric gene silencing and telomere maintenance in *Saccharomyces cerevisiae*.

1Biological Sciences, University of Maryland, Baltimore County, Baltimore, MD, 2Mathematics and Statistics, University of Maryland, Baltimore County, Baltimore, MD

Telomeres, the nucleoprotein structures found at the ends of linear chromosomes, provide a protective function for the genome. Alteration to the chromatin structure at or adjacent to these protective caps leads to dysfunctional telomeres, which are associated with genomic instability and implicated in cellular aging and many types of cancer. In *Saccharomyces cerevisiae*, the enzymes Set1 and Set5 belong to a family of methyltransferases known to target specific lysine residues on histones. The H3K4
methyltransferase Set1 has been linked to both transcriptional activation at gene promoters and silencing at telomeres. Set5, which modifies H4K5, K8, and K12, has recently been shown to aid Set1 in promoting silencing at telomeres. However, while we have some insight regarding the role for Set1 in silencing, the mechanism is still largely unclear. Additionally, it is not known how Set5 contributes to silencing at telomeres. Here, we investigated the role of Set1 and Set5 in the regulation of gene repression at native telomeres in Saccharomyces cerevisiae. Our results suggest that gene derepression in the absence of Set1 and Set5 is largely through a Sir protein-independent mechanism. Instead, our data suggest a link between the regulation of H4K5ac and K4K8ac and Set1- and Set5-mediated gene regulation. Additionally, we determined that transcriptomes from cells lacking both Set1 and Set5 show a strong correlation with transcriptomes belonging to mutants that display defects in telomere maintenance, revealing a specific role for Set5 and Set1 in pathways required for telomere integrity, rather than just gene silencing. In addition, we have determined that the cytoplasmic exonuclease Xrn1 acts synergistically with Set1 to promote gene repression, suggesting a possible link between Set1 and RNA-dependent repression of telomeric genes. Overall, our data provides support for a Sir-independent mechanism for telomeric gene repression by Set1, together with Set5, and identifies potential alternate mechanisms through which Set1 in particular may promote telomeric silencing.

Temperature effects on TPE, trinucleotide repeat stability, and chromosome loss in Saccharomyces cerevisiae.
R. Slate, K. Tatasciore, E. Godfrey, G. Greco, L. Goudsouzian; 1Natural Science, DeSales University, Center Valley, PA

We investigated the influence of temperature on the genetic stability of Saccharomyces cerevisiae through the observation of the telomere position effect, trinucleotide repeat expansion and chromosome loss. Previous research has shown that genes placed adjacent to an S. cerevisiae telomere exhibit reversible transcriptional repression, a phenomenon known as the Telomere Position Effect (TPE). This specific alteration of genetic expression is not observed when the same genes are distanced from the telomeric heterochromatin. Using a cell viability assay, we investigated the ability of an S. cerevisiae telomere to silence the URA3 gene at a modified telomere via TPE at three different temperatures. We found that expression of URA3 was low at 23°C and 30°C relative to expression at 37°C. Our findings are consistent with previous studies which indicated that high temperatures diminish telomere length. Trinucleotide repeats are sequences of DNA composed of a repetitive pattern of three nucleotides. Though trinucleotide repeats exist naturally, expansion of these genomic sequences is known to be a cause of several serious human diseases, such as Huntington's Disease and Fragile X Syndrome. We investigated the relative levels of CTG trinucleotide repeat expansion in the euchromatin of S. cerevisiae grown at 23°C, 30°C, and 37°C. Our data show that temperature affects expansion of CTG trinucleotide repeats in S. cerevisiae. Using an ADE3/8 color assay and a disome strain of S. cerevisiae, we examined the impact of temperature on chromosome loss. Our data indicate a correlation between high temperature and chromosomal instability.

*Impact of ethanol on markers of heterochromatin maintenance and trinucleotide repeat expansion in* Saccharomyces cerevisiae.  
S. Ngan¹, M. Reinert¹, K. Churylo², L. Goudsouzian³;  
¹Natural Science, DeSales University, Center Valley, PA  
²Institute for Physical Science and Technology, University of Maryland - College Park, College Park, MD  
³Laboratory of Pathology, National Cancer Institute, NIH, Bethesda, MD

Using three separate assays, we have examined ethanol’s impacts on gene silencing via the Telomere Position Effect (TPE), trinucleotide repeat expansion, and chromosomal stability in Saccharomyces cerevisiae. Using a cell viability assay, we examined how ethanol influences the repression of gene expression through TPE. Our results show that S. cerevisiae grown in 5% ethanol undergoes increased silencing of a gene placed proximal to a modified telomere. Expansion of trinucleotide repeats is known to be a cause of several serious human diseases, such as Huntington's Disease and Fragile X Syndrome. We investigated the effect of ethanol on the level of CTG trinucleotide repeat expansion in the euchromatin of S. cerevisiae. Our data indicate that the addition of ethanol to the growth medium increases levels of trinucleotide repeat expansion. Genomic instability is a major cause behind many illnesses, including cancer. Using the ADE3/8 color assay with a disomic strain of S. cerevisiae, we investigated ethanol’s impacts on chromosome loss. Our work shows that ethanol increases chromosomal stability in yeast.

*A single cell view of MYC's gene regulatory and oncogenic mechanism.*  
S. Patange¹², M. Girvan³, D. Levens³, D.R. Larson¹;  
¹Laboratory of Receptor Biology and Gene Expression, National Cancer Institute, NIH, Bethesda, MD  
²Institute for Physical Science and Technology, University of Maryland - College Park, College Park, MD  
³Laboratory of Pathology, National Cancer Institute, NIH, Bethesda, MD

We seek to determine how the MYC oncogenic transcription factor modulates stochastic gene expression in single living cells. Several models have recently emerged that question the prevailing view of MYC as a gene-specific transcription factor and instead envision its oncogenic mechanism as a global amplifier to elevate the existing gene expression program in a cell. We evaluated these competing paradigms of MYC’s function to shed light on its in-vivo oncogenic behavior by using single-molecule RNA fluorescence in-situ hybridization (smFISH) and live cell imaging of transcription. To simulate MYC’s oncogenic activity we overexpressed MYC in the U2-OS human osteosarcoma cell line. This cell line contains an exogenous β-globin reporter gene, transcription of which is visualized in live cells by fluorescently tagging the RNA with the MS2-PP7 stem loop system. Our results show that MYC overexpression doubles the population β-globin transcript levels and increases the duration and magnitude of live transcription events. To our knowledge this is the first living, single cell evidence to suggest that MYC's mechanism of action may be extend the duration and initiation rate of active gene periods.

As a way to directly assess the effect of the MYC protein on gene expression, we have also engineered a photo-inducible version of MYC (Pi-MYC) to achieve spatial and temporal control of the transcription factor within living cells. We report the first characterization of Pi-MYC, which translocates to and from cell nuclei within 8 minutes of light induction/removal, faster than any existing translocation-inducible MYC. This allows us to directly measure the way in which a transcription factor modifies the kinetic steps of transcription in living cells.

Role of microRNAs in brain tumors as diagnostic and prognostic markers.
Y. Santana Rivera1,2, E. Lozada Delgado2,3,4, P.E. Vivas Mejia2,4;
1Interdisciplinary Studies Program, University of Puerto Rico Rio Piedras Campus, San Juan, PR,
2University of Puerto Rico Comprehensive Cancer Center, San Juan, PR, 3Biology, University of Puerto Rico Rio Piedras Campus, San Juan, PR, 4Biochemistry, University of Puerto Rico Science Medical Campus, San Juan, PR

Fifteen percent of all primary brain tumors (BT) are Glioblastoma Multiforme (GBM). GBM is the most malignant type of BT; having an unknown cause. It is a type of astrocytoma that arises from astrocytes and supportive brain tissue primarily located in the cerebral hemisphere, spinal cord or brain. Classified from grade I-IV histologically by the World Health Organization (WHO) combining the type of tumor with the assignment of a defined malignancy grade; Grade IV is known as GBM. Currently, most cancers diagnosis are determined by histological examination of the affected tissue obtained by biopsy or surgical removal. These are expensive procedures that can result in risk to patients and required consistent evaluation. Thus giving rise to an interest in the field of circulating nucleic acids as potential biomarkers. Blood-based testing has the ability to carry out screening and repeated sampling in patients undergoing therapy for monitoring the disease. Previous studies have suggested the use of microRNAs as prognostic and diagnostic markers. MicroRNAs are small non-coding RNAs that bind to 3′-untranslated (UTR) regions of target messenger RNAs to regulate protein synthesis. It is relevant the need to find a better and more economic diagnostic model. If a correlation of microRNAs expression can be found between the endogenous control group of microRNAs and the experimental group in symptomatic and asymptomatic plasma and saliva samples from GBM patients, then a technique can be developed for diagnostic and prognostic of GBM, finding a better and cheaper technique that can make the disease diagnostic much easier, assigning a prognosis to each patient. The expression of microRNA-27a, microRNA-1225-5p, microRNA-143, microRNA-92b, and microRNA-27b were evaluated in plasma samples by Real-Time PCR (qPCR) using microRNA-16 as endogenous control. Mann-Whitney statistical test showed significance in microRNAs relative expression when comparing symptomatic and asymptomatic plasma samples for miRNA-92b.

Regulation of proinflammatory chemokine CXCL5 by microRNA hsa-miR-605.
A. Parikh1, S. Ramanathan1, B. Shenoda1, S. Ajit1;
1Pharmacology and Physiology, Drexel University College of Medicine, Philadelphia, PA

Complex regional pain syndrome (CRPS) is a disease characterized by chronic pain and inflammation. Recent studies on CRPS patients have sought to identify biomarkers that can assist physicians in diagnosis and serve as therapeutic targets. MicroRNAs (miRNAs) are small noncoding RNAs that can negatively regulate gene expression by binding to the 3′ untranslated region (3′UTR) of mRNAs. Our previous studies investigating circulating miRNAs in blood from patients with CRPS found a 22-fold downregulation of hsa-miR-605 in poor responders relative to responders prior to ketamine treatment. Here we investigated the functional significance of miR-605 downregulation. This miRNA is predicted to target CXCL5, a proinflammatory chemokine involved in the recruitment and activation of neutrophils.
We hypothesized that the reduced expression of miR-605 in poor responders could contribute to an increase in CXCL5 expression. We confirmed miR-605 binding to CXCL5 3’UTR and an upregulation of CXCL5 mRNA in poor responders relative to responders in whole blood from CRPS patients. We then investigated whether overexpression of miR-605 can decrease endogenous levels of CXCL5 in multiple cell lines. While there was no significant effect in primary endothelial cells, we found a small but consistent decrease of CXCL5 mRNA in miR-605 transfected neuroblastoma cells. Conversely, downregulation of miR-605 in primary endothelial cells resulted in significant upregulation of CXCL5 mRNA. Efforts are underway to determine if these miR-605 induced changes in CXCL5 mRNA are reflected at the protein level, and function as determined by neutrophil migration in vitro. Thus, investigating target mRNAs of differentially expressed miRNAs can provide important insights on aberrant gene expression that contributes to disease pathology.

Identification of growth-suppressive microRNAs that regulate genes involved in cell cycle progression and apoptosis by miRNA library screening.
Y. Byun1, Y. Jeong1, Y. Choi1, J. Yoon1, K. Baek1;
1Graduate School of Biotechnology, Kyung Hee University, Yongin-si, South Korea

Micro(mi)RNAs are small non-coding regulatory RNA molecules, that have a wide impact on the regulation of gene expression. Considerable evidence demonstrates that miRNAs are involved in a variety of fundamental biological processes including cell proliferation, apoptosis, and differentiation. In cancer, miRNAs can function as oncogenes or tumor suppressors to either promote or protect against cancer, respectively. In this study, a screen was performed using 300 miRNA mimics to identify miRNAs that downregulate A549 tumor cell growth. Among 300 miRNAs, we selected miR-28-5p, -323-5p, -510-5p, -552-3p, and -608 that were the most effective in downregulating cell growth. As revealed by flow cytometry, overexpressing miR-28-5p, -323-5p, and-510-5p induced G1 arrest, whereas that of miR-608 induced cell death in a caspase-dependent manner. Quantitative real-time PCR and western blot analyses demonstrated that B cell lymphoma 2-like 1 (BCL2L1), D-type cyclin 1 (CCND1), CCND3, cytochrome b5 reductase 3 (CYB5R3), phosphoinositide 3-kinase regulatory subunit 2 (PIK3R2), specificity protein 1 (SP1), and phosphorylated Akt were all downregulated in miR-608-transfected cells, while Bcl-2-interacting killer (BIK) was upregulated. Moreover, in an NCI-H460 xenograft model, miR-608 was determined to have a suppressive function on tumor growth.

Hox genes are a group of highly conserved transcription factors that regulate anterior-posterior patterning in developing embryos. In mammals there are four clusters (A through D) that contain a total of 39 Hox genes. These genes have to be tightly regulated such that their spatio-temporal expression profile and consequently regulation of their downstream effectors is properly executed. This occurs in part due to enhancers acting both locally and long-range within and around the Hox clusters. Additional transcriptional complexity arises due to the presence of long non-coding RNAs (IncRNAs) that are
embedded within and around the Hox coding regions. lncRNAs have been shown to be linked to rapid epigenetic changes in chromatin states within the Hox clusters. Therefore, it is possible that regulation of lncRNA transcripts may be have an additional input into regulating adjacent coding regions in the Hox clusters during development and organogenesis. For this project, the HoxB cluster is being studied as a model to better understand the regulatory interplay between coding and noncoding transcripts during neural differentiation of mouse embryonic stem cells (mESCs). Interspersed in the region in and around Hoxb4 and Hoxb5 are 3 retinoid dependent enhancer elements and 3 lncRNAs. To understand the interplay between the enhancers and promoters and the temporal order of expression of transcription we are employing single molecule Flourescent in-situ Hybridization (smFISH) approaches. We labelled the Hoxb4 gene and the lncRNAs (Hobbit, HoxBlinclnc, etc) and then probed the mESCs programmed for neural differentiation by Retinoic Acid (RA) treatment. The probe sets were visualized and then each probe set was quantified for the presence of nascent transcripts in the nucleus and the mature single transcripts in the cytoplasm. Our results show that Hobbit and Hoxb4 are activated similarly during neural differentiation. In contrast, HoxBlinclnc is expressed in uninduced mESCs and appears to decrease with neural differentiation. Through this approach, we identified populations of cells with distinct transcription profiles that provide insight into how transcription of the Hoxb4 gene is dynamically correlated with the expression of the lncRNAs, Hobbit and HoxBlinclnc. This approach is allowing us to dissect the order of the regulatory events in the middle of HoxB cluster and to explore long range effects of enhancers on multiple genes.

Nonstop decay in C. elegans: examining a possible role for small noncoding RNAs.
E.M. Youngman1, E. Mortezavi1, W. Gu2, C. Mello3;
1Biology, Villanova University, Villanova, PA, 2Cell Biology and Neuroscience, University of California at Riverside, Riverside, CA, 3Program in Molecular Medicine and HHMI, UMass Medical School, Worcester, MA

In C. elegans, small noncoding RNAs known as 22G RNAs are synthesized by RNA-dependent RNA polymerases and target thousands of protein-coding mRNAs, repetitive sequences, and cryptic transcripts throughout the genome. In some cases, 22G RNA synthesis appears to be triggered as a secondary event downstream of targeting by C. elegans piRNAs (known as 21U RNAs) in a pathway that defends against non-self RNA species. However, the synthesis of many 22G RNAs is unaffected by loss of 21U RNAs, and the triggers for biosynthesis of these 21U-independent 22Gs remain elusive. Using a comparative genomic approach in geographically distributed wild isolates of C. elegans, we have identified a locus (F43E2.6) at which loss of the stop codon is correlated with increased production of 22G RNAs. The F43 mRNA has a short 3’UTR with no further in frame stop codons, raising the intriguing possibility that 22G RNAs could be involved in a nonstop decay pathway in C. elegans. F43 is also targeted by an unusual Dicer product; however this Dicer product does not appear to act as a primary siRNA to trigger F43 22G RNAs. First, the Dicer product is expressed equally in strains with large differences (more than 10 fold) in 22G RNA levels. Second, this product is expressed only during embryogenesis, whereas F43 22G RNAs are expressed most strongly in adults. Third, F43 22G RNAs are genetically independent of the Dicer pathway. We have demonstrated that the 22G RNA expression phenotype at the F43 locus is genetically linked to the locus itself, and are currently generating worms carrying CRISPR-edited F43 loci that bear or lack a stop codon to determine whether the loss of a stop codon is indeed causal for increased 22G RNA production. In addition, we are sequencing small RNAs from additional nonstop and nonsense alleles to ask whether this phenomenon is general, and are using
a genetic approach to ask whether 22G RNAs function in a pathway with the known effectors of nonstop decay *dom-34* and *hbs-1*.

**The Role of Protein Arginine Methylation in the Repression of tRNA Biogenesis under Stress.**
R. Davis\(^1\), E. Milliman\(^1\), N. Likhite\(^1\), C. Jackson\(^1\), M.C. Yu\(^1\);
\(^1\)Biological Sciences, State University of New York at Buffalo, Buffalo, NY

Under favorable conditions, robust tRNA biogenesis by RNA polymerase III (Pol III) is responsible for balancing a cell’s protein synthetic capacity with its growth requirement. As such, regulation of transcription by Pol III is closely linked to a cell’s metabolic activity and Pol III transcription needs to be tightly controlled, especially under stress. Previously, data from our high-resolution genome-wide localization analysis revealed an enrichment of the budding yeast *Saccharomyces cerevisiae* type-I protein arginine methyltransferase, Hmt1, at tRNA genes and mutants lacking Hmt1 display aberrant levels of tRNA (Milliman et al., 2012). In our current study, we have identified a role for Hmt1 in facilitating proper repression of Pol III-mediated transcription under stress. We show that association of Hmt1 to the tRNA genes is dependent on Pol III-transcribed gene activity and we have identified a subunit of Pol III as a substrate of Hmt1. Using a non-methylatable mutant of this subunit, we further demonstrate a role for this methylation in promoting optimal repression of tRNA biogenesis under stress. Lastly, we demonstrate the conservation of this modification in the human homolog of the Pol III subunit. Taken together, our data indicate a novel role for protein arginine methylation in the repression of Pol III-mediated tRNA biogenesis during stress and this role is likely to be evolutionarily conserved.

**MyoD Enhancer RNA in Gene Regulation.**
P. Tsai\(^1\), S. Dell’Orso\(^1\), K. Vivanco\(^1\), J. Rodriguez\(^2\), D.R. Larson\(^2\), V. Sartorelli\(^1\);
\(^1\)NIAMS, NIH, Bethesda, MD, \(^2\)NCI, NIH, Bethesda, MD

Adult stem cells (satellite cells, SCs) in skeletal muscle play significant roles in muscle regeneration and represent important targets for the treatment of muscular dystrophies. Myogenesis, the great ability of SCs to differentiate to skeletal muscle, is carried out by the activity of a series of transcription factors, including MyoD and Myogenin (MyoG), is. The gene expression of the muscle-specific master regulator MYOD1 is modulated by one of its own enhancer, distal regulatory regions (DRR). Enhancer RNAs (eRNAs) are a novel class of noncoding RNAs (ncRNA) expressed from active enhancers in the tissue-specific manner. DRR enhancer element is extensive occupied by its protein MyoD and transcribed into RNA species. This RNA transcripts corresponding to DRR enhancer (DRRRNA) upregulates downstream Myogenin gene. RNA fluorescence in situ hybridization imaged the cellular distribution and dynamic interaction of endogenous DRRRNA and nascent Myogenin RNA. In addition, chromatin isolation by RNA purification reveals that DRRRNA is engaged at the Myogenin locus. RNA pull down coupled to mass spectrometry found that the components of chromatin structure regulator cohesion, SMC3 and NIPBL, are identified as DRRRNA interactors. Similar to DRRRNA, knockdown of either DRRRNA associated–protein SMC3 or NIPBL disrupts myogenesis. Altogether these findings display a functional role of eRNAs in gene regulation by trans-acting. The mechanism by which distal eRNA affects specific gene expression is through organizing chromatin architecture. Insights of eRNA function are expected to advance our
understanding of muscle cell-type-specific transcriptional circuitry and contribute towards a cell-based therapeutic approach for muscle diseases.

*Repeat E anchors Xist RNA to the inactive X chromosome compartment through CDKN1A-interacting protein (CIZ1).*

H. Sunwoo1,2,3, D. Colognori1,2,3, J. Froberg1,2,3, Y. Jeon1,2,3, J.T. Lee1,2,3;
1Molecular Biology, Massachusetts General Hospital, Boston, MA, 2Howard Hughes Medical Institute, Boston, MA, 3Genetics, Harvard Medical School, Boston, MA

X chromosome inactivation is an epigenetic dosage compensation mechanism in female mammals driven by the nuclear long non-coding RNA, Xist. While recent genomic and proteomic approaches have provided a more global view of Xist’s function, how Xist RNA localizes to the inactive X-chromosome (Xi) and spreads in cis remains unclear. Here, we report that the CDKN1-interacting protein, CIZ1, is critical for localization of Xist RNA to the Xi chromosome territory. Stochastic optical reconstruction microscopy (STORM) shows a tight association of CIZ1 with Xist RNA at a single molecule level. CIZ1 interacts with a specific region within Xist exon 7, namely the highly repetitive repeat E motif. Using genetic analysis, we show that loss of CIZ1 and Repeat E phenocopy each other in female cells. In both cases, Xist RNA delocalizes from the Xi and disperses into the nucleoplasm. Interestingly, the Xi is exquisitely sensitive to CIZ1 levels, as either increasing or decreasing CIZ1 levels results in delocalization. This delocalization is accompanied by a decrease in H3K27me3 on the Xi. These data reveal that CIZ1 plays a major role in ensuring stable association of Xist RNA with the Xi.

The *R1* retrotransposon in *Drosophila* rDNA is transcribed by RNA Pol I upon heat shock.

H.S. Raje1; P.J. DiMario1;
1Biological Sciences, Louisiana State University, Baton Rouge, LA

The ribosomal DNA of *Drosophila melanogaster* resides within centromere-proximal nucleolar organizers on both the X and Y chromosomes. Each locus contains approximately 200 tandem rDNA genes that encode 18S, 5.8S, and 28S rRNAs for ribosome biogenesis. Spacer sequences ITS1 and ITS2 located within these rDNA units can be used as markers for pre-ribosomal RNA transcription, but do not contribute to ribosome formation. In arthropods like *Drosophila*, some rDNA units are inserted with R1 or R2 retrotransposons at specific sites within the 28S regions. These units cannot produce functional 28S rRNA and hence do not contribute to the formation of functional ribosomes. It is not yet clear whether R1 has its own promoter, but R2 is co-transcribed with rRNA from the rDNA promoter. Previous data from our lab show that R2 transcription is elevated upon nucleolar stress caused by the *Nopp140* gene deletion as compared to wild-type. To further assess whether R1 and R2 are stress induced retrotransposons, we treated wild type third instar larvae with heat shock. R1 expression was induced upon heat shock as measured by semi-quantitative RT-PCR and qPCR. Expression of R2 and the *copia* retrotransposon, however, did not change upon heat shock. Likewise, transcription of rDNA, as measured by the expression of ITS1 or ITS2, remained unchanged. To determine which RNA polymerase is responsible for R1 expression upon heat shock, we inhibited RNA Pol I transcription in S2 culture cells using a low dose of Actinomycin D or with CX5461. The observed downregulation of R1 expression upon Actinomycin D or CX5461 treatments indicated that R1 is co-transcribed by Pol I along with the rest of
the rDNA. To check for involvement of RNA Pol II, we inhibited Pol II transcription with α-amanitin. Even after inhibition of Pol II, R1 expression was upregulated upon heat shock. This suggests that under heat shock conditions R1 is transcribed by Pol I. Heat shock induced R1 transcription was also assessed in a genome wide PRO-Seq data set submitted to NCBI-GEO. We analyzed R1 and rDNA expression in this data set. Using computational analysis, we compared R1 and rDNA expression patterns upon RNAi mediated depletion of the Heat Shock Factor (HSF) with and without heat shock. Heat shock induced expression of R1 was reduced in the absence of HSF, suggesting HSF plays an active role in R1 induction upon heat shock. Although R1 and R2 elements insert within the rDNA and both are transcribed by Pol I, our observations suggest that they behave differently in their regulated expression. R1 and R2 elements are endogenous markers for generally silent rDNA genes. Any increase in their expression rates would indicate changes in nucleolar chromatin structure.

Optical trapping studies of glmS ribozyme riboswitch folding and catalysis.
A. Savinov1, S.M. Block2;
1Biophysics Program, Stanford University, Stanford, CA, 2Departments of Applied Physics and Biology, Stanford University, Stanford, CA

In many Gram-positive bacteria, expression of glucosamine-6-phosphate synthase (GlmS) is regulated by the glmS riboswitch. This riboswitch, a regulatory element found in the 5’ UTR of the glmS mRNA, controls gene expression by an unusual mechanism: the element folds to form a self-cleaving ribozyme. The self-cleavage reaction, in turn, is activated by the GlmS enzymatic product and cell wall precursor, glucosamine-6-phosphate (GlcN6P), which serves as a cofactor for the ribozyme. Self-cleavage of the riboswitch targets the entire glmS mRNA for degradation by intracellular RNases, thereby downregulating GlmS expression. We used optical tweezers to investigate folding and catalysis of the ribozyme core domain, a minimal version that retains GlcN6P-dependent self-cleavage activity. Measurements of the folding dynamics revealed a series of distinct intermediate states. By applying controlled optical loads and scoring the transition probabilities among these states as a function of force, we determined the free energy landscape of ribozyme formation, from the fully unfolded state to the fully folded state. Single-molecule measurements of self-cleavage in optically trapped ribozymes revealed that the fully folded state was catalytically active in a GlcN6P-dependent manner. The self-cleavage rate was also load-dependent, decaying in sigmoidal fashion with increasing force. Combined, results from our measurements of glmS ribozyme core folding and self-cleavage activity shed light on how folding of specific structural features relates to catalytic function.

Multiple mechanisms coordinately drive RNA-binding protein localization to RNA granules.
X. Wang1, N. Day1, E. Voronina1;
1DBS, University of Montana, Missoula, MT

Protein activity is intrinsically tied to its location in a cell. Many RNA-binding proteins are active when clustered in non-membrane bound RNA granules. One example of RNA granules is the germ granules of the nematode C. elegans, which are required for reproductive cell development and fertility.
binding protein FBF-2 requires localization to the germ granules in order for function. In addition to
germ granules, germ cells contain a variety of other RNA granules. Yet, the mechanisms that direct FBF-2
partitioning between multiple subtypes of RNA granules are unclear. RNA granule assembly is thought to
rely on multiple molecular interactions including protein binding to RNA and protein-protein
interactions mediated either by small linear peptide motifs (SLiMs) or intrinsically disordered regions
(IDRs). RNA-binding protein FBF-2 has both IDRs and SLiMs. Which of these are important for the in vivo
localization of FBF-2?
Localization and function of FBF-2 depends on its association with a small protein DLC-1 (Wang et al.,
2016). DLC-1/LC8 family members promote assembly of protein complexes by interacting with SLiMs in
their binding partners. We found three DLC-1-interacting SLiMs in FBF-2, located in regions of predicted
disorder (IDRs). To test whether SLiMs are required for FBF-2 localization to RNA granules, we mutated
or deleted all three SLiMs and generated an FBF-2 rm variant that fails to interact with DLC-1. FBF-2 rm
did not localize to germ granules when expressed in the worm. Instead, FBF-2 rm was found in distinct
cytoplasmic clusters. Surprisingly, FBF-2 rm enrichment in clusters was also reduced compared to
enrichment of wild type FBF-2 in germ granules.
Prior studies suggested that SLiM multivalency (multiple SLiMs per protein) is instrumental for protein
clustering. To test whether a single SLiM is sufficient for FBF-2 localization to the germ granules, we
generated a transgene with a single DLC-1-binding SLiM. We found an intermediate localization pattern,
where the mutant protein only partially overlapped germ granules.
These data suggest that SLiMs are important for both effective protein clustering in the cytoplasm and
for specific localization to appropriate RNA granules (germ granules) even in the presence of IDRs and RNA-binding activity. Coordinate activity of multiple RNA granule assembly mechanisms is thus required
for regulation of RNA-binding protein localization in vivo.

Single-Molecule Imaging Reveals Dynamic Biphasic Partition of the RNA-Binding proteins G3BP1
and IMP1 in Stress Granules of Living Neuronal Cells.
B. Niewidok1, M. Igaev1, A. Pereira da Graca1, A. Strassner1, C. Lenzen1, R. Kurre2, J. Piehler2, R. Brandt1;
1Neurobiology, University of Osnabrueck, Osnabrueck, Germany, 2Biophysics, University of Osnabrueck,
Osnabrueck, Germany

Maintenance of cellular polarity as well as fast response upon extracellular cues requires fast and tightly
regulated expression of proteins, especially in morphologically complex cells like neurons.
Ribonucleoprotein (RNP) granules contribute to the regulation of gene expression via posttranscriptional
coordination of mRNA translation, localization and degradation. These self-assembling structures lack a
membrane and can be considered as dynamic microcompartments.
The Ras GTPase activating protein SH3 domain binding protein 1 (G3BP1) and the Insulin like growth
factor II mRNA binding protein 1 (IMP1) are two paradigmatic RNA-binding proteins (RBPs) that are
present in cellular stress granules (SGs). Previous studies have shown that these two proteins colocalize
in SGs and that overexpression of either of them is sufficient to induce SG formation (Moschner et al.,
2014). According to in vitro experiments, SGs are formed by liquid-liquid phase separation (LLPS) and
remain amorphous, while being held together by surface tension. However, the dynamic organization of
SGs and their components with single-molecule resolution and, hence, their behavior remain unclear.
To follow the distribution and dynamics of G3BP1 and IMP1 in stressed neuronal cells, we performed
fluorescence decay after photoactivation (FDAP) measurements and single-molecule localization
microscopy (SMLM) of fluorescence-tagged proteins. The complementary approaches allow for
comparing the dynamics of protein exchange between SGs and the local dynamics of protein diffusion and interaction within SGs.

Our data show that IMP1 is largely constrained to SGs, while G3BP1 dynamically shuttles in and out of them. Within SGs on the other hand, both proteins exhibit alternating binding and diffusion with very similar characteristics. Quantitative analyses of the diffusion parameters confirm liquid-droplet like properties of SGs but also reveal remarkably immobile binding sites, which are transiently occupied by both RBPs and which we termed “nanocores”. In conjunction with the very different exchange kinetics observed by FDP, our studies demonstrate an unexpected disconnect between SGs partitioning and internal diffusion and interaction dynamics of G3BP1 and IMP1.

Identification of Rbfox associated proteins in striated muscles by BioID.
T. Govindarajan1, S. Kawamoto1, R.S. Adelstein1;
1Laboratory of Molecular Cardiology, National Heart, Lung, and Blood Institute (NHLBI) - NHLBI, NIH, Bethesda, MD

Rbfox1 and Rbfox2, sequence-specific RNA binding proteins, regulate alternative splicing of a variety of transcripts essential for cardiac and skeletal muscle development. Our lab has previously reported that both Rbfox1/2 undergo tissue-specific alternative splicing and produce multiple isoforms specific to brain, heart and skeletal muscle. However, the functional role of Rbfox isoforms and the associated protein interaction remains to be elucidated. Here, we used a proximity-labeling proteomics approach called BioID (Proximity-dependent Biotin identification) to identify the protein interaction network of individual Rbfox1/2 isoforms. This technique is particularly useful in identifying weak or transient interactions in living cells that are not detected by Co-immunoprecipitation (Co-IP) or yeast two-hybrid systems.

We started our experiments using the C2C12 mouse myoblast cell line as a model since C2C12 cells can be differentiated into myotubes in culture, similar to primary myoblasts. We first used immunofluorescence staining to compare the subcellular localizations of the BioID-Rbfox1/2 with the native protein. The results demonstrate that the fusion protein’s subcellular localization is not altered in comparison to native Rbfox1/2 isoforms. Additionally, all the BioID-Rbfox1/2 isoforms with the RNA recognition motif exhibited similar splicing activities as native proteins. Next, we tested the biotinylation of endogenous proteins in C2C12 cells expressing BioID-Rbfox1/2 isoforms, either in the presence or absence of exogenous biotin, using Western blots probed with Streptavidin- Alexa Fluor 700 conjugate. The results indicate that in the presence of exogenously added biotin, BioID-Rbfox1/2 isoforms strongly stimulate biotinylation of a wide range of endogenous proteins. These biotinylated proteins reside in the same cellular compartment and colocalize with BioID-Rbfox1/2 isoforms by immunofluorescence. These results indicate that BioID-Rbfox1/2 isoforms can be targeted to proper subcellular locations without affecting their activities and can biotinylate endogenous proteins in a proximity-dependent manner.

Next, we used affinity capture to isolate the biotinylated proteins in undifferentiated and differentiated C2C12 cells expressing individual BioID-Rbfox1/2 isoforms and identified them by mass spectrometry for functional characterization. Notably, BioID-Rbfox2 isoforms yielded more than 100 high confidence protein interactions including known interactors of the Rbfox2. The identified protein interactors are directly related to mRNA metabolic processes and post-transcriptional regulation of gene expression.
RNA modifications have long been known to play important structural and functional roles in noncoding RNAs. More recently, however, technological advances in next generation sequencing and mass spectrometry have revealed the distributions of chemical modifications on mRNA transcripts as well. The most abundant internal mRNA modification, $N^\delta$-methyladenosine (m$^\delta$A), is linked to the regulation of mRNA stability, splicing, localization, and translation. However, the mechanisms by which mRNA modifications influence cellular processes remain largely mysterious. Moreover, numerous other modifications have been found on mRNA about which we have an even more limited understanding. We recently reported that $N^\gamma$-methyladenosine (m$^\gamma$A), previously characterized in tRNA and rRNA, occurs on thousands of transcripts in eukaryotic cells. m$^\gamma$A is chemically distinct from m$^\delta$A, carrying a positive charge that can have dramatic effects on RNA structure and folding. m$^\delta$A is also distinct in its distribution, and is enriched around the first splice site. It is found primarily in more structured regions, is dynamic in response to stress, and correlates positively with protein level. While these characteristics suggest that m$^\delta$A has cell biological functions that differ from m$^\gamma$A, many questions remain unanswered. Current work is focused on identifying the machinery that regulates m$^\delta$A installation and understanding how methylation influences transcript fate.

The eukaryotic-specific Rpl22 (eRpl22) family in Drosophila melanogaster includes duplicated ribosomal protein (RP) genes eRpl22 and eRpl22-like that are differentially expressed: eRpl22 is expressed ubiquitously and eRpl22-like expression is tissue-restricted with highest levels in the male germline. Co-expression of both paralogues in the male germline is suggestive of specialized functions for paralogue-specific ribosomes within maturing sperm. Compelling evidence for ribosome heterogeneity at the level of core RPs affecting mRNA translation has recently been shown (Shi et al., 2017). We have proposed that each paralogue is incorporated into ribosomes in early mitotic stages of spermatogenesis. At later stages, however, the role of eRpl22 may change, as the paralogue undergoes testis-specific SUMOylation and phosphorylation, and is sequestered in the nucleoplasm of meiotic spermatocytes (Kearse et al., 2013). Numerous mRNAs transcribed in primary spermatocytes remain translationally inert until later stages. Activation of previously silenced mRNAs as well as translation of mRNAs transcribed in post-meiotic mid to late elongating spermatids requires ribosome activity at stages of spermiogenesis well after meiosis is completed. Based on this temporal cascade of gene expression throughout spermatogenesis, we have proposed that paralogue-specific ribosomes specify a unique translome required for sperm production, with eRpl22-like ribosomes likely translating most testis-specific mRNAs synthesized. To test this hypothesis, we performed RNAseq on testis eRpl22- and eRpl22-like-specific ribosomes, captured by immunoprecipitation using paralogue-specific antibodies from ribosome profiles (polysome fractions). Our preliminary analysis of >1500 RNAs from ~12,000
ribosome-associated RNAs shows distinct classes of mRNAs translated on paralogue-specific ribosomes and numerous non-coding RNAs. mRNAs specifying constitutively expressed genes involved in DNA maintenance and transcription are commonly enriched on eRpl22 ribosomes. Transcripts known to be expressed in early mitotic stages, such genes involved in regulating mitotic nuclear division, are found on both ribosome types, with a slight bias toward eRpl22 ribosomes. Most meiotic and later stage testis-specific transcripts are enriched on eRpl22-like ribosomes. Overall, our RNAseq data are congruent with the proposal that eRpl22 paralogues translate different classes of testis mRNAs. Ongoing experiments include the use of computational tools to determine if conserved mRNA sequences are required for paralogue-specific translation, and the use of stable S2 cell lines transfected with eRpl22-like to explore translation requirements for testis-specific mRNAs.

Understanding the endogenous regulation of Ataxin-1 in SCA-1.
R. Manek1, E. Rodriguez-Lebrón1;
1Pharmacology Therapeutics, University of Florida, Gainesville, FL

Spinocerebellar ataxia type-1 (SCA-1) is an autosomal dominantly inherited, progressive neurodegenerative disease caused by the abnormal expansion of a ‘CAG’ tri-nucleotide repeat within the coding region of the ATXN1 gene. The CAG expansion is translated into a polyglutamine (PolyQ) tract in the N-terminus of the Ataxin-1 protein. Mutant Ataxin-1 expression is necessary for both the onset and progression of this currently untreatable disease. Novel therapeutic strategies such as RNAi that down regulate overall Ataxin-1 protein levels have shown to mitigate SCA-1 associated phenotype in the mouse models of the disease. Thus, understanding the endogenous cellular mechanisms that regulate Ataxin-1 expression, and how this regulation may be disrupted in SCA-1, is key to the development of novel, clinically relevant therapeutics. Here we seek to better define the post-transcriptional regulation of ATXN1 by evaluating the role that the 5'UTR of ATXN1 plays on the expression of Ataxin-1, in the context of both the WT and the CAG-expanded transcript. In order to determine if the 5'UTR ATXN1 can independently regulate Ataxin-1, we have designed highly versatile reporter-based assays. In preliminary studies, we find that the 5'UTR ATXN1 sequence exerts a strong regulation of protein levels (GFP reporter gene). Analysis of steady-state RNA levels by quantitative PCR appear to indicate decrease in RNA levels. Since cellular post-transcriptional gene regulation is mainly exerted by altering mRNA stability and/or translational efficiency, we have designed studies to investigate the role the 5’UTR of ATXN1 plays in regulating ATXN1 mRNA stability and translational efficiency.

Alterations in S-adenosylmethionine synthesis regulate stress granule assembly and composition.
K. Begovich1, J.E. Wilhelm1;
1Biological Sciences, University of California, San Diego, La Jolla, CA

While regulation of RNA metabolism and metabolism are two of the most ancient functions of the cell, there have been relatively few studies into crosstalk between these two regulatory networks. We have recently completed a visual screen of all 440 metabolic enzymes in the S. cerevisiae GFP strain collection to identify metabolic enzymes that assemble into novel structures. This screen identified 17 metabolic enzymes that are localized to stress granules, which are sites of post-transcriptional gene regulation.
This localization does not appear to be used for substrate channeling since the enzymes that are recruited to the stress granules are not in consecutive steps of a biosynthetic pathway. As a result, we examined the possibility that stress granule composition and assembly might be controlled by specific metabolic states and metabolites.

We have found that while many types of stress cause RNA granules to form, only chronic nutrient stress causes metabolic enzymes to be recruited to stress granules. In order to determine whether the products or intermediates of specific metabolic pathways regulate stress granule assembly, we focused on methionine/S-adenosylmethionine biosynthesis since several of the enzymes in that pathway are recruited to stress granules. Interestingly, mutations in this pathway that decrease levels of S-adenosylmethionine (AdoMet) triggered stress granule assembly. In contrast, mutations that increased AdoMet levels blocked stress granule assembly. Further analysis revealed that this assembly defect is specific to the proteins that act at the 5’ end of transcripts arguing that AdoMet acts at a specific step in stress granule assembly. Interestingly, elevated AdoMet only affects the assembly of stress granules that are formed in response to chronic nutrient stress. Thus, chronic nutrient stress triggers the assembly of stress granules that 1) recruit components of the methionine/S-adenosylmethionine biosynthetic pathway and 2) that are regulated by the products of that pathway. This argues that stress granule assembly is differentially regulated in response to distinct metabolic stresses. Furthermore, the role of this metabolic pathway appears to be evolutionarily conserved since the human S-adenosylmethionine synthetase also forms foci in yeast in response to chronic nutrient stress. The targeting of metabolic pathways to sites of post-transcriptional gene regulation presents a new opportunity for understanding how crosstalk between distinct regulatory networks is controlled.

Zthi2 and ZTHI3: Prospects in Breeding and Genetic Engineering for Thiamine Biosynthesis and Accumulation.
T.O. Salaam¹², O.O. Omidiji², I.A. Taiwo², K.O. Adekoya²;
¹Biotechnology, Federal Institute of Industrial Research, Oshodi, Lagos, Nigeria, ²Cell Biology and Genetics, University of Lagos, Lagos, Nigeria

Tropical Zea mays contain significant levels of thiamine, a critical vitamin required for growth and development in living organisms. Thiamine biosynthesis has been studied in several organisms including Arabidopsis, Zea mays and Escherichia coli. The genes involved in Zea mays are Z-thi1 and Z-thi2, ZTHIC, ZTHI3, Ztpk1 and Ztpk2 which code for thiazole synthase, pyrimidine synthase, pyrimidine-phosphate kinase/thiamine mono-phosphate synthase (TMPS) and thiamine pyrophosphokinase respectively. Therefore, it is necessary to determine interrelatiprorgammes.onships that may exist between these bio-synthetic genes in relation to metabolite contents and enzyme activities in Zea mays varieties for thiamine breeding programme. Forty-one Zea mays inbred lines were used in this study and a combination of biochemical and molecular biology techniques (HPLC and spectrophotometry qRT-PCR, SDS-PAGE, Western blotting and sequencing) were employed. We report a significant positive correlation between Zthi2 expression and seed thiamine accumulation thus making it a “candidate” gene for seed thiamine bio-accumulation in Zea mays. The ZTHI3 gene had the highest expression (2.13 - 4.23) but its corresponding enzyme, TMPS, had the least activity (0.080 - 1.424 pmol. mg⁻¹ protein.min⁻¹). Western blot analysis detected the presence of both active di-meric (95 kDa) and inactive mono-meric (55 kDa) forms of the TMPS protein with a greater accumulation of the 55 kDa inactive monomer suggesting a post translational mechanism of regulating its activity. Our results further suggest that TMPS is a rate limiting enzyme in the thiamine bio-synthetic pathway. Thus, making
the Zthi2 and ZTHI3 genes target genes for thiamine bio-accumulation studies and breeding programmes

**Translational regulation of DEAD-box helicase Ded1/DDX3 medulloblastoma mutations.**

N.P. Brown¹, T.A. Bolger¹;

¹Molecular and Cellular Biology, University of Arizona, Tucson, AZ

Alterations in translation regulation have emerged as major contributors to cancer progression, but in many cases the molecular pathology remains unclear. Multiple concurrent genome-wide studies of the most common pediatric malignant brain tumor, medulloblastoma, identified the DEAD-box helicase named DDX3 as a highly mutated gene within multiple subtypes of this disease. Although the overall survival rate is 70-80%, the current treatment protocol for medulloblastoma causes serious long-term cognitive and endocrine side-effects, thus a better understanding of the molecular mechanisms is needed to design effective targeted therapies. DEAD-box proteins are the largest family of RNA helicases, and they have critical roles in multiple aspects of gene expression and RNA metabolism, orchestrating mRNA fate and cellular function. Proposed functions of DDX3 and its yeast ortholog Ded1 include activation and repression of translation; however, the cellular mechanisms are not fully defined. In order to examine the cellular defects caused by the medulloblastoma-associated mutations (mam) identified in DDX3, we made equivalent, conserved mutations in the yeast gene Ded1. Intriguingly, although ded1-mam cells exhibit growth defects, most do not display substantial defects in general translation. Alternatively, we have observed particular 5’ UTR structures of mRNA to be specifically affected in mutant cells using reporters containing stem loops. This may reflect changes in the ability of the ded1-mams to resolve mRNA secondary structures in the 5’ UTR during translation initiation and suggests that translation of a subset of mRNAs may be differentially affected in mutant cells. Quantitative reverse transcription PCR experiments will potentially verify whether specific genes either known to be dependent on Ded1 or contain a long 5’ UTR have altered translational status. We propose that these defects are essentially hypomorphic for DDX3/Ded1 cellular function, and the molecular mechanism will ultimately contribute to the pathology of medulloblastoma.

¹Biology, Waldorf University, Forest City, IA, ²Biochemistry, University of Iowa, Iowa City, IA

Mutations in the human LMNA gene cause a wide spectrum of diseases that include three types of muscular dystrophy: congenital, Limb Girdle Type IB, and Emery-Dreifuss. There are currently no treatments for individuals with these types of muscular dystrophy. The development of treatments requires a thorough understanding of the pathogenic mechanisms caused by mutant lamins. To better understand the molecular basis of the muscle pathology, we generated genetically tractable Drosophila models of lamin-associated muscular dystrophy. Fruit flies with muscle-specific expression of mutant lamins develop muscular dystrophy, characterized by reduced motility and premature death. Depending on the specific mutation, diseased muscles can exhibit abnormally spaced nuclei, atypical chromatin
morphology, nuclear actin rods, increased DNA damage, altered proteostasis, and loss of redox homeostasis. Using human muscle biopsy tissue from individuals with mutations that correspond to the Drosophila models, we observed similar abnormal phenotypes. Therefore, we used Drosophila to genetically test candidate genes for modifier function. Muscle-specific expression of RNAi and over-expression transgenes encoding autophagy and redox regulators and members of the DNA damage response pathway suppressed mutant lamin-induced lethality. Our findings demonstrate that lamins play a vital role in maintaining muscle physiology and genome integrity and offer potential pharmacological targets for therapy.

Nuclear movements are important for multiple cellular functions and are driven by polarized forces generated by motor proteins and cytoskeleton. During skeletal myofiber formation or regeneration, nuclei move from the center to the periphery of the myofiber for proper muscle function. Centrally located nuclei are also found in different muscle disorders. Using theoretical and experimental approaches, we demonstrate that nuclear movement to the periphery of myofibers is mediated by centripetal forces around the nucleus. These forces arise from myofibril contraction and cross-linking that “zip” around the nucleus in combination with tight regulation of nuclear stiffness by lamin A/C. In addition, an Arp2/3 complex containing Arpc5L together with γ-actin is required to organize desmin to cross-link myofibrils for nuclear movement. Our work reveals that centripetal forces exerted by myofibrils squeeze the nucleus to the periphery of myofibers.

**Mechano-protection by lamin-A against DNA damage as the developing heart stiffens and strengthens.**

S. Cho1, S. Majkut1, A. Abbas1, K. Vogel1, M. Vashishth1, J. Irianto1, M. Tewari1, B.L. Prosser3, D.E. Discher1; 1Molecular Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA, 2Department of Physics Astronomy, University of Pennsylvania, Philadelphia, PA, 3Department of Physiology, Pennsylvania Muscle Institute, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Across all terminally differentiated adult tissues, the lamins are the main structural proteins of the nucleus that increase in A- to B-type stoichiometry (‘lamin-A:B’) when plotted versus collagen-I and tissue stiffness [Swift et al, 2013]. To understand mechanisms and functional contributions, beating hearts from chick embryos at different stages were characterized with various perturbations, revealing that lamin-A:B again scales with the progressive increase in collagen-I, and that lamin-A levels change
within ~1 hr when tissue is softened or stiffened by perturbing collagen or actomyosin contractility. Upon tissue softening, phosphorylation and solubilization of lamin-A increase to facilitate its degradation by constitutive matrix metalloproteinase 2 (MMP-2) within the nucleus. DNA damage decreases upon inhibition of actomyosin contractility and moreso if lamin-A is kept high by inhibiting its solubilization. Transcriptional control of lamin-A using retinoids likewise influences DNA damage levels. Isolated cardiomyocytes on collagen-coated soft or stiff gels show that lamin-A again increases monotonically versus matrix stiffness with regulation by phosphorylation and by MMP-2, while decoupling from rhythmic beating. Knockdown of lamin-A in iPS-derived cardiomyocytes on stiff matrices increases frequency of nuclear rupture, loss of DNA repair factors from the nucleus, and DNA damage, with rescue by actomyosin inhibition and by soft matrix. Lamin-A thus couples to actomyosin tension and matrix stiffness in order to minimize DNA damage.

**Exploring genomic reorganization during differentiation of emerin-null and EDMD mutant myogenic progenitors.**

A.G. Liddane¹, J.M. Holaska¹;

¹Pharmaceutical Sciences, University of the Sciences, Philadelphia, PA

The human genome is contained within the nucleus. Genomic organization dynamically changes during development to regulate tissue development and tissue-specific functions. The nucleus is surrounded by a membrane composed of two lipid bilayers called the nuclear envelope. Many integral membrane proteins reside in the nuclear envelope. Recently, some of these nuclear envelope proteins were implicated in regulating genomic organization. Our lab focuses on one of these proteins, emerin, to study its function in the nuclear envelope. We are specifically focusing on how emerin regulates genomic organization and gene expression during development and skeletal muscle regeneration. Chromatin at the nuclear lamina at the nuclear envelope is associated with transcriptional repression. We predict association of repressed chromatin with the lamina is mediated through lamin-binding proteins at the nuclear envelope, including emerin. Supporting this hypothesis, we previously showed emerin was required for genomic organization of selected loci in myogenic progenitors. Chromatin immunoprecipitation followed by sequencing (ChIP-seq) using lamin A antibodies will be performed in differentiating emerin-null and EDMD mutant myogenic progenitors to test how chromatin organization is affected by emerin loss or mutation. How genomic organization is altered in EDMD causing mutants will then be examined. ChIP-seq with emerin antibodies will also be done to test if the interaction of emerin with the genome is sequence-specific. Lamin A/C and B1 as well as emerin antibodies have been optimized for the ChIP-seq. This allows us to move on to ChIP-qPCR. We hypothesize altered genomic organization in EDMD causing mutants will cause significant changes in temporal expression of differentiation genes.

Expression profiling of differentiating myogenic progenitors lacking emerin or expressing EDMD-causing emerin mutants identifies molecular pathways responsible for their impaired differentiation.  
A. Iyer1, J.M. Holaska1;  
1Pharmaceutical Sciences, University of the Sciences, Philadelphia, PA

Mutations in the gene encoding for emerin (EMD), an ubiquitously expressed inner nuclear membrane protein causes X-linked Emery-Dreifuss muscular dystrophy (EDMD), an inherited disorder causing progressive skeletal muscle wasting, irregular heart rhythms and contractures of major tendons. Impaired muscle regeneration is thought to be involved in the skeletal muscle defects seen in EDMD, but the underlying mechanisms remain poorly understood. To identify molecular pathways implicated in the EDMD mechanism, RNA sequencing was performed on differentiating wildtype and emerin-null myogenic progenitors. Our analysis revealed 340 genes were found to be uniquely misexpressed during the transition from day 0 to day 1 of differentiation in wildtype cells. 1,605 genes were found to be uniquely misexpressed in emerin-null cells during this transition. 1,706 genes were found to be shared among both wildtype and emerin-null cells during this transition. Ingenuity Pathway Analysis (IPA) was done on the transcripts uniquely misexpressed in emerin-null cells at this transition. IPA identified significant inhibition of the STAT3 pathway, TGF-β signaling pathway, VEGF signaling pathway and growth hormone signaling pathway. Functional enrichment analysis using IPA identified the significant inhibition of biological functions associated with the growth of muscle tissue and the myogenesis of skeletal muscle. Most disease-causing emerin mutations are nonsense mutations resulting in complete loss of emerin, there are four disease-causing EMD mutations that express emerin protein at near wildtype levels and localize correctly to the nuclear membrane. We hypothesize studying these emerin mutants will elucidate novel emerin functions important for the EDMD disease mechanism. We are currently generating myogenic progenitors (H2K cells) expressing wildtype emerin and each EDMD-causing emerin mutant in an emerin-null background using lentiviral transductions. We have achieved a selection efficiency of about 85% for emerin-null cells transduced with wildtype emerin and these transduced cells maintain their differentiation potential. Importantly, myotube formation and myoblast fusion were rescued in emerin-null cells transduced with wildtype emerin. RNA sequencing analysis will be performed during consecutive days in differentiation of EDMD-causing emerin mutants and wildtype emerin transduced emerin-null cells to identify important changes in the transcriptional program.

Nanoscale Nuclear Envelope Dynamics and Spatial Organization of the Muscular Dystrophy Protein Emerin.  
A. Fernandez1, M. Bautista2, T. Chung1, F. Pinaud1,2,3;  
1Biological Sciences, University of Southern California, Los Angeles, CA, 2Chemistry, University of Southern California, Los Angeles, CA, 3Physics and Astronomy, University of Southern California, Los Angeles, CA

Emery-Dreifuss Muscular Dystrophy (EDMD) is a laminopathy caused by mutations of emerin, an inner nuclear envelope protein that participates to nucleo-cytoskeleton mechanotransductions, maintenance of nuclear shape and nucleus stiffening against applied tensions. The mechanosensing functions of
emerin and the reasons why its mutations cause altered nuclear mechanics and muscle disease remain unclear. To address the molecular pathogenesis of EDMD at the nanoscale we used single molecule and three-dimensional superresolution optical microscopy in human cells. At the nuclear envelope, the diffusional mobility and the spatial organization of wild type (WT) emerin and a variety of clinically relevant emerin mutants were quantified by single particle tracking photo-activated localization microscopy (sptPALM) and direct stochastic optical reconstruction microscopy (dSTORM) imaging in rescued emerin-null cells. We identified different subpopulations of WT emerin associated with the endoplasmic reticulum, the outer or the inner nuclear envelope and show that it forms diffraction-limited nanoclusters at the nuclear membrane. We further show that the diffusion of emerin and its nanoscale clustering are directly impacted by mutations that cause EDMD and that a complex interplay between lamin A binding, actin binding and emerin/emerin interactions dictate the dynamics and the nanoscale spatial distribution of emerin at the nuclear envelope. To study how specific mechanical strains at the nuclear membrane influence the normal and pathogenic nanoscale organizations of emerin, we also developed a simple cell micropatterning strategy that provides control of the nucleus architecture and allows steady-state changes in the mechanical landscape of the nuclear envelope while permitting nanometer accuracy single molecule microscopy. Super-resolution imaging of emerin in nuclei subjected to varying mechanically strains reveals that the mechanotransducing functions of emerin are coupled to its clustering state and its nanoscale distributions within the inner nuclear envelope. Together, sptPALM, dSTORM superresolution imaging, emerin mutants and cell micropatterning reveal subtle biophysical properties of nuclear emerin that would otherwise be undetected by traditional diffraction-limited microscopy techniques and help elucidate key molecular mechanisms of EDMD.

Attractive and repulsive nuclear interactions are regulated by distinct genes linked to Emery-Dreifuss Muscular Dystrophy and Centronuclear Myopathy.

M.A. Collins¹, J.M. Camuglia¹, M. Gutierrez¹, T. Shu¹, E.S. Folker¹;
¹Department of Biology, Boston College, Chestnut Hill, MA

Syncitia, cells with multiple nuclei, are less prevalent than their mononucleated counterparts. However, there are many examples of syncitia in biology. The developing Drosophila blastoderm and skeletal muscle are commonly studied examples as are less frequently studied examples such as placenta and osteoclasts. Yet little is known about how the presence of many nuclei in each of these cells impacts their specific biology. Therefore it is crucial to understand how and when each nucleus interacts with the other nuclei. In skeletal muscle, the rapid movement of myonuclei to the cell center to join already incorporated nuclei suggests attractive interactions. Conversely, there are repulsive interactions between nuclei later in muscle development, which keep nuclei spaced distant from one another. Myonuclei in Drosophila muscles undergo a similar set of dynamic movements during myogenesis. After fusion, nuclei separate into two clusters that move directionally toward opposite poles of the muscle. During directional movement, the nuclei remain in tightly associated clusters. Disruption of two different genes, bocksbeutel (dEmerin) and klarsicht (dNesprin), blocked the initial separation of nuclei into two distinct clusters. This clustering phenotype was similar to nuclear positioning defects caused by the disruption of ensconsin (dMAP7), a MT-associated protein that regulates nuclear movement via microtubules. In ens mutants, nuclei fail to separate into distinct clusters and remain associated together, indicating that the MT machinery responsible for separating nuclei was disrupted. However, live-embryo time-lapse microscopy of bocks depleted embryos demonstrated a nucleus could
occasionally escape the cluster and move directionally, indicating that the force generating machinery and spatial cues were functional. Thus, bocks and klar were necessary to regulate the repulsive interactions between nuclei. Conversely, disruption of Amphiphysin, inhibited the attractive interactions between nuclei. This was evident by the regular dissociation of nuclei from clusters and the presence nuclei in the center of the muscle. Together these data indicate that nuclei do exhibit both attractive and repulsive interactions in skeletal muscle that are regulated by distinct proteins at specific developmental times.

Bocksbeutel regulates nuclear positioning by a klarsicht-dependent mechanism.

T.R. Mandigo¹, A.J. Anderson¹, B.D. Turcich¹, E.S. Folker¹;
¹Biology, Boston College, Boston, MA

Nuclear movement is conserved throughout eukaryotes. Although some mechanisms that drive nuclear movement in diverse cell types have emerged, it is not clear how conserved these mechanisms are between different cell types. Furthermore, the mechanisms by which nuclear movement impacts cellular function are virtually unexplored. To answer these questions, we have focused on the mechanisms of nuclear movement in skeletal muscle. The high correlation between mispositioned nuclei and muscle disease suggests that nuclear position is a critical determinant of muscle function. Furthermore, the factors that have been identified as important for nuclear position in muscle overlap with the factors that move nuclei in most cell types. In these studies we examined genes linked to a specific disease, Emery-Dreifuss Muscular Dystrophy (EDMD), because the proteins encoded by the genes linked to EDMD localize to the nuclear envelope and regulate nuclear movement in other cell types. Although many of these genes have been implicated in nuclear position, the mechanisms by which they contribute to nuclear position are not known. To identify the mechanisms by which these genes regulate nuclear position in muscle, we have determined the network of genetic interactions between EDMD-linked genes that regulate nuclear position during muscle development in Drosophila. The most striking phenotype was the single-file arrangement of nuclei in a klarsicht (nesprin);bocksbeutel(emerin) double-heterozygote. Remarkably, although bocksbeutel and Otefin, another emerin ortholog in Drosophila, genetically interacted to regulate nuclear position, we detected no interaction between Otefin and klarsicht. Based on the genetic interaction between klarsicht and bocksbeutel, we hypothesized that bocksbeutel may affect klarsicht localization. Indeed, immunofluorescence experiments demonstrated that nuclear levels of klarsicht were reduced in bocksbeutel mutant animals compared to controls. Conversely, klarsicht levels were increased in Otefin mutant animals compared to controls. Measurement of klarsicht transcript levels mirrored these changes indicating that bocksbeutel is important for the expression of klarsicht whereas Otefin is necessary to repress klarsicht expression. Together these data suggest that bocksbeutel (Drosophila emerin) indirectly regulates nuclear position by its effects on klarsicht (Drosophila nesprin). Additionally, bocksbeutel-dependent regulation of klarsicht is opposed by the effects of another Drosophila emerin, Otefin.

Lamin A regulates the activity and dynamics of nucleoli.
A.L. Buchwalter1, M.W. Hetzer1;
1Molecular and Cell Biology Laboratory, The Salk Institute for Biological Studies, La Jolla, CA

The nuclear lamina is an intermediate filament meshwork that underlies the nuclear envelope, extends through the nuclear volume, and interacts with the genome. Previous analyses have linked lamins to processes including transcription, replication, gene silencing, and cell migration. However, embryonic stem cells lacking all lamins can proliferate and differentiate1. This surprising finding underscores how little we understand about the essential functions of lamins. Mutations to lamins cause a wide spectrum of pathologies, including Hutchinson-Gilford progeria syndrome (HGPS). HGPS is a rare, fatal premature aging disorder caused by a mutation to lamin A that generates a truncated protein termed progerin. Using HGPS as a model system to probe lamin biology, we discovered that A-type lamins have a role in regulating the activity of nucleoli. Nucleoli are membraneless organelles within the nucleus that coalesce around actively transcribing ribosomal DNA (rDNA) loci. Nucleoli produce ribosomal RNA, participate in ribosome biogenesis, and receive inputs from cellular signaling pathways. In HGPS-derived cell cultures and in normal cells induced to ectopically express progerin, nucleoli are enlarged. In HGPS, enlarged nucleoli are also more active and produce more ribosomes, which in turn results in globally elevated protein translation. Progerin expression drives the global depletion of heterochromatin marks by an unknown mechanism2. We find that loss of repressive DNA methylation on rDNA loci allows their over-activation in HGPS, suggesting that lamin A influences the chromatin state of rDNA. Depletion of lamin A from normal cells also allows nucleoli to expand and produce more ribosomal RNA. Intriguingly, depletion of lamin A increases the nuclear dynamics of nucleoli. We speculate that A-type lamin networks within the nucleus limit both nucleolar mobility and transcriptional activity of rDNA loci. Since the expression of A-type lamins increases dramatically as cells exit pluripotency and varies widely across differentiated cell types, it is possible that nucleolar activity also changes in tandem with shifts in lamin A expression. These findings generate new insight into the cellular defects associated with HGPS and define a new function for lamin A in regulating the nucleolus.

Nuclear shape and architecture influence gene localization, mechanotransduction, transcription, and cell function. Abnormal nuclear morphology and protrusions termed “blebs” are diagnostic markers for many human afflictions including heart disease, aging, progeria, and cancer. Nuclear blebs are
associated with both lamin and chromatin alterations. Currently, it is believed that lamins dictate nuclear morphology, but the contributions of altered chromatin compaction remain unclear. We show that modulating chromatin histone modification state dictates nuclear rigidity and is sufficient to both induce and suppress nuclear blebs. Treatment of mammalian cells with histone deacetylase inhibitors to increase euchromatin or histone methyltransferase inhibitors to decrease heterochromatin results in a softer nucleus and nuclear blebbing, without perturbing lamins. Oppositely, treatment with histone demethylase inhibitors increases heterochromatin and chromatin nuclear rigidity, which results in reduced nuclear blebbing in lamin B1 null nuclei. Notably, increased heterochromatin also rescues nuclear morphology in a lamin A mutant model for the accelerated aging disease Hutchinson-Gilford Progeria Syndrome. Thus, chromatin histone modification state is a major determinant of nuclear blebbing and morphology via its contribution to nuclear rigidity.

Chromatin state contributes to nuclear mechanics.  
J.F. Johnston², S. Mochrie²,³, M.C. King¹;  
¹Department of Cell Biology, Yale School of Medicine, New Haven, CT, ²Department of Physics, Yale University, New Haven, CT, ³Department of Applied Physics, Yale University, New Haven, CT

In mammalian cells, an integrated network of heterochromatin, a polymer mesh of intermediate filaments (lamins), and integral inner nuclear membrane proteins provides a robust nuclear structure that protects the genome. In particular, this network plays a critical role in maintaining nuclear integrity under mechanical strain, yet it is unclear how chromatin, and its condensation state, individually contributes to the overall structure and mechanics of the nucleus. Here we show that deletion of epigenetic modifiers is sufficient to alter nuclear deformability in yeast. We use a novel three-dimensional (3D) image reconstruction software that tracks fluorescently-labeled nuclear envelope fluctuations over time, as well as a novel force spectroscopy assay that employs optical tweezers to directly measure the viscoelastic properties of isolated nuclei. We find that deletion of the heterochromatin reinforcing factor Swi6 (an HP1 orthologue) results in increased nuclear deformability, while loss of the H3K9 demethylase Epe1 (a KDM2B orthologue) that drives heterochromatin spreading results in decreased nuclear deformability. Our results support the hypothesis that changes in epigenetic modifications, in addition to influencing the transcriptome, have a strong influence on nuclear mechanics. As epigenetic modifications of histones are strongly suggested to contribute to certain disease states, understanding how these chromatin changes act in parallel to influence nuclear integrity and genome stability will be essential to elucidating the full effect of epigenetic alterations on disease pathogenesis.

Ablation of SUN2-containing LINC complexes drives defects in developmental myofibrillogenesis and cardiac hypertrophy without fibrosis.  
R.M. Stewart¹, E.C. Rodriguez¹, M.C. King¹;  
¹Cell Biology, Yale School of Medicine, New Haven, CT

The cardiomyocyte cytoskeleton, including the sarcomeric contractile apparatus, forms a cohesive network with cellular adhesions at the plasma membrane and nuclear-cytoskeletal linkages (LINC complexes) at the nuclear envelope. Human cardiomyopathies are genetically linked to the LINC
complex and other components of the nuclear lamina, but a concrete understanding of disease etiology in these patients is lacking. Here we show that disruption of SUN2 LINC complexes in mice produces pronounced defects in sarcomere organization, intercalated disc structure, and integrin engagement at the costamere. These changes initiate early in development with profound alterations in sarcomerogenesis that precede loss of nuclear integrity. Surprisingly, SUN2-null mice display enhanced cardiac contractile function, which is associated with altered integrin activity, increased AKT/MAPK signaling, and cardiac hypertrophy. However, these mice do not exhibit increased fibrosis or up-regulation of pathological hypertrophy markers, suggesting that ablation of SUN2 LINC complex drives hypertrophy but not pro-fibrotic signaling. Together these results suggest a new model for the origin of cardiomyopathies in nuclear envelopopathies and laminopathies.

Coordinated increase of nuclear tension and lamin-A with matrix stiffness out-competes Lamin-B Receptor, which favors soft tissue phenotypes.
J. Irianto1, A. Buxboim1, D.E. Discher1;  
1Molecular Cell Biophysics Lab, University of Pennsylvania, Philadelphia, PA

Matrix elasticity sensed by a cell or measured by a physical probe reflects both the intrinsic softness of the matrix and also how thick or thin the matrix is. Mesenchymal stem cells (MSCs) help show that cells and their nuclei spread in response to a thickness-corrected matrix stiffness, with increases in nuclear tension and nuclear stiffness resulting from increases in myosin-II and lamin-A,C. Linearity between the widely varying projected area of a cell and its nucleus across many matrices, timescales, and myosin-II activity levels indicates a constant ratio of nucleus-to-cell volume. Nuclear envelope fluctuations are suppressed on stiff matrix relative to soft matrix, consistent with a “four-fold increase in tension on the nucleus and also consistent with estimates from traction force microscopy and calculations based on lamin-A,C’s increase. Transcriptomes of diverse tissues and MSCs further show increases in lamin-A,C anti-correlate with levels of lamin-B receptor (LBR), which contributes to lipid synthesis. Adipogenesis (soft) as well as osteogenesis (stiff) of MSCs confirm anti-correlation of protein, and competition of lamin-A,C and LBR for lamin-B is evident in responses to matrix elasticity, various knockdowns, myosin-II inhibition, and constricted migration. Rigidity-driven contractile stress thus tenses and stiffens the nucleus to oppose soft tissue phenotypes.

Dynein pulling forces on ruptured nuclei counteract lamin-mediated repair mechanisms in vivo.
L. Penfield1, B. Wysoolmerski1, R. Farhadifar2, M.S. Mauro1, C.J. Broberg1, M.A. Martinez1, R.J. Biggs3, H. Wu2, D.J. Needleman3, S. Bahmanyar1;  
1Dept. of Molecular Cellular and Developmental Biology, Yale University, New Haven, CT, 2School of Engineering and Applied Science, Harvard University, Cambridge, MA, 3Ludwig Institute for Cancer Research, UC San Diego, La Jolla, CA

Recent work done exclusively in tissue culture cells revealed that the nuclear envelope (NE) undergoes nuclear rupture and repair in interphase leading to transient mixing of nuclear and cytoplasmic components. The duration of transient NE ruptures depends on lamins, however the underlying mechanisms and relevance to in vivo events is not known. Here, we use the C. elegans zygote to show that the NE recovers from lamin- or laser-induced NE ruptures during pronuclear positioning in vivo. By
monitoring the rapid recovery from rupture in the C. elegans zygote, we show that lamin restricts nucleocytoplasmic mixing prior to full recovery of NE rupture sites. Dynein forces that position nuclei increase the severity of, but do not induce, transient NE ruptures. In contrast, increasing dynein forces that facilitate nuclear migration induce irreversible nuclear permeabilization and NE collapse prior to mitotic regulated NE breakdown. Surprisingly, embryonic lethality does not correlate with the high incidence of transient NE ruptures, but rather with stochastic chromosome scattering caused by premature NE collapse, suggesting that embryos can tolerate transient losses of NE compartmentalization. In addition to presenting the first mechanistic analysis of transient NE ruptures in vivo, this work delineates the dynamics of NE rupture and recovery and establishes lamin’s role in promoting NE recovery from rupture by opposing dynein forces that position nuclei.

Dual roles for nuclear envelope constituents in the cytoplasm.
B. KC1, C. Halfmann1, M.H. Alii2, K.J. Roux1,2;
1Enabling Technologies Group, Sanford Research, Sioux Falls, SD, 2Department of Pediatrics, University of South Dakota, Sioux Falls, SD

The nuclear envelope (NE) is a highly specialized extension of the endoplasmic reticulum whose roles include organization of peripheral heterochromatin, separation of the nuclear and cytoplasmic compartments, and nuclear positioning via mechanical linkages with the cytoskeleton. It is therefore perhaps no surprise that mutations in NE constituents are associated with several rare human diseases. Identifying NE constituents and their function in health and disease is key to uncovering the underlying mechanisms of NE-associated diseases. We have utilized the BioID method to identify a lamin-associated transmembrane kinase called VRK2A. We have shown that VRK2A phosphorylates and subtly alters the nuclear mobility of barrier to autointegration factor (BAF), a small dynamic DNA-binding protein that localizes to the nuclear envelope and nucleoplasm with roles in cell division and NE assembly. BAF also exists in the cytosol, where it binds DNA, such as DNA introduced during viral or bacterial infection. We observed that VRK2A co-localizes with BAF at induced cytosolic DNA foci, and depletion of VRK2 significantly increases the number of these cytosolic BAF-DNA foci. Ongoing studies seek to determine the mechanisms by which BAF and VRK2A function to regulate cytosolic DNA and investigate the relevance of this pathway to diseases of the NE.

LAMIN B1 TETHERS TO CHROMATIN AND ORGANIZES ITS HIGH-ORDER STRUCTURE in Mammalian Cells.
Y. Sun1, L. Chang1;
1BIOPIC, Peking University, Beijing, China

Lamin B1 constitutes a key component of nuclear lamina and is implicated in nuclear skeletal, gene regulation, differentiation, and senescence. However, whether and how lamin B1 organizes the three-dimensional (3D) structure of chromatin remain elusive. Here, we applied a combination of chromosome conformation capture (Hi-C), super-resolution imaging, and single chromosomal loci tracking to characterize the chromosome architecture in wild type and lamin B1 depleted human breast tumor cells. Globally, the Hi-C interaction matrices of lamin B1 depleted cells indicate a relative loss of long-range and gain of short-range interactions within chromosomes. At the chromosome territory (CT)
level, trans-interaction between chromosomes increases significantly. At the compartment level, although the overall organization of the chromatin into topologically associated domains (TADs) is conserved, ~10% of genomic regions switches between active (A) and repressive (B) compartments. Through direct measurements of single genomic loci dynamics in living cells, we find that lamin B1 can confine genomic loci dynamics in nuclear periphery. The Ig-like domain of lamin B1 has been known to mediate the interaction between Lamin B1 and chromatin. Disruption of the lamin B1-chromatin interaction by loss of the Ig-like domain resulted in increased chromatin mobility. These results suggest that lamin B1 tethers to chromatin and organizes its 3D structure at the compartment level. We propose that like yeast, mammalian cells also use tethering as a mechanism to organize and compartment their genome to adapt complex intra-nuclear processes.

The role of the BAF/VRK1 signaling axis on the DNA damage response in NGPS.
M.F. El-Sabban1, A.M. Mon1, P. Traktman1;
1Biochemistry and Molecular Biology, Medical University of South Carolina, Charleston, SC

The nuclear envelope is a dynamic structure involved in the regulation of nuclear function and architecture. Adjacent to the inner nuclear membrane (INM) is the nuclear lamina. The lamina is primarily composed of lamins, and provides structural scaffolding and an interface with chromatin. The small dimeric BAF protein is another important component of the lamina. BAF binds to chromatin (both DNA and histones) and to LEM domain-containing proteins of the INM, such as Lap2 and emerin, acting as a bridge that “snaps” DNA to the nuclear lamina. A subset of diseases called laminopathies or envelopopathies result from mutations in several components of the nuclear lamina or envelope. Hutchinson-Gilford Progeria Syndrome (HGPS) and Emery-Dreifuss Muscular Dystrophy (EDMD) are diseases that arise from a lamin A and an emerin mutation respectively. These syndromes highlight the importance of the nuclear envelope’s structural integrity in normal cell function. Nestor-Guillermo Progeria Syndrome (NGPS), a recently discovered novel progerioid syndrome, results from the homozygous inheritance of a mutation that causes an amino acid substitution in BAF from Ala-12 to Thr (A12T). The mechanism of disease pathology is still unclear and the role of the BAF A12T mutation in the disease phenotype has yet to be characterized. NGPS is an envelopopathy in which cells display aberrant nuclear architecture. This phenotype is also seen in cells which are deficient in VRK1, a nuclear kinase that phosphorylates BAF. It has previously been described that BAF A12T mesenchymal stem cells display a defect in their ability to maintain stemness and to differentiate into their known lineages in vitro. We aim to understand whether BAF and VRK1 signaling pathways are affected by the A12T mutation and whether disruption of these pathways in mesenchymal stem cells contributes to the differentiation defect. The literature indicates that VRK1 depletion results in a dampened DNA damage response, and that BAF interacts with DNA damage response proteins. Therefore, we propose that the DNA damage response pathway may contribute to the NGPS phenotypes. Future investigations will address whether involvement of histone modifications and global changes at the epigenetic level drive the disease.

Subcellular localization of dystrophin-associated proteins is altered in Hutchinson-Gilford progeria syndrome cells.
E. Amaro Encarnación1, B. Cisneros Vega1;
1Genética y Biología Molecular, CINVESTAV-IPN, Ciudad de México, Mexico

The dystrophin-associated protein complex (DAPC) provides a link between the extracellular matrix and the cytoskeleton, regulating various cellular processes, including adhesion, cell signaling and cytoskeleton stability. Interestingly, several DAPC components, namely dystrophin Dp71, β-dystroglycan (β-DG) and α-dystrobrevin (α-DB) were found interacting with nuclear lamins (lamin A/C and lamin B1) in the nucleus of different cell lines, which implies that these proteins are involved in nuclear envelope-associated functions. As a first step to elucidate the participation of Dp71, β-DG and α-DB in nuclear structure/function, in this study we analyzed the expression and subcellular localization of these proteins in Hutchinson-Gilford progeria syndrome (HGPS) cells, a well-studied laminopathy characterized by premature aging. Protein localization was analyzed by indirect immunofluorescence and confocal microscopy, while protein levels were assessed by western blotting assays, using primary antibodies against each of these proteins. We found that Dp71, β-DG and α-DB distribute in both the cytoplasm and the nucleus of wild type fibroblasts, while HGPS fibroblasts exhibit decreased nuclear localization for the three proteins. Altered localization of Dp71, β-DG and α-DB in HGPS cells might be related to progerin-induced nuclear morphology abnormalities; however, further experiments are required to define a role for Dp71, β-DG and α-DB in the maintenance of nuclear morphology and their relationship with progerin.

Lamin A/C mutant myonuclei experience nuclear envelope rupture and DNA damage that is reduced upon microtubule stabilization.
T.J. Kirby1,2, A. Earle1,2, G.R. Fedorchak1,2, P. Isermann1,2, C. Brightwell1, C. Fry3, J. Lammerding1,2;
1Weill Institute for Cell and Molecular Biology, Cornell University, Ithaca, NY, 2Meinig School of Biomedical Engineering, Cornell University, Ithaca, NY, 3Department of Nutrition and Metabolism, University of Texas Medical Branch, Galveston, TX

Lamin A/C is an inner nuclear membrane protein that confers the stiffness of the nucleus. Mutations in lamin A/C cause a broad spectrum of human diseases that include various muscular dystrophies and dilated cardiomyopathy. The cause of these tissue-specific diseases is unclear; however, one potential explanation could be that lamin mutations alter the stability of nuclei, which is particularly deleterious in mechanically active tissue. To this end, we found that lamin A/C mutations alter nuclear stability in primary mouse myoblasts, which persists during differentiation into myofibers, resulting in highly elongated myonuclei and severe nuclear damage. Using both endogenous proteins and live-cell reporters, we found that lamin A/C-mutant myonuclei experience transient nuclear ruptures that progressively increase in number during myofiber maturation. This loss of compartmentalizing was associated with an increase in DNA damage, measured by γH2AX and 53BP1 accumulation, and an overall decrease in myofiber viability. This led us to hypothesize that nuclear envelope ruptures are induced by mechanical forces present in differentiated myofibers, resulting in widespread DNA damage and myofiber pathology. Since microtubules are required for nuclear movement, we tested whether microtubules could be involved in inducing myonuclear rupture. We used pharmacological approaches
to either destabilize (nocodazole) or stabilize (paxlitaxel) the microtubule network in lamin A/C-mutant myofibers. Interestingly, the destabilization of microtubules increased the amount of nuclear damage and rupture events, while stabilizing microtubules dramatically reduced nuclear damage and rupture events, which also corresponded to an increase and decrease in DNA damage, respectively. Lastly, to investigate whether the DNA damage in lamin A/C-mutant myotubes may be underlying their decreased viability, we inhibited the DNA damage repair pathways using ATM or DNA-PK inhibitors. Inhibiting the activity of DNA-PK, a kinase required for non-homologous end joining DNA repair, improved the health of lamin A/C-mutant myofibers. Taken together, our findings suggest that lamin A/C mutations associated with muscle disease mechanically weaken the nucleus, and result in severe nuclear damage coupled with increased DNA damage in muscle fibers that could contribute to the muscle-specific phenotypes seen in many laminopathies. Notably, muscle fibers from aged animals and humans also display an elongated nuclear phenotype, similar to what we observed in lamin A/C-mutant animals, suggesting that the mechanical properties of myonuclei may change during normal aging. Future studies will examine whether this contributes to the decline in myofiber health commonly observed with aging.

Visualization of Lamina Association Reveals Functional Organization of Chromosomes.
T.R. Luperchio¹, M.E. Sauria², X. Wong¹, M. Gaillard¹, P. Tsang³, K. Pekrun³, R. Ach³, N. Yamada³, J. Taylor², K. Reddy¹;
¹Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD, ²Biology, Johns Hopkins University, Baltimore, MD, ³Agilent Laboratory, Agilent , Santa Clara, CA

Three-dimensional nuclear organization has been implicated in expression and regulation of the genome. Chromosomes are organized into territories and discrete domains of chromatin exist within the nuclear volume. These domains are suggested to be organized by patterns of gene activity, including active (A) and inactive (B) compartments. The nuclear periphery, which consists of the inner nuclear membrane and associated proteins, forms a sub-nuclear compartment that is mostly associated with transcriptionally repressed chromatin and low gene expression. These regions of chromatin that come in molecular contact with the nuclear periphery are called Lamin Associated Domains (LADs). The 3D organization of LADs has not been investigated in the context of chromosome conformation. Our current work highlights the relationship of LADs, the epigenome and 3D architecture by utilizing “chromosome conformation paints”. We find that LADs are constrained and compacted in a sub-territory in a region we define as the “peripheral zone”. The organization we observe in single cells is directly supported by analysis of both DamID and Hi-C data. Using a refined algorithm to identify active (A) and inactive (B) compartments from Hi-C data, we demonstrate that the LADs correspond to the B compartment. Integration of DamID and Hi-C data also highlights small regions within LADs that seem to escape from the B-compartment and are enriched in regulatory elements. Additionally we directly investigate the relationship of LAD organization on chromatin state and nuclear integrity.

The bacterium Listeria monocytogenes stimulates host exocytosis to promote pathogen uptake. H. Van Ngo¹, M. Bhalla¹, D. Che n¹, K. Ireton¹; ¹Microbiology and Immunology, University of Otago, Dunedin, New Zealand

Listeria monocytogenes is a food-borne bacterium capable of causing gastroenteritis, meningitis, and abortion. Critical for disease is the ability of Listeria to induce its internalization ('entry') into human epithelial cells. One of the major pathways of Listeria entry is mediated by binding of the bacterial surface protein InIB to its host receptor the Met receptor tyrosine kinase. InIB-mediated entry requires localized polymerization of the host actin cytoskeleton. Apart from actin polymerization, roles for other host processes in Listeria entry are unknown. Here we demonstrate that exocytosis in the human cell promotes InIB-dependent internalization. Confocal microscopy imaging of a probe consisting of VAMP3 with an exofacial Green Fluorescent Protein (GFP) tag indicated that focal exocytosis is stimulated during InIB-mediated entry into HeLa cells. Experiments involving chemical inhibitors or RNA interference (RNAi) indicated that exocytosis was dependent on Met tyrosine kinase activity and the GTPase RalA. RNAi-mediated depletion of the v-SNARE protein VAMP3 or the t-SNAREs syntaxin 4 or SNAP23 demonstrated an important role for exocytosis in Listeria internalization. Depletion of SNARE proteins failed to affect actin filaments during internalization, suggesting that actin polymerization and exocytosis are separable host responses. Confocal microscopy imaging of HeLa cells depleted for SNARE proteins indicated that exocytosis was required for delivery of the human GTPase Dynamin 2 to sites of InIB-mediated entry. Importantly, RNAi experiments demonstrated a critical role for Dynamin 2 in internalization of Listeria. Our results identify exocytosis as a novel host process exploited by Listeria for infection. We propose that exocytosis might provide a general mechanism to deliver host membrane-remodeling proteins to sites of InIB-dependent entry.

Automated detection, classification, and verification of distinct modes of exocytosis. F.L. Urbina¹, S.L. Gupton¹; ¹Cell Biology and Physiology, University of North Carolina: Chapel Hill, Chapel Hill, NC

Exocytosis is a fundamental behavior found across eukaryotic cell types, which promotes the secretion of biomolecules into the extracellular space and, in some cases, the insertion of transmembrane proteins and lipids into the plasma membrane. The minimal protein machinery required for a fusion pore to open is the assembly of the SNARE complex. A pH-sensitive variant of GFP (pHluorin) fused to the luminal end of a vesicle-SNARE protein, such as VAMP2, provides a fluorescent intensity readout of fusion pore opening and the subsequent fate of VAMP2. Historically, two modes of SNARE-mediated exocytosis have been recognized. In full-vesicle-fusion (FVF), following the opening of a fusion pore, the vesicle collapses into the plasma membrane, adding both lipids and transmembrane proteins, such as VAMP2, to the plasma membrane. During kiss-and-run vesicle fusion (KNR) the fusion pore opens transiently to secrete cargo; upon closure, the vesicle retreats from the plasma membrane and reacidifies. Previously, VAMP-pHluorin exocytic fusion events have been categorized into these two modes of exocytosis by hand based on their fluorescent profiles. This analysis technique suffers from inherent biased assumptions of what modes of exocytosis exist and reliance on the human eye and

Sunday-256
human pattern recognition to categorize fluorescent profiles, as noted in the literature by the existence of fluorescent profiles that do not fit FVF or KNR. Here, we introduce a novel method to classify exocytic fusion from TIRF time-lapse images of VAMP2-phluorin in embryonic murine cortical neurons. We used an unsupervised hierarchical clustering algorithm to perform class discovery and independently suggest an appropriate number of clusters in which to partition exocytic events. We biologically manipulate the capability of vesicles to fuse using tetanus toxin to verify which clusters represent true, exocytic events. We use HEPES to manipulate vesicle reacidification upon fusion pore closure, and found this affects only specific classes of fusion, leaving others unperturbed. This classification paradigm along with the described manipulations identified two unique, bona fide exocytic fusion event behaviors in addition to FVF and KNR. Surprisingly the distribution of events was not altered by exposure to the neuronal guidance cue netrin-1, previously shown to accelerate VAMP2-mediated exocytosis. However, we found that deletion of the E3 ubiquitin ligase Trim67 biased exocytosis away from FVF and toward exocytic events that feature fusion pore closure, thus identifying TRIM67 as a novel regulator of fusion mode. Current work is investigating whether these modes are associated with other vesicle types and mediated by specific plasma membrane t-SNAREs or vesicle tethering components.

Yck3 dependent phosphorylation of Env7 and its regulation during cell cycle in Saccharomyces cerevisiae.
S.P. Manandhar¹, S.P. Valencia¹, C. Alvarado¹, I. Mansoora¹, E. Gharakhanian¹;
¹Biology, CSULB, Long Beach, CA

Yeast vacuolar fusion and fission is a highly dynamic mechanism that responds to intracellular and extracellular changes working to keep cells intact. This mechanism has been well conserved from yeast to humans. We discovered that Env7 is a conserved vacuolar membrane kinase that is involved in negative regulation of vacuolar fusion during budding and stress, similar to that of Yck3. We have shown that these two vacuolar kinases interact genetically and double delete shows the compromised phenotype [Manandhar, S; Gharakhanian, E., FEMS Yeast Res., 472-80, 2014] Here we also show that the double delete is defective in autophagy further supporting the possible interaction between these two genes. Based on gel shift assay, we have established that the phosphorylation of native Env7 is dependent on Yck3 and can be complemented by exogenously expressed Yck3 in an expression dependent manner. Here we also show that Yck3 directly interacts and phosphorylates Env7 at specific sites. By using site-directed mutagenesis we have identified the Yck3 dependent phosphorylation sites of Env7. Our data strongly suggest that serine residues at positions 323 and 331 (S323 and S331) are the Yck3-mediated phosphorylation sites of Env7 in consistent to the prediction by Bioinformatic analysis. Phosphorylation of Env7 is required not only for the stability of Env7 but also for regulating vacuolar morphology dynamics. Since we have shown that Env7 is essential for normal vacuole dynamics during budding, studies in phosphorylation state and localization of Env7 during cell cycle arrest and progression using confocal microscopy are in progress. We are also currently working on exploring the possible downstream substrates that are likely involved in above mentioned cellular events.

**Exosomes transfer into osteoclasts through bone tissue.**  
N. Takahashi1;  
1Graduate School of Environmental Engineering, The University of Kitakyushu, Kitakyushu, Japan

Many cells secrete vesicles with 10 to 200 nm in diameter called exosomes. It contains nucleic acids such as mRNA and miRNA, which contribute to the transfer of the nucleic acids between cells via blood and body fluids. Recently, we have revealed that exosomes are nucleated materials for mineralization. Thus, exosomes can be deposited in bone mineralized tissue. This means the deposited exosomes can be transferred into osteoclasts through bone metabolism. In this study, we examined the hypothesis of these exosomes are transported by way of bone tissue by in vitro osteoclasts assay using exosome deposited hydroxyapatite.

We extracted exosomes from human osteosarcoma HOS cells and rat mesenchymal stem cells. Mouse macrophage RAW cells were cultured and differentiated into osteoclasts by treatment with RANKL. First, we examined whether exosomes were adsorbed on the surface of hydroxyapatite. We constructed thin apatite layer on the culture dish surface follow layer-by-layer method. Then we loaded the fluorescence labeled exosomes onto the apatite layer. The fluorescence labeled exosomes clearly adsorbed on the surface of the layer. We next examined the exosome transfer from apatite surface to osteoclasts using the exosome adsorbed apatite layer. Osteoclasts were seeded on the apatite layer on which fluorescence-labeled exosomes had been adsorbed. By observation with confocal laser scanning microscopy, fluorescence of the exosomes was observed at the cytoplasm of osteoclasts. This suggests that exosomes can be transferred through bone metabolism. Our results probably indicate that exosome can transfer into cells via not only blood or body fluids but also bone and tissue metabolism. On the other hand, it is unclear how much of exosomes were deposited in the bone tissue and whether the incorporated exosomes regulate the function or activity of osteoclasts.

**Plasma membrane PI(4,5)P2 is critical for secretory granule exocytosis.**  
M. Omar Hmeadi1; N.R. Gandasi1, S. Barg1;  
1Medical cell biology, Uppsala university, Uppsala, Sweden

Phosphoinositides (PIs), including PI(4)P (phosphatidylinositol-4-phosphate), PI(4,5)P2 (phosphatidylinositol-4,5-bisphosphate) and PI(3,4,5)P3 (phosphatidylinositol-3,4,5-trisphosphate), are involved in multiple signaling cascades and play an important role in the regulation of exo- and endocytosis. At least in cell free systems, PI(4,5)P2 and PI(3,4,5)P3 are enriched near docked secretory granule, where they are thought to recruit essential proteins of the exocytosis machinery, such as syntaxin-1A, to the release site. Here we have used high-resolution imaging to analyze local PI dynamics at secretory granule release sites in live insulin-secreting cells. PIs were labeled using PH domains of phospholipase C (PLC)-δ1 (high affinity PI(4,5)P2 sensor), PLC-δ4 (low affinity PI(4,5)P2 sensor), GRP1 (PI(3,4,5)P3), and EGFP-labeled P4M domains (PI(4)P). In intact cells, all tested PI markers distributed evenly across the plasma membrane, without measurable accumulation at granule release sites. In contrast, syntaxin-1A accumulated at granule sites during their docking at the plasma membrane. However, once the cells were permeabilized using α-toxin, a punctate pattern emerged that partially colocalized with docked granules. Depletion of plasma membrane PI(4,5)P2 by recruitment of a 5′-phosphatase strongly inhibited stimulated exocytosis, but had no effect on docked granules or the
distribution of syntaxin-1A. In summary, our data challenge the notion that PIs are involved in the recruitment of secretory granules or syntaxin-1A to the release site.

Plasma membrane LAT recruitment precedes vesicular LAT recruitment to reveal two phases of early T cell activation.
L. Balagopalan1, J. Yi2, T. Nguyen1, A.S. Harned2, K. Narayan3, L.E. Samelson1;
1Laboratory of Cellular and Molecular Biology, National Institutes of Health, Bethesda, MD, 2Center for Molecular Microscopy, National Institutes of Health, Frederick, MD

When a T cell engages cells bearing foreign antigens and becomes activated, an initial event is the formation of structures called microclusters at the contact surface between the cells. Little is understood about how these microclusters form. Some have hypothesized that membrane proteins on the surface of the T cell migrate to the area of contact; others have hypothesized that proteins from cytoplasmic vesicles in the T cell are recruited to form the microclusters. To understand the key events that lead to microcluster formation, we imaged an essential transmembrane signaling molecule LAT and a vesicular SNARE VAMP7 using lattice light sheet microscopy (LLSM). We observed a kinetic lag between microcluster formation and vesicular pool recruitment to the synapse. We also looked at the activated T cell surface with higher spatial and temporal resolution using Total Internal Reflection Fluorescence Simulated Interference Microscopy (TIRF-SIM). Once vesicles were recruited, we captured directed vesicle movement between microclusters where they exhibit decreased motility. Correlative 3D light and electron microscopy revealed an absence of vesicles at microclusters at early times, but an abundance of vesicles as activation proceeded. We propose a model in which cell surface LAT is rapidly recruited and phosphorylated at sites of T cell activation, and the vesicular pool is recruited at later time points and dynamically interacts with microclusters.

EXO70 REGULATES B-CELL MIGRATION.
N.I. Goles1, M. Yuseff2;
1Celullar and Molecular Biology, Pontificia Universidad Católica de Chile, Santiago, Chile

B-lymphocytes are a main part of the adaptive immune system as they are responsible for producing antibodies against foreign antigens and also perform critical roles as antigen presenting cells. To become fully activated, B cells rely on their ability to capture antigens and present them as MHCII-peptide complexes to CD4+ T cells. In order for this process to be efficient, B cells are constantly scanning for antigens within lymph node follicles. Migration is highly dependent on cell polarity, which involves local cytoskeleton remodeling by proteins such as the Arp2/3 complex, as well as polarized trafficking of chemokine receptors and integrins. Interestingly, several reports show that Exo70, a protein of the Exocyst complex, controls both these processes during cell migration, however its role in B cells has not been addressed.

Methods: To address the role of Exo70 in B cell migration, silenced its expression by using two different small hairpin RNAs (shRNAs) against Exo70, that were delivered to the cells using viral vectors. Transmigration of Exo70-silenced B cells B cells was evaluated by Transwell and 2D migration assays using CXCL13 as chemoattractant factor. To investigate the role of Exo70 in the recruitment of the
Arp2/3 complex, towards the leading edge of migrating B cells we used indirect immunofluorescence (IF) in fixed cells that were exposed to CXCL13 and co-immunoprecipitation assays. Results: We show that silencing of Exo70 expression in B cells diminishes their migratory capacity compared to control cells. This was reflected by a decrease in the percentage of migrating Exo70-silenced cells in transwell experiments and an overall reduction of migratory parameters, such as velocity and accumulated distance, in 2D migration assays. Our co-immunoprecipitation assays suggest that Exo70 interacts with the Arp2/3 complex and this interaction increases when B cells are exposed to CXCL13. Accordingly, by using IF, we show that Exo70 localizes towards the migrating front of B cells exposed to the CXCL13. Conclusion: Our data suggest that Exo70 is required for efficient B cell migration, most likely by interacting with the Arp2/3 complex at the migrating front of these cells. Otoferlin is a multivalent calcium‐sensitive scaffold linking SNAREs and calcium channels.
C.P. Johnson1, N. Hams1, W. Qiu1;
1Biochemistry, Oregon State University, Corvallis, OR

Sensory hair cells rely on otoferlin as the calcium sensor for exocytosis and encoding of sound preferentially over the neuronal calcium sensor synaptotagmin. Although it is established that synaptotagmin cannot rescue the otoferlin KO phenotype, the large size and low solubility of otoferlin have prohibited direct biochemical comparisons that could establish functional differences between these two proteins. To address this challenge, we have developed a singlemolecule colocalization binding titration assay (smCoBRA) that can quantitatively characterize full-length otoferlin from mammalian cell lysate. Using smCoBRA, we found that, although both otoferlin and synaptotagmin bind membrane fusion SNARE proteins, only otoferlin interacts with the L-type calcium channel Cav1.3, showing a significant difference between the synaptic proteins. Furthermore, otoferlin was found capable of interacting with multiple SNARE and Cav1.3 proteins simultaneously, forming a heterooligomer complex. We also found that a deafness-causing missense mutation in otoferlin attenuates binding between otoferlin and Cav1.3, suggesting that deficiencies in this interaction may form the basis for otoferlin-related hearing loss. Based on our results, we propose a model in which otoferlin acts as a calcium‐sensitive scaffolding protein, localizing SNARE proteins proximal to the calcium channel so as to synchronize calcium influx with membrane fusion. Our findings also provide a molecular-level explanation for the observation that synaptotagmin and otoferlin are not functionally redundant. This study also validates a generally applicable methodology for quantitatively characterizing large, multivalent membrane proteins. Portions of the presented work are from a recently published paper in the Proceedings of the National Academy of Sciences (Proc Natl Acad Sci U S A. 2017 Jul 25;114(30):8023-8028).
Resealing of tears in the sarcolemma of myofibers is a necessary step in the repair of muscle tissue. Recent work suggests a critical role for dysferlin in the membrane repair process and that mutations in dysferlin are responsible for limb girdle muscular dystrophy 2B and Miyoshi myopathy. Beyond membrane repair, dysferlin has been linked to SNARE-mediated exocytotic events including cytokine release and acid sphingomyelinase secretion. However, it is unclear whether dysferlin regulates SNARE-mediated membrane fusion. In this study we demonstrate a direct interaction between dysferlin and the SNARE proteins syntaxin 4 and SNAP-23. In addition, analysis of FRET and in vitro reconstituted lipid mixing assays indicate that dysferlin accelerates syntaxin 4/SNAP-23 heterodimer formation and SNARE-mediated lipid mixing in a calcium-sensitive manner. These results support a function for dysferlin as a calcium-sensing SNARE effector for membrane fusion events. (Portions of this presentation have been previously published (J Biol Chem. 2016 Jul 8;291(28):14575-84).

Eukaryotic cells rely on vesicle trafficking for growth, differentiation, signaling, and many other crucial cellular functions. Vesicles deliver their cargoes by fusing with cellular organelles or, in the case of exocytosis, with the plasma membrane. These fusion reactions are driven by the assembly of SNARE proteins anchored in the two membranes into membrane-bridging complexes. Other factors, notably Sec1/Munc18 (SM) proteins and multisubunit tethering complexes (MTCs), increase the efficiency and specificity of SNARE complex assembly. MTCs in particular appear to be the major orchestrators of vesicle tethering and fusion, as they interact with SNAREs and most of the other trafficking co-factors, but the underlying molecular mechanisms are incompletely understood.

We are using biochemical and structural methods to study one of the best-characterized MTCs, the HOPS (homotypic fusion and vacuolar protein sorting) complex, which is essential for the fusion of late endosomes. HOPS is a ~660 kDa, hexameric complex and contains the SM protein Vps33 as an integral subunit. Elucidating the architecture of the HOPS complex, and deciphering its interactions with SNARE proteins, will shed light on how SNAREs and MTCs work together to ensure the correct regulation and high specificity of membrane tethering and fusion. The HOPS complex interacts with SNARE proteins not only via their SNARE motifs but also via their N-terminal "regulatory" domains. We are characterizing these interactions using biochemical, crystallographic, and functional methods. In addition, we are working toward a structure of the intact HOPS complex, using the HOPS complex derived from the thermophilic eukaryote Chaetomium thermophilum as a target for cryo-EM.

Coarse-grained simulations of the synaptic neurotransmitter release machinery.
A. Polley1, J. Wang2, J.E. Rothman3, B. O'Shaughnessy1;
1Chemical Engineering, Columbia University, New York, NY, 2Cell Biology, Yale University, New Haven, CT

Synapses are the basic unit of the brain. Cognition and complex behavior rely on tightly controlled release of neurotransmitters (NTs) at synapses, and synaptic misregulation is associated with neurodegenerative or neurodevelopmental disorders such as Alzheimer’s or epilepsy. Synchronized release is accomplished by a machinery that senses $Ca^{2+}$ when an action potential arrives, responds by fusing the synaptic vesicle and plasma membranes, and releases NTs through a fusion pore. SNARE proteins constitute the core of the membrane fusion machinery, and Synaptotagmin (Syt) is the $Ca^{2+}$ sensor, but the mechanisms involved are poorly understood.

Here we quantitatively describe a mechanism of NT release in a molecularly explicit mathematical model representing the detailed architecture and collective behavior of the components of the Ca$^{2+}$-sensing fusion machine. To build the pre-Ca$^{2+}$ fusion machine, our starting point is our coarse-grained (CG) model of SNARE complexes at the fusion site (Mostafavi et al., 2017), to which we now add Syt which was shown to oligomerize into ring-like oligomers in the absence of Ca$^{2+}$ that are disassembled by Ca$^{2+}$ (Wang et al., 2014). How the Syt and SNARE proteins fit together in the synaptic fusion machinery was recently described by the crystal structure of Synaptotagmin-1 (Syt1) and the neuronal SNARE complex (Zhou et al., 2015). Using this information together with an all atom structure of the Syt ring reconstructed from Cryo-EM data, we obtained an all-atom Syt ring dressed with SNAREpins. We coarse grained this structure, representing 4 residues with one CG bead with correct total charge and size, the same CG scheme as for the SNAREpins.

Our highly CG approach has the enormous advantage that we can actually build the fusion machine and run the machine on the long timescales of NT release, implementing the complex collective behavior of its many molecular components. Placing the composite Syt-SNARE structure between membranes, we first equilibrated the pre-Ca$^{2+}$ fusion machine and found that it clamps fusion, importantly.

Incorporating kinetics of Ca$^{2+}$ binding and unbinding to the Syt ring, we found that an action potential that introduces a Ca$^{2+}$ pulse disassembles the ring after a transient, unfettering the SNARE complexes. The SNARE complexes then spontaneously assemble into a circular cluster and pull the membranes into sufficiently close proximity to trigger fusion on physiological timescales. Our model simulates Ca-evoked membrane fusion for release of NTs in molecularly explicit detail for the first time, and suggests that Ca$^{2+}$-mediated disassembly of a Syt ring may control the release of NTs at neuronal synapses.

Elucidating Individual Subunit Positions within the Exocyst Tethering Complex.
D. Lepore1, L. Kenner2, A. Frost2, M. Munson1;
1Biochemistry and Pharmacology, University of Massachusetts Medical School, Worcester, MA,
2Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

The regulation of vesicular traffic to precise intracellular compartments is essential for cell growth, homeostasis, signaling, cell division, and development. Membrane fusion between vesicles and their target membrane is carried out via SNARE proteins; however, additional regulatory control immediately prior to fusion is essential. There are two general classes of tethering proteins that provide this regulation: coiled-coiled tethers and multi-subunit tethering complexes (MTCs). While coiled-coiled
tethers are fairly well characterized, the mechanism of action of many MTCs is not well understood. The exocyst is a hetero-octameric MTC involved in the trafficking of post-Golgi secretory vesicles to sites of polarized exocytosis. Previously, we mapped the subunit connectivity of the exocyst complex and visualized the overall structure using negative stain EM. The challenge remained to map individual subunits into the structure. Using a combination of biochemical techniques including protein tagging, selective degradation of individual subunits, and nanogold labeling of subunits, we are identifying the individual subunits within the structure and modeling the intact exocyst complex. To this end, we visualized an exocyst subcomplex module containing the exocyst subunits Sec3, Sec5, Sec6, and Sec8 using negative stain EM. Additionally, GFP-tagging and SNAP-nanogold labeling are elucidating the position of the NH2 and COOH termini of individual subunits. By determining subunit placement in the three-dimensional structure and with complementary in vivo experiments, we will gain insights into the mechanisms by which exocyst coordinates several protein-protein interactions on both the secretory vesicles and the plasma membrane to mediate vesicle tethering and regulate SNARE-mediated vesicle fusion.

Intra-Endosomal Trafficking Mediated by Lysobisphosphatidic Acid Contributes to Intracellular Release of Phosphorothioate-modified Antisense Oligonucleotides.
S. Wang1, H. Sun1, X. Liang1, S.T. Crooke1;
1Core Research, Ionis Pharmaceuticals, Carlsbad, CA

Chemically modified antisense oligonucleotides (ASOs) with phosphorothioate (PS) linkages are extensively studied as research and therapeutic agents. PS-ASOs can efficiently cleave target RNA through RNase H1 dependent mechanism. A number of receptor proteins and endocytotic pathways are implicated in the intracellular uptake of PS-ASOs be internalized via and are released from membrane-enclosed endocytotic organelles, mainly late endosomes (LEs). This study was focused on the details of PS-ASO trafficking through endocytic pathways. It was found that lysobisphosphatidic acid (LBPA) is required for release of PS-ASO from LEs. PS-ASOs exited early endosomes (EEs) rapidly after internalization and became co-localized with LBPA by 2 hours in LEs. Inside LEs, PS-ASOs and LBPA were co-localized in punctate, dot-like structures, likely intraluminal vesicles (ILVs). Deactivation of LBPA using anti-LBPA antibody significantly decreased PS-ASO activities without affecting total PS-ASO uptake. Reduction of Alix also substantially decreased PS-ASO activities without affecting total PS-ASO uptake. Furthermore, Alix reduction decreased LBPA levels and limited co-localization of LBPA with PS-ASOs at ILVs inside LEs. Thus, the fusion properties of ILVs, which are supported by LBPA, contribute to PS-ASO intracellular release from LEs.

Dynamics of Exocyst Subunit Assembly and Vesicle Fusion, using CRISPR-edited GFP Tagging of Endogenous Loci.
H. Nishida-Fukuda1, I.G. Macara1, S.M. Ahmed1;
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN

The exocyst is an essential complex required for delivery of proteins to the plasma membrane. There is a continuing controversy about whether the exocyst is a stable octamer that binds to the membrane and tethers exocytic vesicles, or is a dynamic complex in which subcomplexes are assembled at the fusion
site. To explore the dynamics of exocyst function we created sfGFP-tagged alleles of 5 exocyst subunits (Sec3, Sec5, Sec6, Sec8 and Exo70) in a mouse mammary epithelial cell, NMuMG, using the CRISPR/Cas9 system, and tracked the arrival of these subunits and of vesicles at the plasma membrane by TIRF microscopy. We transfected VAMP-pHluorin and TFR-pHui to visualize vesicle fusion and mApple-Rab11 to visualize vesicles. We were unable to recover viable cells with fusions of 3 vesicle-associated exocyst subunits (Sec10, Sec15 and Exo84), suggesting that these constructs are non-functional. We discovered that vesicle fusion occurs about 15 seconds after arrival at the membrane. Exo70 and Sec6 arrive at a similar time and disappear immediately after fusion. Interestingly, Sec5 arrives earlier - about 19 seconds prior to fusion - and Sec3 disappears about 4 seconds before fusion occurs. These data suggest that the exocyst is not pre-assembled but instead that subunits arrive and disappear at different times. Using double-tagged cells we are now cross-correlating these events, and can begin to catalog in unprecedented detail the itinerary for vesicle delivery to the plasma membrane, and the mechanisms by which tethering and fusion are regulated.

\(^1\)Molecular Clinical Research Centre, St George's University London, London, United Kingdom, \(^2\)Medical School, King's College London, London, United Kingdom, \(^3\)Virus Reference Department, Public health England, London, United Kingdom, \(^4\)Department of Plasma Proteins, Sanquin Research, Amsterdam, Netherlands

Vascular endothelial cells secrete the adhesive and procoagulant protein Von Willebrand factor (VWF) from specialised secretory organelles called Weibel-Palade bodies (WPB). A potent trigger for WPB exocytosis is an elevation of intracellular free Ca\(^{2+}\) concentration ([Ca\(^{2+}\)]\(_i\)), that can be mediated by hormone action, mechanical stresses or cell damage. Although several cytosolic Ca\(^{2+}\)-binding proteins including calmodulin and the Annexin A2:S100A10 complex have been implicated in WPB exocytosis, the existence of WPB-associated Ca\(^{2+}\)-sensors involved in detecting and transducing acute increases in [Ca\(^{2+}\)]\(_i\) into exocytosis remains unclear. Here we show that synaptotagmin 5 (SYT5) is recruited to WPBs and regulates Ca\(^{2+}\)-driven WPB exocytosis in human endothelial cells. qPCR analysis of human endothelial cells revealed the presence of mRNA for 10 of the 17 known SYT isoforms; five Ca\(^{2+}\)-dependent (1, 2, 3, 5 and 9) and five Ca\(^{2+}\)-independent (11, 14, 15, 16 and 17). Analysis of the subcellular distribution of epitope-tagged constructs of each of these 10 SYTs showed that SYT5 localized almost exclusively to WPBs. SYT17 showed partial localization to WPBs in some cells while all other SYTs localized to other subcellular compartments. Live-cell imaging of fluorescent WPB exocytosis in cells either depleted of SYT5 by shRNA or overexpressing SYT5-EGFP showed an inhibition or enhancement of histamine-evoked WPB exocytosis respectively. Similar results were obtained in biochemical studies of histamine-evoked VWF propeptide (VWFpp) secretion. Overexpression of a SYT5 Ca\(^{2+}\)-binding deficient mutant, Asp197Ser SYT5-EGFP, inhibited histamine-evoked WPB exocytosis. Depletion of SYT17 produced a very small reduction in histamine-evoked VWFpp secretion, while overexpression of SYT17 had no effect. We propose that SYT5 is a WPB-associated Ca\(^{2+}\)-sensor for regulated secretion of VWF from vascular endothelial cells.

Co-regulation of the Glycine max soluble N-ethylmaleimide-sensitive fusion protein attachment protein receptor (SNARE)-containing regulon occurs during defense to a root pathogen.

K. Sharma1;

1BIOLOGICAL SCIENCES, MISSISSIPPI STATE UNIVERSITY, Starkville, MS

Heterodera glycines, also known as Soybean Cyst Nematode (SCN) is a major pathogen of soybean (Glycine max), causes nearly one billion dollars loss in U.S. every year (Wrather et al. 2001; Wrather and Koenning, 2006; Smolik and Draper, 2007; Koenning and Wrather, 2010). Efforts to combat SCN include production of resistant soybean varieties, use of nematicides, improved crop rotation, and bio-control methods (Wrather et al. 1984; Chang et al. 2011). However, effective control has not been achieved yet. Study of host plant interactions at the cellular level is important as it may provide new species-specific means of controlling SCN (Klink et al. 2007). We are conducting various molecular approaches to find actual cellular mechanism of host resistance. Closer study of infected cells in resistant variety G. max [Peking/PI548402] and susceptible variety G. max [Williams 82(PI518671)] through laser microdissection have resulted various unique genes present in G. max [Peking/PI548402] (Klink et al. 2007; 2009). Overexpression of these genes in susceptible cultivar G. max [Williams 82(PI518671)] have resulted resistance by inducing incompatible reaction and RNA interference of these genes in resistant genotypes resulted susceptible reaction, thereby inducing compatible reaction (Matsye et al. 2012; Pant et al. 2014). In this approach we have overexpressed the components of the Soluble N-ethylmaleimide-sensitive fusion (NSF) Attachment Protein (SNAP) REceptor (SNARE) complex that helps in docking of the vesicles to the membrane and subsequent release of the vesicular contents to the apoplast (Jahn and Fasshauer et al. 2012; Matsye et al. 2012; Pant et al. 2014). There are many proteins that play significant role in this process however, the core components of this study are syntaxin 121 (SYP121), Synaptosomal-associated protein 25 (SNAP-25), Synaptotagmin (SYT), Synaptobrevin (SYB), Secretion 1/mammalian uncoordinated-18 ([Sec1]/Munc18), and N-ethylmaleimide-sensitive fusion protein (NSF). Syntaxin 121, G. max homolog of Saccharomyces cerevisiae, Suppressors of sec1 (SSO1) known as PENETRATION1 (PEN1) in Arabidopsis thaliana, (Collins et al. 2003) function in resistance to Heterodera glycines. Co-expression of SYP121 with SNARE homologs results elevated transcripts in infected cells inducing resistance reaction.

Cryo-EM Structure of the Exocyst Complex.

K. Mei1, Y. Li2, S. Wang1, G. Shao3, J. Wang2, Y. Ding3, G. Luo4, P. Yue1, J. Liu2, X. Wang2, M. Dong3, H. Wang2, W. Guo1;

1Department of Biology, University of Pennsylvania, Philadelphia, PA, 2School of Life Sciences, Tsinghua University, Beijing, China, 3National Institute of Biological Sciences, Beijing, China

The fusion of secretory vesicles to their target compartments requires the proper function of the tether family of proteins at various stages of vesicular trafficking. The exocyst is an evolutionarily conserved hetero-octameric protein complex that tethers post-Golgi secretory vesicles to the plasma membrane for exocytosis, and is implicated in many cellular processes such as cell polarization, cytokinesis, ciliogenesis and tumor invasion. Using cryo-electron microscopy (cryo-EM) and chemical cross-linking mass spectrometry (CXMS), we solved the structure of the fully assembled yeast exocyst complex. Our atomic model revealed the architecture and hierarchical interactions of the complex, and led to the
identification of helical regions that nucleate the assembly of the exocyst at its core. Sequence analysis suggest that these regions are conserved evolutionarily across eukaryotic systems. Further cell biological studies suggest a mechanism for exocyst assembly that leads to vesicle tethering at the plasma membrane.

Oxidative stress impedes trafficking and increases vesicular accumulation of amyloid precursor protein in HTB-11 neuroblastoma cells.
A.R. Haber¹, G. Gomez¹;
¹Biology, University of Scranton, Scranton, PA

Oxidative stress has been known to impede neuronal function, resulting in impediments that are associated with neurodegenerative disorders such as Alzheimer’s disease. Increased oxidants have been known to affect amyloid precursor protein (APP) localization to the membrane; however, it is unclear whether this is due to trafficking dysfunction or to downregulation of APP expression. We therefore aimed to explore this further using HTB-11 neuroblastomas as the model for this study. HTB-11 cells were grown in 100 nM retinoic acid (RA) to induce differentiation morphological and functional neuronal phenotypes. Oxidative stress was induced with tert-butyl hydroperoxide at concentrations ranging from 1 µM to 31 µM. Cells were then stained using anti-APP and conjugated to AlexaFluor 647, and a FITC-conjugated lectin to label the membranes of vesicles. Confocal microscopy was used to image samples to obtain a 3D image of the cells, and used to quantify both the expression of APP via fluorescence intensity and pixel count, and endocytosis using fluorescence of endocytotic markers. The Manders colocalization analysis (using ImageJ) was used to quantify the percentage of APP that colocalized to the membranes, and thus determine if there are changes in the association of APP to membranes due to oxidative stress. We found that increasing concentrations of tert-butyl hydroperoxide induced an increase in the expression of APP, but did not cause a change in the colocalization of APP to the vesicle membranes. Lectin staining showed that vesicles under oxidative stress tended to accumulate in the cell body rather than dispersing throughout the cell. These results suggest that oxidative stress primarily impeded vesicle traffic, resulting in concomitant accumulation of vesicular APP that did not localize to the plasma membrane. An understanding of the effects of oxidative stress on the trafficking of APP will help to increase our understanding of one of the fundamental aspects of Alzheimer’s disease pathology.

Cholangiocyte intercellular communication via polarized exosome release.
L.C. Doskey¹, B.A. Davies¹, L.O. Morton², J.R. Jefferson³, C.N. Rozeved¹, C. Tseng¹, N.F. LaRusso¹, D.J. Katzmann¹;
¹Department of Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, ²Division of Gastroenterology, Mayo Clinic College of Medicine, Rochester, MN, ³Chemistry Department, Luther College, Decorah, IA

Cholangiocytes, epithelial cells of the bile duct, separate the lumen of the bile duct (apical surface) from the peribiliary space (basolateral surface). Cholangiocyte communication via these different surfaces is distinct. Exosomes, a more recently appreciated mode of intercellular communication, are released by the fusion of multivesicular bodies with the plasma membrane. We have investigated polarized
exosome secretion in cholangiocyte communication and machinery contributing to this process. The Normal Human Cholangiocyte (NHC) cell line was cultured in transwells, and microscopy and trans-epithelial electrical resistance were used to validate the formation of a restrictive monolayer suitable for our studies. Isolation of the exosome-enriched fractions from apical and basolateral conditioned media were performed. Nanoparticle tracking analysis, immuno-electron microscopy, and western blotting supported the conclusion that NHC release exosomes both apically and basolaterally. These exosome-enriched fractions exhibited interesting differences: more particles were released apically, and the apical particles contained more RNA and cholesterol. Examination of contents by silver staining and western blotting revealed that multiple proteins are differentially enriched between the apical and basolateral exosome fractions. Similarly, profiling of miRNA contents identified species that are enriched in apical or basolateral exosomes. The signaling activities of apical and basolateral exosomes were examined in both apical and basolateral target models. Treatment of polarized NHC via the apical surface (i.e. apical model) with exosomes resulted in distinct activation profiles with apical exosomes evoking greater activation. By contrast, exosome treatment of human THP-1 macrophage cells (i.e. basolateral model) resulted in distinct activation profiles with basolateral exosomes evoking greater activation. These results supported the conclusion that cholangiocytes release different populations of exosomes from their apical and basolateral surfaces to mediate distinct intercellular communication. Perturbation of cellular machinery implicated in exosome biogenesis altered apical and basolateral exosome secretion. Our data suggest that the mechanisms driving apical and basolateral exosome biogenesis are to some extent distinct.

Unconventional release of fusogenic nonenveloped reoviruses.
N.M. McMullen1, C. Pan1, R. de Antueno1, G.J. Gaspard1, D.P. MacKenzie1, K.M. Proudfoot1, R. Duncan1;
1Microbiology and Immunology, Dalhousie University, Halifax, NS

Fusogenic reoviruses are nonenveloped viruses with segmented dsRNA genomes. As with most nonenveloped viruses, virus-induced cell lysis is the primary mechanism for reovirus release from cells. Fusogenic reoviruses are the only known examples of nonenveloped viruses that induce cell-cell fusion and syncytium formation. Syncytigogenesis is mediated by a virus-encoded fusion-associated small transmembrane (FAST) protein, which are both necessary and sufficient to induce membrane fusion. FAST protein-induced syncytium formation enhances localized direct cell-cell spread of the infection, followed by eventual syncytial lysis and release of infectious virus particles for systemic dissemination of the infection. Recent findings in the field suggest that various nonenveloped viruses, including hepatitis A virus and poliovirus, can also be released non-lytically from cells inside extracellular vesicles (ECVs) that derive from endosomal sorting complexes required for transport (ESCRT)- or autophagy-dependent pathways. Interestingly, western blotting revealed FAST proteins are embedded in the membrane of ECVs, and transmission electron microscopy and cryoelectron microscopy discovered significant levels of non-enveloped virions associated with ECVs, suggesting ECV and virus release may be associated. We further investigated these processes to determine whether this virus release pathway occurred non-lytically, and whether FAST proteins or syncytium formation contribute to non-lytic virus release. Kinetic analysis of virus release using various cell lines infected with fusogenic reoviruses was coupled with live-cell imaging using the membrane impermeable small molecule dye Sytox, which fluoresces when bound to nucleic acid inside cells, to assess plasma membrane integrity. Results indicate release of substantial quantities of infectious virus particles from cells prior to any evidence of reduced plasma membrane integrity, indicative of non-lytic virus release. Genetic and pharmacologic approaches are being used to
asses the involvement of ESCRT machinery and autophagy pathways in the mechanism underlying this non-lytic virus release mechanism.

**CSF-1R SIGNALING ON INTERNAL VESICLES INVOLVES LYN TYROSI NE KINASE.**

L. Monga1;  
1Biology and microbiology, South Dakota State University, Brookings, SD

CSF-1R SIGNALING ON INTERNAL VESICLES INVOLVES LYN TYROSI NE KINASE Louise Monga, Lu Huang, Jared Wollman, Natalie Thiex Department of biology and microbiology, South Dakota State University, Brookings, South Dakota Colony stimulating factor-1 (CSF-1) is a growth factor that mediates growth, proliferation and differentiation of macrophages by binding to its receptor, colony stimulating factor-1 receptor (CSF-1R). Upon activation by CSF-1, CSF-1R becomes phosphorylated and rapidly internalized. During this time, CSF-1R signals through the MAPK and Akt/PI3K pathways. Previous work assumed CSF-1R signaling originated at the plasma membrane. Yet, when internalization of the receptor is prevented, the downstream signaling cascade (measured by Akt and ERK phosphorylation) is impaired, indicating that internalization of the receptor is necessary for full signaling. Using immunofluorescence and immunoblot, we show the presence of phosphorylated (active) CSF-1R on macropinosomes, suggesting that receptor signaling continues following internalization and subsequent trafficking. However, it is not known how similar or different the membership of the CSF-1R signaling complex is at the plasma membrane or internal vesicles. Using immunofluorescence, we showed that Lyn protein kinase colocalizes with CSF-1R on macropinosomes a few minutes following stimulation of macrophages with CSF-1. The duration of the colocalization correlated with the duration of the presence of phospho-CSF-1R on macropinosomes. These findings suggest that Lyn is a CSF-1R signaling partner on macropinosomes, but its mechanism of action in this context is not well understood. Spatiotemporal organization of proteins in the cell is crucial for complete and proper signaling. CSF-1R has a relatively simple signaling pathway than most receptor tyrosine kinases. Signaling from internal membranes may provide opportunities for signal integration or spatial control of signal shape and amplitude.

**Regulation of COPI vesicle transport via Scyl1 methylation under ER-stress.**

S. Matsuzaki1,2; G. Amano2; Y. Mori3; D. Kobayashi1; H. Takamura2; K. Miyoshi2; T. Yoshimura2; F. Saika1; N. Kiguchi1; T. Katayama3; S. Kishioka1;  
1Department of Pharmacology, Wakayama Medical University, Wakayama, Japan; 2Molecular Brain Science, Osaka University, United Graduate School of Child Development, Suita, Japan; 3Anatomy, International University of HEALTH and WELFARE School of Medicine, Narita, Japan

Cumulative evidences have shown the importance of ER-stress in pathology of neurodegenerative diseases, such as Alzheimer’s disease, Amyotrophic lateral sclerosis, etc. To elucidate the pathogenesis of neurodegenerative diseases from the viewpoint of ER-stress, we screened the altered genes in SK-N-SH cells under the condition of tunicamycin-induced ER-stress by the gene fishing method. As the result, we found that Protein arginine N-methyltransferase 1 (PRMT1) is up-regulated in SK-N-SH cells under ER-stress. Based on this result, we examined the role of PRMT1 in the ER-stress related pathway and
organelle and found that PRMT1-knockdown cells showed the abnormal Golgi formation and increased UPR. To elucidate the mechanism of these alterations, we screened the methylated proteins as substrates of PRMT1 under ER-stress condition by immunoprecipitation-mass spectroscopy, and identified Scy1-like protein 1 (Scy1). Scy1, a member of the Scy1-like family of catalytically inactive protein kinases, was recently reported to function in retrograde COPI-mediated intracellular transport. Interestingly, Scy1 has also been identified as a gene product that is lost in an animal model of motor neuron disease, the muscle-deficient mouse. In the motor neuron of the above model animal, the protein circulation system between ER and Golgi apparatus was abnormal due to dysfunction of COPI transport. In consequence, UPR may be accerelated. Thus, we present the effect of Scy1 arginine methylation on the COPI vesicle transport. This study provides novel insights into the pathogenesis of neurodegenerative diseases caused by ER stress.

Regulation of the COPII outer coat by O-GlcNAc.
B.M. Condon1, N.J. Cox1,2, T.R. Meister1, B.J. Bisnett1, E. Soderblom3, M. Boyce1;
1Biochemistry, Duke University, Durham, NC, 2Pharmacology, Duke University, Durham, NC, 3Proteomics and Metabolomics Core Facility, Duke University, Durham, NC

Collagen is the most abundant human protein by mass, and is the main component of bone, cartilage, and other connective tissues. Collagen is first synthesized intracellularly, then trafficked to the extracellular space via the secretory pathway. This process depends on the coat protein complex II (COPII) pathway, which is responsible for trafficking cargoes from the endoplasmic reticulum (ER) to the Golgi. Proper trafficking of proteins is essential for their function, and defects in the COPII pathway result in human diseases, including osteogenesis imperfecta and cranio-lenticulo-sutural dysplasia (CLSD) due to failed collagen export. Although the structure and function of COPII proteins have been well-studied, the regulation of COPII by cellular stressors and other signaling events is poorly understood. Recently, regulation of COPII by post-translational modifications (PTMs), such as phosphorylation and ubiquitination, has been reported. Our lab and others have also identified O-linked β-N-acetylglucosamine (O-GlcNAc) on three COPII components. O-GlcNAc is a dynamic PTM that is responsive to cellular signals, including nutrient, oxidative, and ER stressors, leading us to hypothesize that O-GlcNAc may regulate COPII activity. To test this, we manipulated intracellular O-GlcNAc levels and quantified the COPII components present in membrane and cytoplasmic fractions. Under normal conditions, COPII components were found predominantly in the membrane fraction, but the three O-GlcNAcylated COPII components—Sec23, Sec24, and Sec31—were found predominantly in the cytoplasmic fraction when we elevated O-GlcNAc levels. Because sequential recruitment of COPII components to the ER membrane is essential for their function, this result suggests that O-GlcNAc levels may impact COPII vesicle trafficking. To investigate this possibility, we monitored a GFP-tagged cargo from the ER to the Golgi in live cells and observed a marked delay in cargo delivery to the Golgi when O-GlcNAc levels were elevated. We also utilized mass spectrometry to identify 10 O-GlcNAcylated residues on Sec31A, the COPII outer coat component which permits COPII vesicles to accommodate large cargoes like collagen. Interestingly, all 10 O-GlcNAcylated residues fall within Sec31A’s flexible hinge region or a known protein-binding domain. We are currently investigating the functional impact of these O-GlcNAcylated sites on collagen export and COPII vesicle trafficking of other cargoes. These results provide a greater functional understanding of a ubiquitous but poorly understood PTM, and yield important insight into the mechanism of regulation of an essential cellular trafficking pathway.

The large Sec7 ARF guanine nucleotide exchange factor GBF1 contains a PIP-binding domain essential for its membrane recruitment and cellular function.  
J.M. Meissner¹, J.M. Bhatt¹, E. Lee³, M.L. Styers², A.A. Ivanova³, R.A. Kahn³, E.S. Sztul¹;  
¹Department of Cell, Developmental and Integrative Biology, University of Alabama at Birmingham, Birmingham, AL, ²Department of Biology, Birmingham-Southern College, Birmingham, AL, ³Department of Biochemistry, Emory University School of Medicine, Atlanta, GA

ADP-ribosylation factors (ARF) are key components of the vesicle budding process essential for intracellular transport of a variety of cellular materials. The ARF guanine nucleotide exchange factors (GEFs) are cytosolic proteins that undergo cycles of membrane association and dissociation, with only the membrane-localized pool catalyzing ARF activation. Thus, mechanisms that recruit GEFs to membranes directly control the sites and timing of ARF activation. Small GEFs are recruited to membranes through phosphoinositide (PIP) binding by a pleckstrin homology (PH) domain and lipid binding is absolutely required to support the functionality of these GEFs. The large GEFs (GBF1, BIG1/2) lack PH domains, and their mechanisms of recruitment are poorly understood. We focused on GBF1, a GEF that localizes to and catalyzes ARF activation on compartments at the ER-Golgi interface. The PH domains of small GEFs are immediately downstream from the catalytic Sec7 domain. In the large GEFs, that position is occupied by homology downstream from Sec7 number 1 (HDS1) domain. We posited that HDS1 may act in a manner similar to PH with regard to the regulated membrane recruitment.

Thus, we did a structure-function analysis of HDS1 to assess its participation in GBF1 recruitment to Golgi membranes. The ~173 residue HDS1 domain contains 5 α-helices. We targeted highly conserved motifs for mutagenesis within α-helix 1, 3, 4 and 5. The targeting of GBF1 lacking mutations in HDS1 to Golgi membranes was assessed by immunofluorescence of fixed cells and by live cell imaging approach. Golgi recruitment was observed for all constructs, except the GBF1 with mutation in α-helix 1, which was impaired in Golgi association and was predominantly detected in a diffuse cellular pattern. We posited that HDS1 function may be analogous to a PH domain to recruit GBF1 to membranes via direct binding to one or more lipids. We purified full length GBF1 with different point mutations from mammalian cells and by the nitrocellulose strip lipid binding and liposome flotation assays we show that GBF1 binds PIPs, with preference for PI3P, PI4P and PI(4,5)P2, and that this binding is mediated by the HDS1 domain. Our results suggest that HDS1 acts in a manner similar to the PH domain in small GEFs, and by binding specific PIPs regulates GBF1 recruitment to Golgi membranes.

Considering that GBF1 activates ARF while associated with Golgi membrane, we tested the role of PIP binding in GBF1 cellular function. We document that mutation within α-helix 1 in HDS1 domain that reduce the binding of full-length GBF1 to membranes and prevent PIP binding, also inhibit the ability of GBF1 to activate ARF and support Golgi homeostasis.

The role of the N terminus, Sec7 domain, and C terminus of GBF1 in +RNA viral replication.
G.C. Sager1, E.G. Viktorova2, J.M. Meissner3, E.J. Lee1, C.A. Pocognoi2, G.A. Belov2, E.S. Sztul1;
1Cell, Developmental, and Integrative Biology, University of Alabama at Birmingham, Birmingham, AL, 2Department of Veterinary Medicine, Virginia-Maryland Regional College of Veterinary Medicine, University of Maryland, College Park, College Park, MD

All viruses are obligatory parasites and must utilize cellular factors to support their replication. The guanine nucleotide exchange factor GBF1 is essential for replication of various +RNA viruses, such as Flaviviruses and Enteroviruses. GBF1 is an enzyme that catalyzes GDP/GTP exchange on ARFs - small GTPases that regulate multiple facets of cellular physiology including cytoskeletal rearrangements, secretory and endocytic traffic, and metabolic homeostasis. In uninfected cells, GBF1 associates with Golgi membranes where it activates ARF to support Golgi homeostasis and secretory traffic. In virus-infected cells, GBF1 is recruited to replication complexes to support viral replication. The exact mechanism through which GBF1 facilitates viral replication remains enigmatic. Thus, we initiated a detailed structure-function analysis of GBF1 with the goal of identifying its activities that support viral replication. We constructed 12 GBF1 mutants, with amino acid substitutions in the most conserved domains. Four constructs contain mutations in the N terminus since deletion of this region has been shown to prevent GBF1 from supporting replication (GBF1/N5,6AA; GBF1/Y7,8AA; GBF1/Δ10; and GBF1/Δ37). Three constructs contain substitutions within the catalytic Sec7d (GBF1/E794K binds ARF but can’t catalyze GDP/GTP exchange; GBF1/7ΔA doesn’t bind ARF; and GARG contains a Sec7d from another non-Golgi factor). Four constructs contain substitutions or deletions in different domains downstream of the catalytic Sec7d (GBF1/LF926AA in HDS1; GBF1/LF1266AA in HDS2; GBF1/PLL1544AAA in HDS3; GBF1/1-1531 lacking HDS3 and the C-terminal region; and GBF1/1-1674 lacking the C-terminal proline-rich domain). We report that the GBF1 constructs exhibit different abilities to target to the Golgi and support Golgi homeostasis and secretion in uninfected cells, as well as differences in their ability to target to viral replication complexes and support viral replication in cells infected with polio-virus replicon.

Isoform Specialization Among the Sec23 Gene Family Has Significant Consequences for Polarized Growth.
M. Chang1, J. O'Sullivan1, M. Bezanilla2;
1Biology Department, University of Massachusetts, Amherst, Amherst, MA, 2Biology Department, Dartmouth College, Hanover, NH

Polarized secretion is essential for cell biological processes across the tree of life. In particular walled organisms, such as yeast, filamentous fungi, and plants use polarized secretion to divide and grow thereby providing excellent model systems to unravel the molecular mechanisms controlling this process. For polarized growth, an active secretory system is required to deliver specific building materials to the growth region. As part of the secretory pathway, transport from the endoplasmic reticulum (ER) to the Golgi apparatus, which is mediated by the coat protein complex II (COPII) is therefore a prerequisite for polarized secretion. We have investigated the role of COPII in the juvenile tissue of the moss P. patens, which grows exclusively by polarized secretion. Interestingly in P. patens, small gene families encode each of the subunits of the COPII complex. To investigate whether these
small gene families are redundant, we analyzed the loss of function phenotype resulting from silencing Sec23, a component of the inner coat of COPII, which is encoded by seven highly similar genes. To our surprise, we found that silencing Sec23D cause a severe growth defect, while silencing the remaining six Sec23 genes had no significant defect. Coding sequence complementation showed partial functional redundancy between only Sec23D and Sec23E, suggesting that Sec23D and to a limited extent Sec23E play pivotal roles during polarized secretion, we found that Sec23D localizes to the ER and partially overlaps with the Golgi. In addition, Sec23D heterodimerizes with two of the seven Sec24 genes in moss, suggesting that Sec23D is a canonical COPII component. To analyze the role of Sec23D, we generated a sec23d null mutant using CRISPR-Cas9 genome editing. We found that the sec23d null mutant grows very slowly, suggesting a strong defect in secretory activity. In support of this, we observed significant defects in ER morphology, with a subset of cells accumulating large ER aggregates. The ER aggregates form on the order of days, potentially inhibiting cell growth. From these data, we hypothesize that Sec23D plays a central role in COPII function during polarized growth.

3D ultrastructural analysis of the progressive restructuring of the endoplasmic reticulum by a coronavirus provides insight into its subversion of the ERAD tuning pathway.
E.M. Mihelc1, S.A. Tinney1, S.C. Baker2, J.K. Lanman1;  
1Biological Sciences, Purdue University, West Lafayette, IN, 2Microbiology and Immunology, Loyola University Chicago Stritch School of Medicine, Maywood, IL

Viruses commonly modify organelle membranes and subvert cellular pathways for the various stages of their lifecycles. Coronaviruses extensively utilize the endoplasmic reticulum (ER), inducing drastic architectural changes to the ER through the course of infection. ER membrane is used for both formation of double-membrane vesicles (DMVs) associated with replication, as well as for assembly and envelopment of new virions. Early in infection, the ER is utilized to form DMVs, which have been shown to contain markers for the ER-associated degradation (ERAD) tuning pathway. ERAD tuning vesicles, termed EDEMosomes, bud from the ER and are rapidly trafficked to lysosomes for degradation. Unlike EDEMosomes, DMVs are bounded by two lipid bilayers, are believed to remain connected to the ER via a membranous network, and accumulate within the cell over the course of infection. In this work, we sought to visualize coronavirus-induced restructuring of the ER as it progresses through the infection. Specifically, we investigated how this class of EDEMosome-type vesicles form from the ER, and whether they are able to evade the degradative fate of an EDEMosome. In order to observe morphological changes both at high resolution and over a large cellular volume, we used large-volume EM tomography to image the ER at different timepoints post-infection and to perform detailed 3D analysis of the structures within the volumes. In one volume (dimensions ~8 x 8 x 2 µm), we observed nearly 700 DMVs in the cytoplasmic space. Analysis of the images reveals that DMV inner vesicles form first on or within the ER, then obtain an outer bilayer by budding out of the ER, and eventually separate from the ER. At late timepoints in infection, the ER’s role in infection shifts as it accommodates the assembly and budding of new virus particles into its lumen. Concurrent to this architectural restructuring, we observed that the number of DMVs drastically decreases, and DMVs can be visualized inside lysosomal compartments. Chloroquine treatment prevented the decrease in DMVs, indicating that DMVs indeed are degraded in lysosomes and thus follow the ERAD tuning pathway to its end. Live cell fluorescence imaging experiments are underway to further characterize the dynamics of coronavirus interaction with this pathway. In conclusion, 3D ultrastructural analysis of coronavirus-infected cells allowed us to
observe the morpho-functional flux of the ER by an obligate pathogen and to move toward a functional understanding of the involvement of cellular pathways in infection.

TMEM116: A Transmembrane Protein of Unknown Function that is Regulated by a Bidirectional Promoter.
D. Grits¹, Y. Bikard¹, A. Stamatia¹, J. Viviano¹, M. Orr¹, R. Rubenstein¹,²; ¹Pulmonary Medicine, Children's Hospital of Philadelphia, Philadelphia, PA, ²Pulmonary Medicine, University of Pennsylvania, Philadelphia, PA

Our group has previously shown that ERp29 (Endoplasmic Reticulum Protein of 29 kDa), a novel molecular chaperone of the Endoplasmic Reticulum, has increased expression in response to sodium 4-phenylbutyrate (4PBA, Suaud, et al., JBC, 2011), the prototype corrector of F508del CFTR trafficking (Rubenstein, et al., JCI, 1997). Our group also demonstrated that ERp29 promotes biogenesis of the cystic fibrosis transmembrane conductance regulator (CFTR, Suaud, et al., JBC, 2011), as well as regulates the biogenesis of the epithelial sodium channel, ENaC (Grumbach, et al., AJPCell, 2014). Interestingly, the expression of ERp29 is regulated by an ~1.4 kb bidirectional promoter that regulates the expression of TMEM116, a transmembrane protein of unknown function, in the opposite direction. As it is suggested that proteins found on bidirectional promoters often interact with or regulate one another, we chose to investigate the function of TMEM116. We initially compared TMEM116 expression to that of ERp29 in response to 4PBA treatment. TMEM116 expression increased over time in 4PBA-treated IB3-1 CF bronchiolar epithelial cells and in MDCK cells. This increase in TMEM116 expression temporally correlated with the time-dependent increase in ERp29 expression seen with exposure to 4PBA (Suaud, et al., JBC, 2011), suggesting that TMEM116 and ERp29 expression are coordinately regulated by 4PBA through this bidirectional promoter. We also performed initial immunofluorescence experiments with two different commercial antibodies to TMEM116 that yielded conflicting data; one antibody suggested that TMEM116 was localized to the nuclear membrane, while the other suggested its localization to endomembrane compartments such as the Golgi and endoplasmic reticulum. To address these conflicting data, we performed subcellular fractionation experiments, and observed that TMEM116 was present in both the cytosolic fraction (containing the endomembrane compartments) and in the nuclei, but with greater amounts of TMEM116 in the cytosolic fraction. These data are consistent with the hypotheses that the expression of ERp29 and TMEM116 are coordinately regulated by their shared bidirectional promoter, and that they are likely both present in similar endomembrane compartments.

Autophagosome formation is involved in unconventional secretion of CFTR.
S. Noh¹, M. Lee¹;
¹Department of Pharmacology, Severance Biomedical Science Institute, Yonsei University College of Medicine, Seoul, South Korea

CFTR is a cyclic AMP-dependent chloride channel that mediates electrolyte transport across the luminal surface of epithelial cells. ΔF508-CFTR is the most common disease-causing mutation in CF patients. We have previously reported that Golgi reassembly stacking protein (GRASP) is required for an unconventional secretory pathway of core-glycosylated CFTR that bypasses the usual route for Golgi-
dependent membrane traffic. We also showed that core-glycosylated CFTR can reach the plasma membrane and function as Cl- channel by blockade of ER-to-Golgi transport or overexpression of GRASP. The aim of the present study is to demonstrate that autophagy pathway is involved in GRASP-dependent unconventional trafficking of CFTR. Blockade of ER-to-Golgi transport induced the increase of autophagic flux and relocalization of GRASP55 to ER exit sites which is known as sites for autophagosome biogenesis. Surface biotinylation assay of CFTR was performed using PI3K class3 inhibitor, siRNA of PI3KC3 or siRNA of ATG in HEK293 cells transfected with ΔF508-CFTR and GRASP55. Wortmannin and 3-methyladenine, the inhibitor of PI3KC3 which is well known for playing a crucial role in autophagy signaling pathway, inhibited the unconventional trafficking of CFTR to plasma membrane. Knock-down of PI3KC3 reduced the cell surface expression of ΔF508-CFTR in cell GRASP55 overexpressed. In addition, depletion of components which play a role in the autophagosome formation (ATG1, ATG5, ATG7 and ATG8), but not that of lysosome fusion (Vamp7), inhibited unconventional surface trafficking of ΔF508-CFTR. Taken together, our data suggest that factors involved in early autophagosome formation, but not those involved in the late steps of lysosome fusion and degradation pathway, is associated with GRASP-dependent unconventional exocytosis of CFTR in mammalian cells.

Tubular ER shaping protein Reticulon4a/NogoA influences protein trafficking through the secretory pathway.
R. Mukherjee1, D.L. Levy1;
1Molecular Biology, University of Wyoming, Laramie, WY

The endoplasmic reticulum (ER) is a complex membranous system consisting of flat sheets and interconnected curved tubules, which conventionally correspond to rough and smooth ER, respectively. The ER is also continuous with the nuclear envelope and functionally linked to nearly every other organelle in the secretory pathway. Several curvature stabilizing membrane proteins, including reticulons (RTNs) and REPs/DP1/Yop1p, shape the tubular ER. In this study, we examined the role of Rtn4a/NogoA in protein trafficking through the secretory pathway in cultured HeLa cells. Ectopic overexpression of Rtn4a by ~46 fold enhanced the N-glycosylation and maturation of two plasma membrane markers, Integrin β1 and MHC-I/HLA-A. The mature forms of Integrin β1 and MHC-I, containing complex type N-glycans, were increased by ~3-fold and ~1.6-fold respectively, compared to controls. We also observed increased trafficking of these proteins to the cell surface without changes in their overall levels. Overexpression of Rtn4a did not alter the levels of some important glycosyltransferases and ER stress related chaperones, ruling out some potential mechanisms of action. Rtn4b and REEP5 overexpression, that also affect ER morphology, did not impact cell surface amounts of Integrin β1 and MHC-I, suggesting the effect might be specific to Rtn4a and not overall ER morphology. As previously described, Rtn4a overexpression led to proliferation of the tubular ER, with a more than 2.5-fold decrease in ER sheet volume. Interestingly, we observed a more disperse Golgi morphology concomitant with a drastic increase in Golgi volume, suggesting that altered Golgi morphology might contribute to observed effects of Rtn4a overexpression. Sec31A (a binding partner of COPII in anterograde vesicles) and ERGIC 53 (a marker of ER-Golgi intermediate compartments) also exhibited more scattered distributions in contrast to their perinuclear localization in control cells. In contrast to what we observed for Integrin β1 and MHC-I, ectopically expressed secreted alkaline phosphatase activity in the media was diminished upon Rtn4a overexpression. These results suggest that Rtn4a plays important but differential roles in the trafficking of membrane-bound and secreted proteins. Our
current focus is on studying the roles of other RTNs in protein trafficking and elucidating how Rtn4a influences the secretory pathway.

Unstacking the stacking problem of Golgi.
B.K. Jain¹, D. Bhattacharyya²;
¹Bhattacharyya Lab, ACTREC, Tata Memorial Centre,, Kharghar, Navi Mumbai, India

Shape regulation of dynamic organelles is a fundamental cell biological problem and the mechanism that regulates Golgi apparatus stacking is still not completely understood. The Golgi apparatus is an important organelle for membrane trafficking and protein processing. In Eukaryotes, Golgi has varying structure: from dispersed cisternae in S.cerevisiae to stacked cisternae in Pichia pastoris and laterally connected ribbon of cisternal stacks in higher eukaryotes like mammals. The mechanisms that generate the cisternal stack organization is not elucidated clearly yet. In mammalian cells GRASPs are reported to be the controlling factor for the cisternal stacking. However, depletion of yeast GRASP homolog Grh1 in Pichia.pastoris has no effect on Golgi stacking. This suggest potential existence for other universally conserved factors. Genes expressing Series of potential such factors were individually deleted in a two color Pichia pastoris strain with endogenous GFP tagged early Golgi cisterna and Ds-Red tagged late Golgi cisterna and consequently cisternal stacking was monitored in these knock out strains. An increased inter-cisternal distance between medial and late Golgi compartment was observed in the deletion mutants of a family of Golgi resident proteins with completely different known functions. Electron microscopy suggests that frequency of TGN peeling from the cisternal stack is highly increased in these mutants. Results suggests the factors are directly or indirectly responsible for maintaining stacking of Golgi Cisternae. These factors possibly maintain their stacking function simultaneously along with their more recognized functions although it is yet to be discovered how they accommodate so. It is possible that these factors probably play similar role in higher order eukaryotes suggesting an universal role as Golgi stacking factors.

Novel interactions of clathrin adaptors at the TGN in yeast.
J.Y. Martinez-Marquez¹, M.C. Duncan¹;
¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Correct membrane traffic is important to target transmembrane proteins to their planned location in the cell. Transmembrane protein traffic through the trans-Golgi Network (TGN) is a highly regulated step. From the TGN, transmembrane cargo proteins can be targeted to different compartments of the cell. Traffic of cargo proteins from the TGN depends in part on clathrin coat assembly through the coordinated action of clathrin adaptor proteins. In the budding yeast, Saccharomyces cerevisiae, TGN clathrin adaptors include the epsins (Ent3/5), Gga1/2 and the AP-1 complex. The recruitment of these clathrin adaptors to sites of clathrin coat formation is highly regulated. Correct recruitment of these clathrin adaptors is important for adequate traffic at the TGN. Recent studies in our lab suggest additional players involved in clathrin adaptor regulation for traffic at the TGN.

apKC Influences Golgi Integrity.
E.J. Tisdale1, C.R. Artalejo1;
1Pharmacology, Wayne State Univ. School of Medicine, Detroit, MI

A variety of signaling molecules have been shown to play a critical role in the regulation and the coordination of intracellular membrane transport. In that regard, we are actively characterizing the role of atypical Protein Kinase C (apKC) in membrane trafficking in the early secretory pathway, a bona fide oncogene that contributes to the pathogenesis of a variety of cancer-types. apKC in tandem with GAPDH, an apKC substrate, are critical downstream effectors for the small GTPase Rab2 that facilitates maturation of pre-Golgi intermediates for incorporation into the Golgi and mediates vesicle formation for cargo recycling from the cis Golgi network back to the ER. We have now found that ectopically overexpressed apKC in normal rat kidney cells caused a striking disorganization/fragmentation of the Golgi complex similar to that observed in various cancer cells, suggesting that apKC is a contributing factor to Golgi homeostasis. The observed Golgi morphological changes induced by apKC ectopic expression in NRK cells was reversed/rescued by expression of siRNA to apKC, which led to intact and compact Golgi structures and thereby confirming specificity. Because the Golgi is a major site for microtubule (MT) formation, and apKC binds directly to MTs, we evaluated the organization of the MT network by indirect immunofluorescence. The apKC transfected cells contained an unstacked/unlinked Golgi ribbon associated with and/or aligned along MT tracks that labeled with an anti-tyrosinated tubulin antibody. These results suggest that apKC overexpression affects a subpopulation of MTs, some of which are anchored to the Golgi and that support structural integrity.

SYP73 Anchors the ER to the Actin Cytoskeleton for Maintenance of ER Integrity and Streaming in Arabidopsis.
P. Cao1, L. Renna1, G. Stefano1, F. Brandizzi1;
1Plant Research Laboratory, Michigan State University-US Department of Energy, East Lansing, MI

The endoplasmic reticulum (ER) is an essential organelle that spreads throughout the cytoplasm and undergoes extensive remodeling. In plants, the remodeling and motility of the ER rely mainly on actin and to a minor extent on microtubules. Although the actomyosin system has been suggested functional for ER streaming in plant cells, the mechanisms underlying stable interaction of the ER membrane with actin are unknown. We demonstrate here that SYP73, a member of the plant Syp7 subgroup of SNARE proteins is a novel ER membrane-associated actin-binding protein. We show that overexpression of SYP73 causes a striking rearrangement of the ER over actin and that, similar to mutations of myosin-XI, loss of SYP73 reduces ER streaming and affects overall ER network morphology and plant growth. We propose a model for plant ER remodeling whereby the dynamic rearrangement and streaming of the ER network depend on the propelling action of myosin-XI over actin coupled with a SYP73-mediated bridging, which dynamically anchors the ER membrane with actin filaments.

1Molecular and Cellular Biology Program, Faculty of Medicine, Universidad de Chile, Santiago, Chile, 2Department of Biology, Faculty of Chemistry and Biology, Universidad de Santiago de Chile, Santiago, Chile, 3Pathophysiology Program, Faculty of Medicine, Universidad de Chile, Santiago, Chile, 4Millennium Nucleus of Ion Channels-Associated Diseases (MiNICAD), Santiago, Chile, 5Center for Bioinformatics and Molecular Simulation, Núcleo Científico Multidisciplinario, Universidad de Talca, Talca, Chile

TRPM4 is a Ca2+-activated non-selective cationic channel involved in a wide variety of physiological and pathophysiological processes. Altered activity, expression and localization of these channels might trigger several pathophysiological conditions. Indeed, TRPM4 plasma membrane overexpression has been related to cardiovascular and neurodegenerative diseases and cancer. Therefore, the mechanisms involved in the regulation of TRPM4 activity constitute an important area of biomedical research. Protein-Protein Interactions (PPIs) control the expression, trafficking, localization and biophysical properties of ion channels. Thus, the identification of novel TRPM4-related PPIs and their characterization might contribute to dissect the regulatory mechanisms of this channel. Interestingly, bioinformatics analyses of the primary sequence of TRPM4 allowed us to identify a putative interacting motif to End Binding (EB) proteins, novel members of the microtubule plus-end tracking proteins. These proteins bind a consensus motif (SxIP) in their substrates and are involved in a plethora of cellular processes, including growing dynamics of the microtubule cytoskeleton, focal adhesion dynamics, cell migration and protein trafficking, targeting and localization. Here, we provide novel data suggesting that TRPM4 interacts with EB proteins. Moreover, we show that the mutation (TRPM4ASWIP and TRPM4SWNN) of the putative EB-binding motif abolishes the TRPM4-EB interaction. We also found that these mutant variants show a reduced expression of the mature population of the channel and display an endoplasmic reticulum (ER)-like distribution. Furthermore, these mutant variants present a decreased expression in the plasma membrane, consistent with a reduction in the whole-cell electrophysiological recordings. Conversely, we demonstrated that the expression of a soluble fragment containing the wild type N-terminal region of TRPM4 (EGFP-N-TRPM4WT) reduces the membrane expression of TRPM4. Moreover, we show that the interference of this interaction might constitute a mechanism to modulate dynamics of Focal Adhesions (FAs), reducing cell migration and invasion. These results suggest that EB interaction is necessary for the proper trafficking and activity of TRPM4 at FAs. These findings might contribute to the understanding and characterization of novel mechanisms involved in TRP channel trafficking/localization, and could be applied to the design of therapeutic strategies against TRPM4 gain-of-function-associated pathologies.

VLDL Receptor is required for non-genomic progesterone-dependent signaling to release oocyte meiotic arrest.
N. Nader1, M. Dib1, R. Courjaret1, R. Hodeify2, R. Machaca1, J. Graumann3, K. Machaca1;
1Research, Weill Cornell Medicine - Qatar, Doha, Qatar, 2American University of Ras Al Khaimah, Ras al Khaimah, United Arab Emirates, 3Max Planck Institute for Heart and Lung Research, Bad Nauheim, Germany

Progesterone (P4) is a steroid hormone that controls female reproductive state and other physiological processes. P4 mediates transcription-dependent signaling in target cells through its nuclear receptor, and in addition activates rapid non-genomic signaling through membrane progesterone receptors (mPR). mPRs are 7-TM integral membrane proteins, that are coupled to various signaling modules, including cAMP, MAPK, and Ca2+ signals. However, the immediate mechanisms of action downstream of mPR remain in question. One of the best studied models of P4 non-genomic action is the release of oocyte meiotic arrest in the frog. Herein we used an untargeted quantitative proteomics approach to define the mPR interactome to better delineate non-genomic P4-mPR signaling. We identify the VLDL Receptor (VLDLR) as an mPR partner protein that preferentially interacts with mPR that localizes to the plasma membrane (PM) in Xenopus oocytes. Knocking down VLDLR abolishes P4-induced oocyte maturation, a phenotype that is rescued by overexpressing VLDLR or mPR. Mechanistically, we show that the VLDLR is required for the trafficking and PM residence of mPR. mPR needs to localize to the PM to mediate its signaling function. Taken together, our data define a novel function of the VLDLR as a trafficking chaperone required for the subcellular localization of mPR and as such non-genomic P4-dependent signaling.

Arf4 is Regulated by ArfGAP1 and Facilitates Sorting of ERGIC53 on pre-Golgi Membranes.
S. Yilmaz Dejgaard1,2, R. Luo3, P.A. Randazzo3, J.F. Presley1;
1Anatomy and Cell Biology, McGill University, Montreal, QC, 2Medical Biology, Near East University, Nicosia, Cyprus, 3National Cancer Institute, National Institutes of Health, Bethesda, MD

In humans four highly-homologous Arf proteins (Arf1, Arf3, Arf4 and Arf5) are Golgi-associated. They are divided into the Class I Arfs (Arf1 and Arf3), and the Class II Arfs (Arf4 and Arf5). The Class I Arfs have been extensively studied. However, the Class II Arfs are more poorly understood. In particular, the biological roles of Class II Arfs in the ER-Golgi system are unclear, although one study employing siRNA knockdowns (Volpicelli-Daley et al. Mol. Biol. Cell 16:4495-508; 2005) has found evidence that retrograde trafficking of KDEL receptor from Golgi to ER requires a function of the Class II Arfs (Arf4 and Arf5) that is not supplied by Class I Arfs. Additionally, the mechanisms by which Class II Arfs associate with the Golgi apparatus are unclear, with conflicting studies suggesting recruitment of GFP-tagged Class II Arfs to membrane by brefeldin A-sensitive GEFs similarly to Class I Arfs (Chun et al., Mol. Biol. Cell 19:3488-500; 2008) or recruitment of HA-GFP-tagged Class II Arfs to membrane by a distinct mechanism insensitive to brefeldin A (Duijsings et al., Traffic 10:316-23; 2009). In this study, we further investigate the functions of Class II Arfs as well as the mechanisms by which they are recruited to Golgi membranes. We find that brefeldin A-sensitive Golgi membrane association of Class II Arfs is reduced or abrogated in the presence of a C-terminal HA or HA-GFP tag unless a spacer is employed, possibly because of the presence of negatively charged residues in the HA tag. Thus we employed GFP tags separated from
Class II Arfs by spacers for further studies. Using these tagged Arfs, we find that a major fraction of Arf4-GFP is recruited to early Golgi and pre-Golgi membranes in NRK and HeLa cells, consistent with previous reports (Hamlin et al. J. Cell Sci. 127:1454-63; 2014). Further consistent with a role in the early secretory pathway, we find that siRNA depletion of Arf4 results in a loss of local recycling of GFP-ERGIC53/p58 from pre-Golgi structures in HepG2 cells, suggesting a unique role for Arf4 in sorting of recycling cargo receptors from peripheral pre-Golgi structures. Arf4-GFP, but not tagged Class I Arfs, can be distributed to pre-Golgi structures by siRNA or pharmacological perturbations directed against ArfGAP1, suggesting Arf4 is primarily regulated by ArfGAP1 on these pre-Golgi structures. Supporting this, we conduct in vitro studies in which we find that ArfGAP1, but not ArfGAP2 stimulates coatamer-dependent GTP hydrolysis by Arf4.

OS9 and FBXO6 contribute to CD147 levels.
I. Tobey1, S. Cornett2, I. Masteika1, A. Mercado1, D. Mena1, J. Castorino1;
1Natural Science, Hampshire College, Amherst, MA

CD147 (Basigin, BSG, Emmprin) is part of the immunoglobulin superfamily initially discovered on the surface of tumor cells and found to induce the activity of several matrix metalloproteinases (MMPs). Because the activation of MMPs contributes to metastasis, regardless of cancer type, CD147 plays a key role in the spread and invasiveness of many types of cancer cells (Iacono, Brown, Greene, & Saouaf, 2007; Tortora, Funke, & Case, 2007; Yang & Chen, 2013). Downregulating CD147 expression by targeting the intercellular proteins that shuttle CD147 to the cell’s surface may help prevent metastasis of cancerous cells. Through a search on the BioGRID, we identified a cluster of seven proteins of interest: SEL1L, OS9, SYVN1, VCP, FBXO6, CAND1, and CUL3. All of these proteins have been identified to play roles in the endoplasmic reticulum (ER). These proteins hypothetically interact with CD147 as well as with each other (Bennett, Rush, Gygi, & Harper, 2010; Liu et al., 2012; Tyler et al., 2012; Yu et al., 2013). After overexpression of SEL1L, SYVN1, VCP, CAND1, and CUL3 had no impact on CD147 levels, we have narrowed our focus to OS9 and FBXO6. OS9 is a lectin, binding to terminally misfolded proteins and delivering them to ubiquitin complexes such as the SEL1L-HRD1 (Christianson, Shaler, Tyler, & Kopito, 2008; Tyler et al., 2012). FBXO6, an F-box protein, is a substrate recognition component of the SCF (Skp, Cullin, F-box containing) complex, a subsection of E3 ubiquitin ligases. FBXO6 is thought to bind to misfolded proteins in the ER and then bind SCF, leading to the ubiquitination and degradation of the target protein (Yoshida et al., 2003). Our western blot results show that knockdown of OS9 via small interfering RNA (siRNA) led to an increase of CD147 expression levels in HEK293 cells. Conversely, overexpression of OS9 resulted in a decrease in CD147 protein levels. After transfecting HEK293 cells with OS9 fluorescent fusion proteins, we used fluorescent microscopy to observe OS9 in many vesicles throughout the cells. FBXO6 siRNA-mediated knockdown resulted in an increase of CD147 however, overexpressing FBXO6 also led to a higher level of CD147 expression. FBXO6 fluorescent fusion proteins localized primarily in a perinuclear dot approximately 2 μm in diameter. While OS9 and FBXO6 were previously described as ER-resident, our localizations are very distinct, thus we are in the process of identifying the cellular structures to which these proteins localize. These data suggest that both OS9 and FBXO6 may play a role in trafficking CD147 to the cell’s surface.

Rab GTPases regulate membrane trafficking at the stages of vesicle formation, movement and fusion with target compartments. Rab11 GTPase coordinates trafficking at biosynthetic and endocytic recycling routes acting at the trans-Golgi network (TGN), post-Golgi vesicles and recycling endosomes. Rab11 Binding Protein (Rab11BP) has long been described as a potential Rab11 effector but its function remains unknown. The structure of Rab11BP includes a Rab11 binding domain and several domains presumably involved in protein-protein interactions, which include an FFAT-like domain, a proline rich domain and seven WD40 repeats typical of scaffold proteins. Here we used shRNA silencing experiments to first evaluate whether Rab11BP is involved in the Rab11-dependent endocytic recycling of transferring receptor (TfR) and then assessed the protein traffic between the endoplasmic reticulum (ER) and Golgi. We silenced Rab11BP expression with shRNA using lentiviral transduction or microinjection. Rab11BP-silenced cells showed normal TfR endocytosis and recycling analyzed by FACS. However, the distribution of KDEL-GFP and the retrograde-impaired mutant KDEL(D193N)-GFP indicated that Rab11BP functions in Golgi-to-ER retrograde trafficking. Rab11BP silencing led the KDEL-GFP to change its distribution from a predominant ER location to an accumulation at the cis-Golgi, colocalizing with Giantin, while the Golgi-retained mutant KDEL(D193N)-GFP remained unaffected. This indicates an impaired retrograde Golgi-to-ER transport without affecting the anterograde transport from ER to Golgi, which likely impact on the ER function of KDEL-bearing chaperones. Rab11BP silencing decreased TGN46, furin, M6PR and calnexin protein levels and induced the characteristic fragmentation of the TGN associated with an impaired Golgi-to-ER transport. These results indicate that Rab11BP is required for retrograde transport from the Golgi-to-ER contributing to the maintenance of the Golgi structure and homeostasis. As to our knowledge Rab11 has not been involved in this step of the biosynthetic trafficking, our results suggest that Rab11BP might have functions independently of Rab11.

Temporal distribution of the Hantavirus Nucleocapsid Protein in human pulmonary cells (A549) infected with Rio Mamore hantaviruses.

J.V. de Carvalho¹, D.M. de Melo², G. Sabino-Santos Jr², L.T. Figueiredo ³, L.L. da Silva¹;
¹Department of Cell and Molecular Biology, University of Sao Paulo, Ribeirão Preto, Brazil, ²Department of Biochemistry and Immunology, University of Sao Paulo, Ribeirão Preto, Brazil, ³Department of Clinical Medicine, University of Sao Paulo, Ribeirão Preto, Brazil

Hantaviruses are zoonotic diseases of great clinical importance that affect humans and are distributed worldwide. The transmission to humans is by inhalation of contaminated aerosolized excreta from infected rodents and can cause different pathologies. Despite its great importance, little is known about
the replicative cycle and which cell compartments the hantaviruses use for their assembly and budding. Herein, we examine the subcellular distribution of the nucleocapsid (N) protein of hantavirus (Rio Mamore Virus) in different times post infection (p.i.). The N protein is the most abundant viral protein in infected cells and plays several roles during viral assembly and budding. Using fluorescence microscopy, we show that during the replicative cycle, the N protein accumulates in the juxtanuclear region and is also found in puctate structures scattered throughout the cytoplasm that increase in size over the time of infection. These larger structures probably represent "viral factory units". To identify the compartments in which the protein N is located, we examined its localization relative to markers of Golgi compartments (Giantin and TGN46) and early endosomes (SNX2). We found that the N protein colocalize with trans-Golgi network proteins at 48, 72, 96 and 120 h p.i., suggesting that Golgi compartments are the main sites of assembly and viral budding. It was also found that the N protein partially colocalizes with SNX2, suggesting a role for early endosomes in viral assembly. Additional studies with cellular and viral markers at the ultrastructural level could provide more information about the viral assembly and budding processes. Also, it would be interesting to analyze the participation of Golgi to endosome transport factors of the host cell that may contribute to these events. A better understanding of these events will reveal important aspects for the elaboration of strategies aimed at inhibiting viral replication.

Specificity in membrane fusion is essential for proper organelle maturation. The homotypic fusion and vacuolar protein sorting (HOPS) complex facilitates the tethering of apposing membranes, promotes SNARE complex assembly, and is required for membrane docking and fusion in the classical endolysosomal system, but it is not known how the HOPS complex functions in specialized cell types to facilitate the biogenesis of cell type-specific lysosome-related organelles. Buff (bf) mice, which have a missense mutation in the HOPS complex subunit Vps33a, are hypopigmented, suggesting that the HOPS complex plays a specific role in the biogenesis of melanosomes, lysosome-related organelles required for melanin synthesis and storage. To understand the function of Vps33a in the melanosomal pathway, we analyzed immortalized melanocytes from bf mice (melan-bf cells). Unexpectedly, we show by light and electron microscopy that these cells are hyperpigmented with large, mature melanosomes localized to the cell periphery. The enlarged bf melanosomes maintain an elongated shape and do not appear to represent fused melanosome clusters. This difference in hypopigmentation in the keratinocytes of bf mice and hyperpigmentation in the epithelial melanocytes of bf mice indicate that the HOPS complex may play a role in melanin transfer from melanocytes to keratinocytes. Using immunofluorescence microscopy, we show that lysosomal and melanosomal proteins exist in distinct compartments in melan-bf cells, demonstrating that the bf mutation in Vps33a does not affect protein sorting from early endosomes or the segregation of melanosomal and endolysosomal organelles. Our studies suggest that
the HOPS complex has a specific and unexpected role in regulating the maturation of melanosomes. Future studies will aim to identify a direct or indirect mechanistic role for the HOPS complex in melanosome maturation and function.

Identification of novel regulators for myosin V-mediated cargo transport.
S. Wong1, L. Gal2, N. Harpaz3, M. Schuldiner2, L.S. Weisman1,3;
1Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI, 2Department of Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, 3Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

Transport of organelles to their correct intracellular locations is essential for cellular function and homeostasis. In most cells, long-range movement of organelles occurs on microtubules via kinesin and dynein motors. Some cargoes are then transferred to myosin V motors, which provide short-range transport on actin filaments to the final destination. Thus, the spatial and temporal regulation of cargo release from myosin V likely specifies the terminal destination. It is largely unknown how this regulation is achieved. In the budding yeast, Saccharomyces cerevisiae, the yeast vacuole, similar to the mammalian lysosome, is one of six organelles moved by a myosin V motor, Myo2. Early in the cell cycle, Myo2 binds the vacuole specific adaptor, Vac17, and transports a portion of the vacuole into the bud. Later in the cell-cycle, the vacuole detaches from Myo2 and Vac17 is degraded. Previous work identified some key genes that regulate the termination of vacuole transport. Much of this regulation requires the Vac17-PEST sequence, a motif found in rapidly degraded proteins. An E3 ubiquitin ligase, Dma1, binds to a residue in the PEST sequence, Vac17-pT240, and ubiquitylates Vac17 to target it for degradation. Notably, Dma1 activation requires that another residue in the PEST sequence, Vac17-S222, is phosphorylated by the p21-activated kinase Cla4. Since Dma1 recruitment is not sufficient to ubiquitylate Vac17, additional genes likely play a role in Vac17 degradation and the release of the vacuole from Myo2. To identify these potential genes, we performed a whole-genome, high content screen to identify mutants with elevated levels of Vac17, a phenotype that correlates with defects in vacuole transport. Interestingly, we identified two genes previously shown to regulate vacuole fusion. Notably, mutating other genes involved in vacuole fusion did not disrupt the disengagement of the vacuole from Myo2 or Vac17 turnover. This suggests that the two genes have novel, previously unknown roles in releasing Myo2 from the vacuole. Our data suggest that these two genes regulate phosphorylation of Vac17 residues outside of the PEST sequence. Previously identified regulators acted solely on the PEST sequence, suggesting that these new regulators act in a novel step in vacuole transport. Moreover, while these regulators are required for the degradation of Vac17, they are not required for Vac17 ubiquitylation. Thus, we hypothesize that these regulators are required for the detachment of Myo2 from Vac17 and the vacuole, and suggest that Vac17 must be released from Myo2 before it is degraded. Our data suggests novel roles for these genes in vacuole delivery, and provide new insights into the termination of myosin V-mediated cargo transport.

¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Genetics and Molecular Biology, UNC Chapel Hill, Chapel Hill, NC, ³Biology, UNC Chapel Hill, Chapel Hill, NC

The degradation of cell surface proteins is important for cellular homeostasis and responses to environmental changes. This multi-step process involves regulated endocytosis followed by transit through endosomal compartments before delivery into the proteolytic compartment. Although much is known about the early steps of endocytosis at the plasma membrane and the terminal steps at the late endosome, gaps remain in our understanding of how cargo transits from the plasma membrane to the late endosome and whether active protein sorting is important during intermediate steps. Here, we report that non-endocytic clathrin adaptors, Ent5, Ent3, Gga2, and Appl4, play key roles in post-endocytic sorting of degradative cargo in response to multiple environmental signals in Saccharomyces cerevisiae. We show close proximity between non-endocytic clathrin adaptors and cargo en-route to the vacuole using bi-molecular fluorescence complementation. Furthermore, degradative cargo transits through the trans-Golgi network (TGN) after endocytosis and loss of non-endocytic clathrin adaptors causes accumulation of cargo at the TGN. Finally, inhibiting exit from the TGN also blocks degradative traffic. These data support a direct role for non-endocytic clathrin adaptors in post-endocytic sorting of cell surface proteins to the vacuole and, suggest that the TGN is a major sorting station for endocytosed plasma membrane proteins destined to the vacuole.

SNX-BAR mediated retrograde trafficking of yeast synaptobrevin/Snc1 is conferred by its transmembrane domain.
M. Ma¹, L. Purushothaman², M. Babst³, C. Ungermann², C.G. Burd¹;
¹Department of Cell Biology, Yale University, New Haven, CT, ²Department of Biology/Chemistry, University of Osnabruceck, Osnabrück, Germany, ³Department of Biology, University of Utah, Salt Lake City, UT

Synaptobrevin/VAMP2 is an essential SNARE protein that has been extensively studied in its role in synaptic vesicle fusion. However, how synaptobrevin is sorted for trafficking within the cell is not well understood. A unique structural feature of synaptobrevin is a conserved aromatic motif on the cytosol-proximal interface of the juxtamembrane region that has been proposed to confer a 35° tilt angle in the transmembrane domain, allowing conserved basic residues in the transmembrane domain to interact with the membrane surface. The aromatic motif has been shown to promote binding of calmodulin and phospholipids, and to facilitate SNARE complex assembly. In yeast, the synaptobrevin homologue Snc1 has been shown to require the aromatic motif for proper trafficking. We demonstrate that the basic residues on the cytosol-proximal surface of the Snc1 transmembrane domain play an important role in promoting sorting of Snc1 into retrograde trafficking pathways. Additionally, we demonstrate that the Snx4-Agt20 SNX-BAR dimer, which functions in retrograde trafficking of Snc1, binds preferentially to anionic membranes and we propose this contributes to Snc1 recognition and sorting out of the endosome. We further characterize Snc1 trafficking pathways in yeast and propose a bifurcated trafficking model for Snc1 where endocytosed Snc1 and Snc1 on the late/pre-vacuolar endosome are returned to the Golgi via two different retrograde pathways.

Sorting nexin 3 drives phagosomal compaction of Borrelia burgdorferi in primary human macrophages.
M. Klose¹, S. Linder¹;
¹Institute for Medical Microbiology, Virology and Hygiene, University Medical Center Eppendorf, Hamburg, Germany

Borrelia burgdorferi is the causative agent of Lyme disease, a multisystemic disorder affecting primarily skin, joints and nervous system. Macrophages and dendritic cells counteract Borrelia dissemination in the human body through capturing, internalization and subsequent degradation of spirochetes. Internalization of B. burgdorferi by primary human macrophages involves compaction of helical borreliae into Rab22a-positive phagosomes that are contacted by Rab5a vesicles. Compaction of the phagosomal surface proceeds by membrane extrusion at the contact sites of Rab5a vesicles. This step is crucial for further processing and elimination of borreliae in phagolysosomes. A screen for regulators of phagosomal membrane tubulation indentified sorting nexin 3 (SNX3). Indeed, both overexpressed and endogenous SNX3 and Rab22a were found to colocalize at borreliae-containing phagosomes during early and late steps of phagosome maturation. Accordingly, compaction of borreliae is reduced in macrophages depeleted for SNX3 and can be rescued by expression of an siRNA-insensitive SNX3 wt construct, but not by a construct defective in phosphoinositide binding. Live cell imaging further showed that Rab22a-positive phagosomes are also positive for PI(3)P, and that SNX3 is recruited to these phagosomes via Rab5a positive vesicles. We propose a mechanism for SNX3 regulation of borreliae phagosome maturation through recruitment of SNX3/Rab5a vesicles to PI(3)P/Rab22a phagosomes, which leads to reduction of the phagosomal surface through membrane tubulation. Our results thus reveal SNX3, in cooperation with PI(3)P, Rab22a and Rab5a, as an important regulator of Borrelia intracellular processing by macrophages, supporting elimination of infecting spirochetes by the human immune system.

Structural basis for the hijacking of endosomal sorting nexin proteins by Chlamydia trachomatis.
B. Paul¹, H.S. Kim¹, M.C. Kerr¹, W.M. Huston², R.D. Teasdale¹, B.M. Collins¹;
¹Institute for Molecular Bioscience, The University of Queensland, Brisbane, Australia, ²School of Life Sciences, The University of Technology, Sydney, Australia

During infection chlamydial pathogens form an intracellular membrane-bound replicative niche termed the inclusion, which is enriched with bacterial transmembrane proteins called Inclusion membrane proteins (Incs). Incs bind and manipulate host cell proteins to promote inclusion expansion and provide camouflage against innate immune responses. Sorting nexin (SNX) proteins that normally function in endosomal membrane trafficking are a major class of inclusion-associated host proteins, and are recruited by one of the Chlamydial Incrs; IncE/CT116. Crystal structures of the SNX5 phox-homology (PX) domain in complex with IncE define the precise molecular basis for these interactions. The binding site is unique to SNX5 and related family members SNX6 and SNX32. Intriguingly the site is also conserved in SNX5 homologues throughout evolution, suggesting that IncE captures SNX5-related proteins by mimicking a native host protein interaction. These findings thus provide the first mechanistic insights
both into how chlamydial Incs hijack host proteins, and how SNXS-related PX domains function as scaffolds in protein complex assembly.

Salmonella exploits the host endolysosomal tethering factor HOPS complex to promote its intravacuolar replication.

A. Sindhwani1, S.B. Arya2, H. Kaur1,2, D. Jagga1,2, A. Tuli2, M. Sharma1;
1Department of Biological Sciences, Indian Institute of Science Education and Research Mohali, Mohali, India, 2Cell Biology and Immunology, CSIR-Institute of Microbial Technology, Chandigarh, India

Intracellular pathogens have devised various strategies to subvert the host membrane trafficking pathways for their growth and survival inside the host cells. Salmonella is one such successful intracellular pathogen that extensively remodels the host endolysosomal compartments to establish its vacuolar niche within the host cells that is conducive for its replication, also known as the Salmonella-containing vacuole (SCV). Vacular Salmonella initiates and maintains a prolonged interaction with endosomes and lysosomes of the host cell in the form of interconnected network of tubules (Salmonella-induced filaments or SIFs), gaining access to both membrane and fluid-phase cargo from these compartments. This is essential for vacuolar membrane integrity and intravacuolar nutrition. Here, we have identified the multisubunit lysosomal tethering factor-HOPS (HOMotypic fusion and Protein Sorting) complex facilitates acquisition of endolysosomal content by SCVs, providing membrane for SIF formation, and nutrients for intravacuolar bacterial replication. HOPS subunits were enriched in the SCV fraction from 3 hr to 10 hr post infection as revealed by density gradient ultracentrifugation of Salmonella infected HeLa cell homogenates. Not surprisingly, lysosomal small GTPase Arl8b that promotes membrane localization of HOPS complex was required for HOPS recruitment to SCVs and SIFs. Depletion of various HOPS subunits significantly reduced the bacterial load in non-phagocytic and phagocytic cells as well as in a mouse model of Salmonella infection. SCV interaction with dextran-loaded lysosomes and SIF formation was significantly impaired in HOPS depleted cells. Further, using auxotrophic strains of Salmonella that are deficient in proline biosynthesis, we demonstrate that SCV access to external proline requires HOPS-mediated interaction with the endolysosomal compartment. We found that Salmonella effector SifA in complex with its binding partner; SKIP, interacts with HOPS subunit Vps39 and mediates recruitment of HOPS subunits to SCV compartments. Our findings suggest that Salmonella recruits the late endosomal and lysosomal tethering factor-HOPS complex to its intracellular vacuole for access to membrane and nutrients, ensuring its growth and survival within the host cells.

Increased biogenesis and fusion of early endosomes promotes complement activation in the retinal pigment epithelium.

L. Tan1,2, G. Kaur1,2, K.A. Toops1, N. La Cunza1,2, G. Rathnasamy1, A. Lakkaraju1,2,3;
1Department of Ophthalmology and Visual Sciences, University of Wisconsin-Madison, Madison, WI, 2Department of Pharmaceutical Sciences, University of Wisconsin-Madison, Madison, WI, 3Graduate Program in Cellular and Molecular Biology, University of Wisconsin-Madison, Madison, WI

Deregulation of the complement system and consequent inflammation are strongly associated with age-related macular degeneration (AMD), which causes irreversible blindness in millions of older adults
worldwide. The RPE, a monolayer of post-mitotic cells that sits beneath the photoreceptors, is the first line of defense against abnormal complement activation. Recent work from our lab has identified two rapid mechanisms – recycling of complement regulatory proteins and membrane repair by lysosome exocytosis - that help the RPE curtail complement-mediated inflammation (Tan et al., PNAS, 2016). We have previously reported that in models of macular degeneration, accumulation of vitamin A metabolites in the RPE results in increased levels of cholesterol, which activates acid sphingomyelinase (ASMase), the enzyme that hydrolyzes sphingomyelin to ceramide (Toops et al., Mol Biol Cell, 2015). Here, using high-speed live-cell imaging of primary RPE monolayers, we show that excess ceramide on the apical plasma membrane of the RPE results in an increase in early endosome biogenesis. We also observed formation of enlarged endosomes following increased fusion between nascent endosomes, which is likely driven by non-bilayer phases formed by ceramide. Live-cell imaging revealed that these enlarged early endosomes are significantly less motile than the smaller endosomes. Our data suggest that these features are caused by cholesterol-induced elevation of ceramide on the plasma membrane, which promotes inward budding. Consistent with this hypothesis, removal of excess cholesterol in models of macular degeneration restores the early endosome size and motility. Recent studies show that early endosomes regulate intracellular complement activity by internalizing the complement protein C3, whose cleavage is the initial step that triggers complement attack. To dissect how enlargement of early endosomes might affect complement regulation in the RPE, we examined the co-localization of C3 with early endosomes in the RPE in a mouse model of inherited macular degeneration (Abca4-/-). Our data revealed that RPE in Abca4-/- mice stain more strongly for C3. Importantly, these signals co-localize with the early endosome marker EEA1. This is accompanied by increased formation of active C3 cleavage products in the RPE of Abca4-/- mice compared to age-matched wild-type. Altogether our data suggest that in models of macular degeneration, increased biogenesis and fusion of apical early endosomes in the RPE could contribute to deregulation of complement system by increasing generation of active intracellular C3.

**TFEB regulates lysosomal positioning by modulating TMEM55B expression and JIP4 recruitment to lysosomes.**

R.A. Willett¹, J.A. Martina¹, G. Hammond², J.P. Zewe², R. Puertollano¹;

¹NHBLI, National Institute of Health, Bethesda, MD, ²Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Lysosomal distribution within cells is directly linked to the role of lysosomes in many cellular functions, including autophagosome degradation, cholesterol homeostasis, antigen presentation, and cell invasion. Moreover, alterations in lysosomal positioning contribute to different human pathologies, such as cancer, neurodegeneration and lysosomal storage diseases. Here we report the identification of a novel mechanism of lysosomal trafficking regulation. We found that the lysosomal transmembrane protein TMEM55B promotes recruitment of JIP4 to the lysosomal surface, thus inducing dynein-dependent transport of lysosomes toward the microtubules minus-end. Accordingly, over-expression of TMEM55B causes lysosomes to collapse into the cell center, whereas depletion of either TMEM55B or JIP4 results in dispersion toward the cell periphery. TMEM55B levels are transcriptionally upregulated following TFEB and TFE3 activation by starvation or cholesterol-induced lysosomal stress. TMEM55B or JIP-4 depletion abolishes starvation-induced retrograde transport of lysosomes and prevents fusion between autophagosomes and lysosomes. JIP4-mediated retrograde transport is also observed upon induction of lysosomal stress by sodium arsenite or curcumin though a mechanism that requires MAPK activation.
Overall, our data reveal a novel role of TMEM55B linking lysosomes to microtubule motors and suggest that the TFEB/TMEM55B/JIP4 pathway plays a critical role in cellular adaptation to stress by coordinating control of lysosomal movement in response to variations in nutrient and cholesterol levels.

**VMAT2 and SLC35D3 sort from endolysosomes to dense granules during megakaryocyte differentiation to proplatelets.**

1Pathology and Laboratory Medicine, Children’s Hospital of Philadelphia, Philadelphia, PA, 2Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, 3Physiology, University of Pennsylvania, Philadelphia, PA, 4Cell and Molecular Biology Graduate Group, University of Pennsylvania, Philadelphia, PA, 5Pediatrics, Children’s Hospital of Philadelphia, Philadelphia, PA, 6Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Dense granules (DGs) are lysosome-related organelles (LROs) in platelets that store small molecules like calcium, ADP, and serotonin and larger polyphosphates. Release of these contents during platelet activation is necessary for efficient clot formation during vascular injury. Hence, defects in DG formation, as occurs in Hermansky-Pudlak syndrome (HPS), result in excessive bleeding and bruising. However, how DGs are formed within the nucleated platelet precursors, megakaryocytes (MKs), is not known. In particular, while putative DG transmembrane proteins have been identified, how and when DG membrane contents are delivered is not at all known. We first sought to determine the localization of these putative DG proteins, SLC35D3 and VMAT2, in MKs. SLC35D3 was previously shown to localize to early endosomes labeled by Syntaxin-13 in multinucleated but intact MKs; our new data with live cell probes further indicate that these endosomes also harbor VMAT2 and are unusually acidic as assessed by labeling with acidotropic agents. Preliminary data further suggest that these endosomes are a type of hybrid organelle with features of both early and late endosomes. Next, we visualized SLC35D3 and VMAT2 at later stages of MK differentiation in an attempt to capture protein sorting during DG maturation. Our lab previously showed that DG biogenesis occurs at a later stage of MK differentiation than previously thought. After maturation, MKs undergo morphological changes to form proplatelets, which are long “beads on a string” structures from which platelets are shed. Using vital imaging with mepacrine, which label DGs in platelets, we observed separation of mepacrine from lysosomal markers during this stage of differentiation. By utilizing an engineered stem cell line that differentiates to MKs and mimics MK maturation to proplatelets, we show that both SLC35D3 and VMAT2 co-segregate from acidic compartments with mepacrine in proplatelets. Lastly, we tested the putative sorting signals in SLC35D3 and VMAT2 in binding AP-3, an adaptor protein complex that is mutated in HPS types 2 and 10. Using a yeast two-hybrid and GST pulldown assays, we demonstrate that SLC35D3 relies on its tyrosine-based sorting signal to bind in vitro to AP-3. By contrast, VMAT2’s putative dileucine-based sorting signal did not bind to AP-3 in vitro; nevertheless preliminary data suggest that it is required for effective cosegregation with mepacrine in proplatelets. Together, our data suggest a model in which DGs mature in proplatelets by cargo delivery from unusually acidic endo-lysosomes, somewhat akin to models of melanosome (another type of LRO) biogenesis in melanocytes.

Regulated recruitment of C9orf72 to lysosomes supports diverse signaling and degradative functions.
J. Amick1, A. Tharkeshwar1, C. Amaya1, S.M. Ferguson1;
1Cell Biology, Yale University, New Haven, CT

Expansion of a hexanucleotide repeat in an intron of the C9orf72 gene causes amyotrophic lateral sclerosis and frontotemporal dementia (ALS-FTD), two related neurodegenerative diseases. These insights from human genetics have stimulated significant interest in understanding C9orf72 functions. However, beyond bioinformatics predictions that have suggested structural similarity to a subset of DENN domain containing proteins that include folliculin (FLCN), the Birt-Hogg-Dubé syndrome tumor suppressor, little was known until recently about the normal cellular functions of the C9orf72 protein. To address this problem, we used genome editing strategies to investigate C9orf72 interactions, subcellular localization and knockout (KO) phenotypes. We found that C9orf72 robustly interacts with SMCR8 and WDR41 (proteins of previously unknown function). Epitope tag insertion into the endogenous human C9orf72 gene locus, allowed us to establish that C9orf72 dynamically binds to the cytoplasmic surface of lysosomes and that such localization is negatively regulated by amino acid availability. Analysis of C9orf72 KO cell lines revealed diverse phenotypes that are consistent with a function for C9orf72 at lysosomes. These include abnormally swollen lysosomes in the absence of C9orf72, impaired responses of mTORC1 signaling to changes in amino acid availability (a lysosome-dependent process) and defects in lysosome-mediated recycling of both endocytic and autophagic cargoes. Through the use of additional CRISPR-Cas9 knockin and knockout strategies targeted towards SMCR8 and WDR41, we have gained new insights into specific roles for individual components of the C9orf72-SMCR8-WDR41 complex in regulating complex assembly, recruitment to lysosomes and downstream effects on mTORC1 signaling. Collectively, these results identify strong, constitutive, physical interactions between C9orf72, SMCR8 and WDR41 and support an important lysosomal site-of-action for this protein complex. Such insights are relevant for both interpreting the contributions of C9orf72 haploinsufficiency to neurodegenerative disease as well as understanding the fundamental mechanisms that match lysosome function to ongoing changes in cellular demand.

pHLARE: a ratiometric pH-biosensor for measuring lysosomal pH.
B.A. Webb1,2, D.L. Barber2;
1Biochemistry, West Virginia University School of Medicine, Morgantown, WV, 2Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA

Lysosome functions in nutrient sensing, metabolic adaptation, and quality control of proteins are central to normal cell biology, and dysregulated lysosome functions are increasingly being recognized as determinants in disease pathologies. Central to normal lysosome functions is maintaining an exceptionally low pH of ~5.0 for the activity of luminal acid-activated proteases, phosphatases, and phospholipases. Dysregulated lysosomal pH (pHlys) occurs in diseases such as neurodegenerative disorders and diabetic nephropathy, where pHlys is constitutively increased, which is predicted to decrease protein degradation and promote protein aggregation. Conversely, a current view that has not be effectively validated is that pHlys is decreased in cancers, presumably to enable increased autophagy and biomass production. Accurately measuring pHlys, however, is limited by currently available pH
sensing probes such as Lysosensor, Lysotracker, or fluorescein-conjugate dextran that are incorporated into cells by phagocytosis and accumulate not only in lysosomes but also in endosomes and other intracellular vesicles. To resolve this limitation we generated a ratiometric genetically encoded lysosomal pH-biosensor, pHLARE (pH Lysosomal Activity Reporter), which encodes the lysosome membrane protein LAMP1 tagged at the luminal domain with superfolderGFP (sfGFP) and at the cytoplasmic domain with mCherry. We confirmed that pHLARE localizes predominantly to lysosomes by showing co-localization with endogenous LAMP1 and with live-cell imaging confirming localization in vesicles with Rab7 but not Rab5. We also confirmed that between pH 5.0 and 6.5 pHLARE has pH-sensitive sfGFP and pH-insensitive mCherry emissions, determined in buffers containing the protonophore nigericin. With calibrated ratiometric values, we determined pHlys in CCL39 hamster lung fibroblast cells and MCF7 human breast cancer cells to be 5.32 +/- 0.43 and 5.13 +/- 0.21, respectively. Acute treatment with the V-ATPase inhibitor bafilomycin increased pHlys to 6.78 +/-0.42 in CCL39 cells and to 6.64 +/-0.46 in MCF7 cells. Our findings validate pHLARE as a new reagent to accurately measure pHlys dynamics that can be used for understanding lysosome function and dysfunction. pHLARE will also be useful in revealing regulators of pHlys that could be therapeutic targets, for example to retain a lower pHlys with neurodegenerative disorders and maintain activities of acid-activated proteases for protein degradation.

**The Structure of Melanoregulin Reveals a Role for Cholesterol Recognition in the Protein’s Ability to Promote Dynein Function.**

X. Wu¹, A.K. Rout¹, M. Strub¹, J.A. Hammer¹, N. Tjandra¹;

¹NHLBI, National Institutes of Health, Bethesda, MD

Melanoregulin (Mreg) is the product of the dilute suppressor locus, an extragenic suppressor of the coat color defect exhibited by myosin Va null mice. Mreg is a small, highly-charged, multiply-palmitoylated protein that is present on the limiting membrane of melanosomes. Previous studies have implicated Mreg in the transfer of melanosomes from melanocytes to keratinocytes (Wu et al, PNAS 2012), and in promoting the microtubule minus end-directed transport of these and related organelles by binding to RILP, a Rab7 effector that recruits the dynein motor complex (Ohbayashi et al, JCS 2012; Wu et al BBRC 2012). Here we shed new light on the possible molecular function of Mreg by solving its structure using nuclear magnetic resonance (NMR). The structure reveals bands of positive and negative charge that occupy opposite sides of the protein’s surface, and that sandwich a putative, tyrosine-based (Y166) cholesterol recognition sequence (CRAC motif). We confirmed that cholesterol interacts with Mreg, as residues S163 and L168 within the CRAC motif show the largest NMR chemical shift change upon cholesterol addition. Importantly, Mreg containing a function blocking point mutation within its CRAC motif (Y166I) still targets to late endosomes/lysosomes, but no longer promotes their microtubule minus end-directed transport. Reversing the charge of three closely-spaced acidic residues (D177, E180, and D181) also inhibits Mreg’s ability to drive these organelles to microtubule minus ends, but only partially. We propose that cholesterol recognition alters Mreg’s orientation on the membrane in such a way as to allow it to interact with a component(s) involved in dynein recruitment (e.g. RILP), and that this interaction is further promoted by the acidic patch. Finally, we draw comparisons between Mreg and the protein ORP1L, which controls the microtubule minus end-directed transport, positioning and fate of late endosomes in part by recognizing both cholesterol and components that target dynein.

Niemann-Pick disease type C (NPC) is a rare genetic cholesterol storage disorder caused by mutations in the NPC1 protein. Mutations in this trans-membrane protein lead to a block in normal cholesterol efflux from the late endosomes and lysosomes. Pan-histone deacetylase inhibitors (HDACi) such as Vorinostat (SAHA) can correct the cholesterol accumulation phenotype in NPC1 patient fibroblast cells. We screened 125 HDAC inhibitors that targeted either individual HDACs or classes of HDACs to identify which were necessary for cholesterol clearance in NPC1 patient-derived fibroblast cells. We used a high-throughput microscopy screening assay to identify compounds that resulted in cholesterol clearance from these cells. We have determined that the important targets for HDAC inhibition for cholesterol clearance in NPC1 fibroblasts are HDACs 1, 2, and 3.

Superparamagnetic iron oxide nanoparticles (SPIONs) have mainly been used as cellular carriers for genes and therapeutic products, while their use in subcellular organelle isolation remains underexploited. We engineered SPIONs targeting distinct subcellular compartments. Dimercaptosuccinic acid-coated SPIONs are internalized and accumulate in late endosomes/lysosomes, while aminolipid-SPIONs reside at the plasma membrane. These features allowed us to establish standardized magnetic isolation procedures for these membrane compartments with a yield and purity permitting proteomic and lipidomic profiling. We validated our approach by comparing the biomolecular compositions of lysosomes and plasma membranes isolated from wild-type and Niemann-Pick disease type C1 (NPC1) deficient cells. Our lipidomics analysis revealed the buildup of several species of glycerophospholipids and other storage lipids in late endosomes/lysosomes of NPC1 KO cells. While the plasma membrane proteome remained largely invariable, we observed pronounced alterations in several proteins linked to autophagy and lysosomal catabolism reflecting vesicular transport obstruction and defective lysosomal turnover resulting from NPC1 deficiency. Thus the use of SPIONs provides a major advancement in fingerprinting subcellular compartments, with an increased potential to identify disease-related alterations in their biomolecular compositions.

Extracellular oligomers made from the microtubule-associated protein, tau, induce focal accumulation of endogenous neuronal tau coupled to alterations in microtubule-based fast axonal transport.
E. Swanson¹, L. Breckenridge¹, L. McMahon², S. Som³, I. McConnell¹, G.S. Bloom¹,²,⁴;
¹Department of Biology, University of Virginia, Charlottesville, VA, ²Department of Cell Biology, University of Virginia, Charlottesville, VA, ³Department of Biomedical Engineering, University of Virginia, Charlottesville, VA, ⁴Department of Neuroscience, University of Virginia, Charlottesville, VA

Insoluble hyperphosphorylated aggregates of the microtubule-associated protein, tau, define a subset of neurodegenerative disorders known as tauopathies, of which Alzheimer’s Disease (AD) is the most prevalent. Extracellular tau can induce the accumulation and aggregation of intracellular tau, and tau pathology can propagate along defined neuroanatomical networks in a manner that recapitulates the temporal spread of pathology observed upon post-mortem analysis of diseased tissue. There are six splice variants of central nervous system tau, and various oligomeric and fibrillar forms are associated with neurodegeneration in vivo. The particular extracellular forms of tau capable of transferring tau pathology from neuron to neuron remain ill-defined, as do the consequences of intracellular tau aggregation on neuronal physiology. This study was undertaken to compare the effects of extracellular tau monomers, oligomers and filaments comprising various tau isoforms on the behavior of cultured wild type neurons. This work demonstrates that tau oligomers provoke accumulation of endogenous intracellular tau much more effectively than monomers or fibrils. This effect is most pronounced for oligomers comprising isoforms with 2, as opposed to 0 or 1 N-terminal inserts, and for those isoforms with 4, rather than 3 microtubule binding repeats. A mixture of all 6 isoforms most potently provokes focal, intracellular tau accumulation and extensive tau accumulation is associated with invasion of tau into the somatodendritic compartment. Finally, this work shows that 2N4R oligomers perturb fast axonal transport of membranous organelles along microtubules. Intracellular tau accumulation is often accompanied by increases in the run length, run time and instantaneous velocity of membranous cargo, and these alterations in fast axonal transport are diminished in neurons not expressing tau. This study provides a physiologically relevant model of tau propagation in neurons, and indicates that extracellular tau oligomers can disrupt normal neuronal homeostasis by triggering focal tau accumulation and loss of the polarized distribution of tau, and by hyperactivating fast axonal transport. Additionally, by identifying tau species involved in cellular dysfunction, it provides potential targets for much needed therapies in AD and non-Alzheimer’s tauopathies.

A Novel Lysosome-to-Mitochondria Signaling Pathway and its Role in Disease.
A. Norambuena⁵, H. Wallrabe⁶, Z. Svindrych¹, D. Bigler Wang¹, J. Burks², R. Cao², S. Hu², G.S. Bloom¹,³,⁴;
¹Department of Biology, University of Virginia, Charlottesville, VA, ²Department of Biomedical Engineering, University of Virginia, Charlottesville, VA, ³Department of Cell Biology, University of Virginia, Charlottesville, VA, ⁴Department of Neuroscience, University of Virginia, Charlottesville, VA

Inter-organelle communication is an emerging topic in cell biology, however little is known about the underlying mechanisms, its functional consequences or its potential role in disease pathogenesis. We
have developed a two-photon fluorescence lifetime imaging assay that detects mitochondrial activity in live cultured cells by monitoring autofluorescence of the mitochondrial coenzyme, NAD(P)H. Variation in enzyme-bound NAD(P)H is used as a read-out for changes in mitochondrial activity. In primary mouse cortical neurons and human NPC-derived neurons, nutrient-mediated activation (i.e., insulin, or arginine plus leucine) of the lysosome-associated, multi-subunit protein kinase complex, mTORC1, stimulates perikaryal mitochondrial activity within minutes. This effect is negatively regulated by: 1) Torin1, an inhibitor of mTOR, the catalytic subunit of mTORC1 and mTORC2; 2) knocking down Raptor, an essential mTORC1 subunit; or 3) forcing mTORC1 to associate with the plasma membrane instead of lysosomes. In addition, we found that this nutrient-induced mitochondrial activity (NiMA) pathway does not involve mTORC2 activity nor expression of eIF4E, which mediates mTORC1-regulated mRNA translation. NiMA was found to occur independently of autophagy or fatty acid transport into mitochondria, but was significantly reduced by amyloid-β oligomers (AβOs), which trigger Alzheimer’s disease (AD), and which we previously found to activate mTORC1 at the plasma membrane, but not at lysosomes (Norambuena et al. 2017. Alzheimers & Dementia 13: 152-167). In addition, we observed that either forcing mTORC1 to lysosomes, or downregulating the activity of either of two endogenous, lysosome-associated mTORC1 inhibitors, the TSC or GATOR1 complexes, leaves mitochondria insensitive to nutrient stimulation. In line with these results, NiMA was also disrupted in human fibroblasts obtained from patients affected by tuberous sclerosis, a genetic disorder triggered by dysfunctions in the TCS complex. Finally, using multi-parametric photoacoustic microscopy (Ning et al, 2015. Scientific Reports 5: article # 18775), which allows high-resolution and quantitative imaging of hemodynamics and oxygen metabolism in the live mouse brain, we also found that arginine plus leucine significantly alter cerebral oxygen consumption in vivo. Collectively, these results indicate that lysosomal mTORC1 couples nutrient availability to mitochondrial activity, thus functionally connecting these two organelles. This novel pathway also represents a new mechanistic link connecting metabolic alterations to mitochondrial diseases.

--JIP3 suppresses the development of amyloid plaque pathology by promoting the axonal transport of lysosomes.
S. Gowrishankar1, 2, Y. Wu1, 2, S.M. Ferguson1;
1 Cell Biology, Yale School of Medicine, New Haven, CT, 2 Neuroscience, Yale School of Medicine, New Haven, CT

Lysosome-filled axonal swellings are a major, but poorly understood feature of Alzheimer’s disease amyloid plaques. It is not clear what causes these axonal lysosomes to accumulate at amyloid plaques or whether they contribute to the disease pathology. Our previous characterization of these lysosomes at amyloid plaques led us to propose a model where these axonal lysosomes accumulate due to a local defect in their retrograde transport and maturation and represent pathologically meaningful sites of Aβ production. To test this hypothesis, we have sought to develop mouse genetic strategies to alter axonal lysosome abundance and examine the impact on amyloid plaque pathology. To this end, we identified JIP3 as a candidate for regulating axonal lysosome abundance and validated such a function through extensive cell biological characterization of JIP3 KO mouse neurons. These efforts revealed that JIP3 is an important regulator of the transport, abundance and maturation state of axonal lysosomes. Furthermore, we observed multiple similarities between the axonal lysosomes that accumulate in JIP3 KO neurons and those that build up around amyloid plaques. This includes a build up of amyloid precursor protein (APP), (BACE1) and presenilin 2 (PSEN2). The high levels of these proteins on axonal lysosomes from JIP3 KO neurons suggested that loss of JIP3 is accompanied by an increase in the
processing of APP into Aβ peptides. Indeed, we detected significantly elevated Aβ levels in the JIP3 KO neurons. Finally, we tested the in vivo relationship between JIP3-dependent axonal transport of lysosomes and amyloid plaque pathology by reducing JIP3 gene dosage in a mouse model of Alzheimer’s disease. These experiments revealed that loss of JIP3 was accompanied by an increase in soluble Aβ levels, amyloid plaque size, abundance and axonal dystrophy. These results collectively support a model wherein efficient retrograde axonal lysosome transport and maturation acts as a negative regulator of APP processing and the development of amyloid plaque pathology.

**Cofilin-actin rods as mediators of α-synuclein-induced synaptic dysfunction in Parkinson’s disease.**

M.I. Oliveira da Silva¹,², T.F. Outeiro³, J.R. Bamburg⁴, M.A. Liz¹,²;

¹IBMC – Instituto de Biologia Molecular e Celular, Universidade do Porto, Porto, Portugal, ²Instituto de Investigação e Inovação em Saúde, Universidade do Porto, Porto, Portugal, ³University Medical Center Göttingen, Göttingen, Germany, ⁴Colorado State University, Fort Collins, CO

Cofilin, a major regulator of actin filament severing and turnover, has received increasing attention in neurodegenerative diseases due to its ability to modulate actin in synapses and in neurites form rod-shaped inclusions containing coflin and actin. These structures have been mainly studied in the context of Alzheimer’s disease (AD) as possible mediators of axonal transport alterations and synaptic dysfunction in hippocampal neurons. Cofilin-actin rods are formed upon coflin hyperactivation by dephosphorylation, leading to co-assembly in a 1:1 complex with actin, which bundle into rods under conditions of oxidative stress. A role for the cellular prion protein (PrPc) in inducing the cognitive deficits in a mouse model of AD has been previously documented, where it serves as a co-receptor for Aβ oligomers and is required for Aβ oligomer induction of coflin-actin rods. In Parkinson’s disease (PD), in addition to the characteristic motor symptoms, cognitive impairment and dementia are often present and may be associated with α-synuclein accumulation in the hippocampus. In this work we addressed whether cognitive dysfunction in PD might be mediated by coflin pathology induced by alpha synuclein. In this respect, we observed that the overexpression of α-synuclein in hippocampal neurons induces the formation of coflin-actin rods. Moreover, our results point to a partial involvement of the PrPC in the α-synuclein-induced rod formation. Currently we are assessing rod formation in vivo through the evaluation of brains from a neuronal overexpressing α-synuclein PD mouse model, which presents cognitive dysfunction. Simultaneously, we are further dissecting the impact of α-synuclein on coflin/actin pathology in hippocampal neurons as well as the underlying molecular mechanisms. Importantly, we will determine the consequences of α-synuclein-induced actin cytoskeleton damage for neuronal function. In summary, our goals aim at validating coflin/actin pathology as a novel therapeutic target for PD dementia.

This work was financed by the project Norte-01-0145-FEDER-000008 - Porto Neurosciences and Neurologic Disease Research Initiative at I3S, supported by Norte Portugal Regional Operational Programme (NORTE 2020), under the PORTUGAL 2020 Partnership Agreement, through the European Regional Development Fund (FEDER); and by Luso American Development Foundation (FLAD).
Neurodegenerative diseases are debilitating, incurable and often fatal. As our population ages, the incidence of these diseases has increased and we still know little about what causes them. Further complicating matters, the overwhelming majority of diagnoses involve no genetic component. Recent evidence points to the contributions from epigenetic mechanisms to neurodegenerative disease etiology and progression. Epigenetics is broadly defined as any change in gene expression where the underlying DNA sequence is unaltered. Chromatin, a complex primarily involving DNA and histone proteins, controls access to the DNA. Changes in chromatin structure, brought by mechanisms such as the post-translational modifications (PTM) of histones, regulate gene transcription. Here, we characterize the epigenetic landscape of neurodegenerative diseases such as Amyotrophic Lateral Sclerosis (ALS) and Parkinson’s Disease (PD). Exploiting yeast and human models of ALS and PD, we have characterized changes in histone PTM levels and find distinct histone modification profiles for each of these ailments. Our results suggest that epigenetic mechanisms play an important role in ALS and PD and are an attractive new target in the development of novel therapeutics and treatments for these devastating diseases.

Significant evidence supports a crucial role for the autophagy-lysosomal pathway in the degradation of misfolded proteins that accumulate in numerous neurodegenerative disorders, including Parkinson’s disease (PD). Lysosomes and autophagosomes, the two major degradative components of this pathway, are believed to be, in part, regulated by the action of the transcription factor EB (TFEB). TFEB is normally sequestered inactive in the cytosol but accumulates in the nucleus upon activation by various cellular and lysosomal stresses where it binds to a 10bp CLEAR (Coordinated Lysosomal Expression and Regulation) promoter motif and upregulates the transcription of numerous lysosomal and autophagy genes. Supporting a role for TFEB activity in neuroprotection, nuclear TFEB is selectively reduced in human AD, ALS, and PD brains and co-localizes with alpha-synuclein in Lewy bodies (Decressac 2013 PNAS; Wang 2016 Neurosci J). PD meta-GWAS (Nalls 2014 Nat Genet) and other studies have also identified mutations in several direct targets of TFEB (e.g. GBA, VPS35) as genetic causes or risk factors for PD. Furthermore, TFEB viral overexpression is reported to be protective in a rat model of alpha-synuclein toxicity (Decressac 2013 PNAS) and multiple rodent models addressing amyloid beta and tau pathology (Xiao 2014 & 2015 J Neurosci; Polito 2014 EMBO Mol Med). These studies highlight the current well-founded enthusiasm for targeting TFEB activation as a novel therapeutic intervention to treat diseases associated with autophagy and lysosomal dysfunction, like PD. The purpose of the present study was to therefore identify a panel of TFEB target genes that provides a reliable, CNS-relevant transcriptional profile readout for TFEB activation and can consequently serve as a valuable assay tool for research and drug development efforts. Although hundreds of TFEB target genes have been
identified, previous transcript profiling has largely been carried out in immortalized cell lines rather than in disease-relevant CNS cell types. We evaluated the mRNA expression profile of a curated list of published TFEB target genes following TFEB overexpression in human iPSC-derived astrocytes and dopaminergic neurons, rat cortical neurons, and a HeLa cell reference line. Of the 85 genes tested, 27% were significantly upregulated in response to TFEB overexpression in both the HeLa and one CNS cell type, with 5% significantly upregulated across all cell lines tested (fold-change > 1.4). These identified responsive subsets could be used to confidently demonstrate TFEB target engagement and function across both CNS and non-CNS cell types frequently used for drug discovery.

Prion-like transmission of mutant huntingtin aggregates in Drosophila brains.
K.M. Donnelly1, M. Pearce1;
1Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

Huntington’s Disease (HD) is an inherited neurodegenerative disorder caused by an autosomal dominant mutation in the gene that encodes the protein huntingtin (Htt). This mutation results in expansion of a polyglutamine (polyQ) region located near the N-terminus of the Htt protein. Expanded polyQ stretches prevent the Htt protein from folding properly and causes it to self-assemble into protein aggregates that are visible as dense, proteinaceous inclusions within neurons and glia in HD patient brains. Mounting evidence supports the hypothesis that mutant Htt aggregates and pathogenic aggregates associated with other neurodegenerative diseases (e.g. Alzheimer’s disease, Parkinson’s disease, and amyotrophic lateral sclerosis) spread between cells in a manner similar to infectious prions. These aggregates can transfer to neighboring cells and there cause nucleated aggregation of native proteins. This “prion-like” transfer is thought to contribute to pathogenesis in neurodegenerative diseases. We have previously used the model organism Drosophila melanogaster to demonstrate prion-like transfer of mutant Htt aggregates from neurons to phagocytic glia in intact brains (Pearce et al., 2015, Nat Commun). These experiments use the Gal4-UAS and QF-QUAS binary expression systems to generate transgenic flies that express mutant and wild-type Htt proteins in independent cell populations in the same brain. Our studies also exploit the ability of mutant Htt aggregates to effect prion-like conversion of wild-type Htt expressed in “recipient” cells as a reporter for cytoplasmic entry of aggregates originating in “donor” cells. Applying a similar experimental paradigm, we have recently found that mutant Htt aggregates transfer from pre-synaptic olfactory receptor neurons (ORNs) to post-synaptic projection neurons (PNs) in the Drosophila brain. Remarkably, ORN-to-PN transfer of Htt aggregates requires the glial phagocytic receptor, Draper. These results indicate that mutant Htt aggregates transfer between diverse cell types in intact brains and suggest that phagocytic glia promote trans-synaptic aggregate transmission. A better understanding of the molecular mechanisms that allow pathogenic aggregates to spread between neurons and glia will lead to the identification of novel therapeutic targets to combat these fatal disorders.

Investigating Natural Remedies to Alleviate Parkinsons Manifested Symptoms.
C. Leonce¹, D. Sanzhikov², A. Patel⁵, A. Suryanarayanan², B. Peethambaran⁵;
¹Chemistry and Biochemistry, University of the Sciences, Philadelphia, PA, ²Biology, University of the Sciences, Philadelphia, PA

Parkinson's Disease (PD) is the second leading neurodegenerative disease in the United States and currently has no treatment that targets the pathogenesis. It causes degeneration of neurons of the substantia nigra pars compacta (SNc), thereby decreasing the release of dopamine from these cells. We have employed rotenone to induce PD-like symptoms in SH-SY5Y cells and it was observed that nerve cells pretreated with the extract of *Achillea millefolium* were protected from damage induced by rotenone. To identify the neuroprotective compounds in this extract, gravity column chromatography was used to separate and collect fractions from yellow and red flowers of *A. millefolium*. These fractions were air-dried and the dried extract was dissolved in DMSO to pretreat the SH-SY5Y nerve cells and test if neuroprotective compounds in that fraction could protect from 500 nM rotenone damage. The number of cells viable or damaged was analyzed using MTT assays. It was concluded that the fraction 4 from the yellow flowers of *A. millefolium* did protect the cells from rotenone induced damage to a significant degree. Future directions is to identify the major compound in the fraction 4 and use in silico modeling analysis to determine its targets. The data from this research project would lead to development of a novel natural neuroprotective compound that could be used as a supplemental to reduce neuro-degeneration in PD patients.

ASM regulates the autophagic process by controlling lysosomal biogenesis in Alzheimer's disease.
H. Jin¹, J. Lee¹, M. Jeong¹, S. Han², J. Bae²;
¹College of Veterinary Medicine, Kyungpook National University, Daegu, Korea, ²Department of Physiology, School of Medicine, Kyungpook National University, Daegu, Korea

In Alzheimer's disease (AD) abnormal sphingolipid metabolism has been reported, although the pathogenic consequences of these changes have not been fully characterized. Here we show that acid sphingomyelinase (ASM) is increased in fibroblasts, brain and/or plasma from patients with AD and in AD mice, leading to defective autophagic degradation due to lysosomal depletion. Partial genetic inhibition of ASM (ASM+/-) in a mouse model of familial AD (APP/PS1) ameliorated the autophagocytic defect by restoring lysosomal biogenesis, resulting in improved AD clinical and pathological findings, including reduction of amyloid-beta deposition and improvement of memory impairment. Similar effects were noted after pharmacologic restoration of ASM to the normal range in APP/PS1 mice. Autophagic dysfunction in neurons derived from familial AD patient-induced pluripotent stem cells (iPSCs) was restored by partial ASM inhibition. Overall, these results reveal a novel mechanism of ASM pathogenesis in AD that leads to defective autophagy due to impaired lysosomal biogenesis, and suggests that partial ASM inhibition is a potential new therapeutic intervention for the disease.

Mechanism of glycan binding by α-Synuclein.
H. Fung1, K. Acosta3, M. Biro1, E. Rhoades1;
1Department of Chemistry, University of Pennsylvania, Philadelphia, PA, 2Department of Biochemistry and Biophysics, Perelman School of Medicine, Philadelphia, PA

α-Synuclein (α-Syn) is the key constituent of Lewy bodies, the pathological hallmark of synucleinopathies such as Parkinson’s disease. While a significant amount of research has been dedicated to studying α-Syn aggregation and disease mechanisms, the biological functions of the protein remain poorly understood. α-Syn is predominantly expressed in the brain and is likely involved in the regulation of synaptic vesicles. Our lab has recently discovered that the α-Syn is a glycan binding protein with specificity for complex N-linked glycans. Data suggests that N-terminal region of α-Syn is involved with recognition of and binding to glycans, prompting us to further investigate the mechanism of glycan binding. As all five point variants of α-Syn linked to Parkinson’s disease – A30P, E46K, A53T, H50Q, and G51D, are located in the N-terminal domain, we investigated the impact of these mutations in glycan binding. Using a combination of biophysical approaches, we probed the structural and thermodynamic features of α-Syn mutants upon binding glycans, as well as their impact in internalization of α-Syn by neuronal lineage cells. Further biophysical characterization of this novel glycan binding activity of α-Syn and its disease mutants will provide more insights into the mechanism of glycan binding and its significance. Identification of putative glycosylated protein partners will significantly advance the understanding of α-Syn’s native functions in the cell.

Effects of mild running on substantia nigra during early neurodegeneration.
M.F. Almeida1, C.M. Silva1, R.S. Chaves1, N.C. Lima4, R.S. Almeida4, K.P. Melo1, M. Demasi3, T. Fernandes4, E.M. Oliveira5, L.E. Netto1, S.M. Cardoso3, M.F. Ferrari1;
1Instituto de Biociencias, Universidade de Sao Paulo, Sao Paulo, Brazil, 2University of Taubate, Taubate, Brazil, 3Butantan Institute, Sao Paulo, Brazil, 4School of Physical Eduvation and Sports, Universidade de Sao Paulo, Sao Paulo, Brazil, 5Faculty of Medicine, University of Coimbra, Coimbra, Portugal

Physical exercise has been postulated as an intervention that may attenuate progression of system aging. Moderate physical exercise acts at molecular and behavioral levels, such as interfering in neuroplasticity, cell death, neurogenesis, cognition and motor functions. Considering that the effects of physical exercise in early stages of protein aggregation remains poorly understood, the objectives of the present study is to evaluate the effects of physical exercise on oxidative stress, proteostasis, mitophagy and TrkB receptors levels and trafficking in the substantia nigra of aged rats during early neurodegeneration promoted by rotenone exposure. Aged male Lewis rats (9 months old) were exposed to rotenone 1mg/kg/day (8 weeks) and 6 weeks of moderate treadmill running, beginning 4 weeks after rotenone exposure. Substantia nigra was extracted and submitted to the analysis of proteasome and antioxidant enzymes activities, hydrogen peroxide levels and Western blot to evaluate the levels of tyrosine hydroxylase (TH), alpha-synuclein, TOM-20, PINK1, TrkB, SLP1, CRMP-2, Rab-27b, Beclin-1 and LC3II. It was demonstrated that moderate treadmill running, practiced during early neurodegeneration, prevented the increase of alpha-synuclein and maintained the levels of TH unaltered in substantia nigra of aged rats. Physical activity also stimulated autophagy, measured by an upregulation of 30% in beclin-1 levels and LC3II degradation, but decreased proteasome activity, in rotenone-exposed aged rats.
Mitophagy was impaired after rotenone exposure, as TOM-20 levels increased 40% indicating mitochondria accumulation, whereas physical training during early neurodegeneration prevented that increase. PINK1 levels showed a tendency of decrease in substantia nigra of aged rats exposed to rotenone, which was not present in exercised rats. Physical activity also prevented H2O2 increase during early neurodegeneration, although the mechanism involved remains to be elucidated, since the antioxidant enzymes evaluated did not changed. TrkB levels and its anterograde trafficking in substantia nigra seem not to be influenced by moderate treadmill running during early neurodegeneration. In conclusion, moderate physical training could prevent early neurodegeneration in substantia nigra through the improvement of autophagy and mitophagy.

Decoupling the effect of mutant amyloid precursor protein (APP) from the effect of plaque on axonal transport dynamics in the living mouse brain: A correlation MRI-microscopy study.
C.S. Medina1, F. Chaves1, R.E. Jacobs2,3, E.L. Bearer1,4;
1Pathology, University of New Mexico Health Sciences Center, Albuquerque, NM, 2Zhilka Institute, University of Southern California, Los Angeles, CA, 3Beckman Institute, California Institute of Technology, Los Angeles, NM, 4Marine Biological Laboratory, Woods Hole, MA

The parent protein for amyloid plaques, amyloid precursor protein (APP), mediates cargo-motor attachments for intracellular transport. Axonal transport is decreased and the distal location of accumulation is altered in transgenic mice expressing human APP with the Swedish and Indiana mutations (APPSwInd) linked to Familial Alzheimer’s Disease, as detected by time-lapse magnetic resonance imaging (MRI) of transport in living mouse brains (Bearer et al. 2017). Transport is also altered in brains of Down syndrome mice with 3 copies of APP gene. Questions now become whether expression of mutated APP effects transport dynamics independent of plaque, and do plaques alone contribute to transport defects? To address these we used the Tet-Off system to decouple expression of APPSwInd from presence of plaques, and then studied transport using our MRI technique in three experimental groups of transgenic mice in which the timing and duration of APPSwInd expression, and thereby plaque formation, was altered with doxycycline: Group A (+ plaques, + APPSwInd); Group B (+ plaques, no APPSwInd), and group C (no plaques, + APPSwInd). Manganese-enhanced MRI (MEMRI) allows us to perform cell biological experiments in live animals with T1-weighted MRI in a Bruker 11.7T scanner (Medina et al 2016). Time-lapse MR images were captured before and after stereotactic injection of Mn2+ (3-5nL) into CA3 of the hippocampus at successive time-points. Images of multiple individuals were aligned and processed with our automated computational pipeline (Medina et al. 2017) and statistical parametric mapping (SPM) performed. After MRI brains were harvested for histopathology or biochemistry. Results show that within group between time-point have altered transport locations as well as diminished transport in all groups compared to wildtype (p<0.05 FDR n=36). Preliminary ANOVA between-group comparisons both by SPM and by region of interest measurements of images support the visual impression that APPSwInd expression alone may compromise transport. Groups A and B displayed plaques, but not C, and Western blots showed APPSwInd expressed 3.2-fold over normal at sacrifice in Groups A and C but not B, with Aβ detected only in Groups A and B, where phospho-tau was also present in dystrophic neurites surrounding plaques. Cholinergic neurons that project to hippocampus from the medial septal nucleus were decreased in Group C (p=0.0006 by ANOVA, n=15). Isolated hippocampal vesicles contained Mn2+, as well as Trk (NGF receptor), Rab 5 and 7 (associated with transport vesicles), suggesting a distinct vesicle population is
affected by these APP mutations. These surprising results implicate mutated APPSwlnd in transport defects, separable from the effect of plaque. Supported NS062184 and MH096093.

Transcription derepression of Fuz triggers apoptosis and contributes to polyglutamine neurodegeneration.
Z. Chen 1, H. Chan 1;
1School of Life Sciences, The Chinese University of Hong Kong, Hong Kong, Hong Kong

Planar cell polarity (PCP) describes a cell-cell communication process through which individual cells coordinate and align on a tissue plane. In this study, we demonstrated that overexpression of Fuz, the human orthologue of the Drosophila melanogaster PCP gene fuzzy (fy), triggered neuronal apoptosis via the Dishevelled (Dvl)/Rac1 GTPase/MEKK1/JNK/caspase signalling axis. We further discovered that endogenous Fuz expression was upregulated in patients with spinocerebellar ataxia type 3 (SCA3), one of nine polyglutamine (polyQ) neurodegenerative disorders. Interestingly, Fuz gene induction was consistently observed in models of other polyQ diseases, including Huntington’s disease. And downregulation of Fuz expression rescued polyQ-associated cytotoxicity, and neurodegeneration in Drosophila. At a mechanistic level, we demonstrated that the transcriptional regulator Yin Yang 1 (YY1) associates with Fuz promoter, such that overexpression of YY1 caused hypermethylation of Fuz promoter, leading to transcriptional repression of Fuz. Soluble YY1 protein level was reduced in polyQ diseases. Such reduction perturbed the function of YY1, and led to induction of Fuz expression followed by neuronal apoptosis. In summary, our findings unveil a polyQ pathogenic pathway that involves YY1-mediated Fuz induction-promoted apoptotic cell death in polyQ diseases. Targeting this novel pathway may be of therapeutic potential.

Tauopathies are a group of neurodegenerative diseases characterized by pathognomonic protein inclusions formed by abnormal accumulation of microtubule-associated protein named tau. Clinical phenotypes of tauopathies manifest as cognitive impairment and behavioral disturbance. The aggregation of tau remains a central target for drug discovery, however no disease-modifying treatments exist. The mechanistic target of rapamycin (mTOR) signaling has emerging evidence in regulating cellular proteostasis through the uncovered cytosolic and lysosomal L-arginine sensing pathways. Our group has previously discovered a unique interaction between tau aggregation and mTOR signaling linked to L-arginine metabolism. In both human Alzheimer’s disease patient samples and tau transgenic mice, we observed dysregulated L-arginine metabolism and uncoupled mTOR signaling proteins associated with tau pathology. G protein coupled receptor family C, group 6 member A
(GPRC6A) was recently deorphanized by basic L-amino acids, especially L-arginine. We posit that GPRC6A mediates extracellular sensing of L-arginine to regulate mTOR complex 1 (mTORC1) signaling. We hypothesize that decreased GPRC6A signaling inhibits mTORC1 activation, thus clearing tau during tauopathies. By utilizing tau overexpressing cell lines and tau transgenic mice, we blocked GPRC6A activity with novel allosteric antagonists and downregulated GPRC6A expression via shRNA constructs. We found that both pharmacological allosteric antagonism and genetic downregulation of GPRC6A inhibited mTORC1 signaling, promoted proteostasis and significantly reduced total tau in tauopathy cells. This is the first study to uncover the mTORC1 signaling mediated by extracellular sensing of L-arginine through GPRC6A. Therapeutics that modulate GPRC6A activity may potentially provide new treatments to clear protein aggregates in tauopathies and other proteinopathies.

Aβ Oligomers Mediate its Synaptotoxic Effects through AMPK-dependent Increase in Mitochondrial Fission in Pyramidal Neurons.
A. Lee¹, C. Kondapalli³, T. Lewis³, G. Mairet-Coello⁵, F. Polleux¹;
¹Neuroscience, Columbia University, New York, NY, ²UCB Biopharma, Brussels, Belgium

Alzheimer’s Disease (AD) is the most common form of dementia leading to socially devastating cognitive defects with currently no effective treatment. Current evidence shows that during the early stages of AD progression, oligomeric, soluble forms of Aβ42 peptide trigger the loss of excitatory synapses (synaptotoxicity) in cortical and hippocampal pyramidal neurons (PNs) even prior to the formation of insoluble Amyloid-β plaques in AD animal models. Previous work from our lab, as well as others, uncovered (1) that Aβ42 oligomers over-activate the stress-response AMP-activated kinase (AMPK) in a CAMKK2-dependent manner and (2) that pharmacological or genetic inhibition of CAMKK2 or AMPK protects hippocampal PNs from Aβ42-mediated loss of excitatory synapses observed in the hAPPswe,IND transgenic AD mouse model (J20) in vivo (Mairet-Coello et al. Neuron 2013). However, the relevant downstream effectors and the cellular processes involved in AMPK-dependent synaptotoxicity are poorly understood. We recently identified that AMPK over-activation by Aβ42 oligomers triggers spatially restricted MFF-dependent mitochondrial fission and ULK2-dependent mitophagy in dendrites, resulting in both reduction of mitochondrial length and density. In the presence of oligomeric Aβ42, knockdown of MFF prevents mitochondrial fission, whereas genetic ablation of ULK2 still allows mitochondrial fission to occur without the subsequent degradation of mitochondria. Most importantly, both of these manipulations can prevent the synaptotoxic effects of Aβ42 oligomers, suggesting that the total volume of dendritic mitochondria plays a critical role in maintaining excitatory synapses. In parallel, we observe that a profound structural remodeling occurs specifically in the apical tufts of dendrites of CA1 PNs, a portion of the dendritic arbor where we also detect dramatic synaptic loss in the J20 AD mouse model. Overall, our project elucidates the cellular and molecular mechanisms mediating the effects of Aβ42 oligomers on mitochondrial defects, synaptic maintenance and their functional impact on hippocampal circuit in AD.

¹CIBQA, Universidad Bernardo O Higgins, Santiago, Chile, ²Neurology, University Texas Health Science Center, Houston, TX

**Introduction:** The blood brain barrier (BBB) is a layer of tightly packed cells that regulates the entry of substances into the brain, while maintaining the removal of toxic molecules. Unfortunately, recent evidence suggests that BBB impairment may precede or even exacerbate Alzheimer’s disease pathology. Even though Aβ-oligomers are believed to play a crucial role in Alzheimer’s until today is not clear whether they are being transported through the BBB or if they cause BBB disruption. Herein, we aim to elucidate the role of Aβ oligomers in BBB breakdown related to Alzheimer’s disease. **Material and methods:** We used an in vitro BBB-model composed of brain endothelial cells and measure the transcytosis of FITC-labeled Aβ-oligomers. Also we used a PAMPA assay to evaluate different Aβ species (Aβ monomers, Aβ-oligomers and fibrils). In addition, we evaluated in vivo BBB integrity in AD-mice by following the brain penetrance of fluorescent-dyes. **Results:** Aβ-oligomers cross an in vitro BBB-model, affecting the levels of tight junctions of brain vascular cells. In transgenic mice of Alzheimer’s disease we observed increased brain penetrance of fluorescent-dyes (FITC-albumin), as well as penetrance of radioactive-labeled oligomers. In the PAMPA assay we observed differential pass of misfolded Aβ species through the membrane. In addition, we observed decreased levels of tight junctions and increased inflammation. **Discussion:** In this work, we demonstrated that Aβ-oligomers affect BBB integrity in vitro and in vivo, decreasing the levels of tight junctions. The effect of Aβ-oligomers and AD-pathology over BBB integrity markers and Aβ receptors is currently under investigation. Funding FONDECYT 11130561.

**Insulin exerts a protective effect against MPP+ induced toxicity in C6 glial cells by regulating the levels of alpha-synuclein and insulin signaling molecules.**

S. Kim¹;
¹Pharmacology and Toxicology, Kyung Hee University School of Dentistry, Seoul, South Korea

Parkinson’s disease (PD) is the second most common neurodegenerative disorder after Alzheimer’s disease (AD) associated with mitochondrial dysfunction mediated by oxidative stress. Astrocytes regulate neuronal function via the modulation of synaptic transmission and plasticity, secretion of growth factors, uptake of neurotransmitters, and regulation of extracellular ion concentrations and metabolic support of neurons. Therefore, this study was undertaken to investigate the mechanism of action of insulin on a 1-methyl-4-phenylpyridinium (MPP+) induced toxicity of events associated in cell viability and toxicity to the expression profile of cell signaling pathway proteins and genes in rat C6 glial cells. The various concentrations of MPP+ alone inhibited cell viability in a dose-dependent manner. Pretreatment of insulin prevented the cell death and lowered the intracellular reactive oxygen species and calcium ion influx by MPP+. Insulin also suppressed the α-synuclein and elevated the insulin signaling pathway molecules IR, IGF-1R, IRS-1 and IRS-2 in C6 cells through phosphorylation of Akt/ERK survival pathways. Moreover, insulin inhibits MPP+-induced Bax to Bcl-2 ratio. These results suggest that insulin has a protective effect on the MPP+-toxicity in C6 glial cells.

Mitochondrial Ubiquitin Ligase Mul1 Mediates an Early Stress Protection of Neuronal Mitochondria From Degradation by Parkin-Mediated Mitophagy.
R. Puri\textsuperscript{1}, J. Yun\textsuperscript{2}, M. Guo\textsuperscript{3}, Z. Sheng\textsuperscript{1};\textsuperscript{1}Synaptic Functions Section, National Institute of Neurological Disorder and Stroke, National Institutes of Health, Bethesda, MD, \textsuperscript{2}The Buck Institute for Research on Aging, Novato, CA, \textsuperscript{3}Department of Neurology, UCLA David Geffen School of Medicine, University of California, Los Angeles, CA

Parkin-mediated mitophagy is an essential process for maintaining neuronal mitochondrial integrity and turnover. Identifying new molecular regulators of mitophagy is key to finding new therapeutic strategies. In this study, we show that loss of MUL1 enhances Parkin-mediated mitophagy in mouse primary cortical neurons exposed to mitophagy-inducing stress. Loss of MUL1 or over-expression of dominant negative mutants of MUL1 induces biphasic change (hyper-fusion followed by fragmentation) in mitochondrial morphology. Mitochondrial fragmentation is associated with the loss of mitochondrial membrane potential, reduced ATP synthesis and translocation of mitophagy markers (Parkin, p62 and LC3) to damaged mitochondria. We further show that removing MUL1 causes an increase in Mitofusin-2 (Mfn-2) protein levels. Over-expression of Mfn-2 but not of Mitofusin-1 (Mfn-1) induces a biphasic change in the mitochondrial morphology similar to the loss of MUL1. Over-expression of loss of function mutant of Mfn-2 (K109A) in MUL1 depleted neurons partially rescues the change in mitochondrial morphology. We find that increase in Mfn-2 levels with loss of MUL1 decreases the mitochondria-endoplasmic (mito-ER) coupling in neurons. In particular, we show Mfn-2 increase weakens the close contact between the two organelles and reduces the efficiency of IP3-induced Ca\textsuperscript{2+} transfer from ER to mitochondria. We further demonstrate that over-expressing a mito-ER tether protein tyrosine phosphatase interacting protein -51 (PTPIP51) that enhances mito-ER interaction partially rescues mitochondrial morphology, mitochondrial Ca\textsuperscript{2+} load and reduces Parkin-mediated mitophagy in MUL1 depleted neurons. Our findings reveal MUL1-Mfn2 pathway acting as a gatekeeper to maintain neuron mitochondrial quality by regulating mito-ER interaction before the activation of Parkin-mediated mitophagy.

Releasing Synaptphilin Removes Stressed Mitochondria from Axons Independent of Mitophagy under Pathophysiological Conditions.
M. Lin\textsuperscript{1}, X. Cheng\textsuperscript{1}, P. Tammineni\textsuperscript{2}, Y. Xie\textsuperscript{1}, B. Zhou\textsuperscript{1}, Q. Cai\textsuperscript{2}, Z. Sheng\textsuperscript{1};\textsuperscript{1}Synaptic Function Section, National Institute of Neurological Disorders and Stroke, NIH, Bethesda, MD, \textsuperscript{2}Department of Cell Biology and Neuroscience, Rutgers, The State University of New Jersey, Piscataway, NJ

Chronic mitochondrial stress and impaired transport are central problems associated with neurodegenerative diseases. Long-term cumulative stress leads to axonal accumulation of damaged mitochondria that not only produce energy less efficiently, but also release harmful reactive oxygen species. Therefore, the early removal of defective mitochondria from axons constitutes a critical step of mitochondrial quality control. Here we investigate axonal mitochondrial response to mild stress in wild-
type neurons and chronic mitochondrial defects in Amyotrophic Lateral Sclerosis (ALS)- and Alzheimer’s disease (AD)-linked neurons. We show that stressed mitochondria are removed from axons triggered by the bulk release of mitochondrial anchoring protein syntaphilin via a new class of mitochondria-derived cargos independent of Parkin, Drp1 and autophagy. Immuno-electron microscopy and super-resolution imaging show the budding of syntaphilin cargos, which then share a ride on late endosomes for transport toward the soma. Releasing syntaphilin is also activated in the early pathological stages of ALS- and AD-linked mutant neurons. Our study provides new mechanistic insights into the maintenance of axonal mitochondrial quality through SNPH-mediated coordination of mitochondrial stress and motility before activation of Parkin-mediated mitophagy. The effects of Shroom2 knockdown on the axonal transport of mitochondria.

B. Pratt¹, G. Cammarata¹, C. Devitt², C. Lee², J.B. Wallingford², L.A. Lowery¹;
¹Biology, Boston College, Chestnut Hill, MA, ²Molecular Biosciences, University of Texas at Austin, Austin, TX

Dynamic distribution of mitochondria in axons is crucial for neuronal function. The mechanisms of axonal transport are complex and highly regulated in order to achieve the optimal distribution. Defects in the axonal transport of mitochondria have been linked with neurodegenerative diseases. Mitochondrial movement along axons is dynamic. Mitochondria display bidirectionality, travelling in both retrograde and anterograde directions. Rates vary and are inconsistent, with mitochondria often stopping, starting, and changing speed and direction. Distinct mechanisms of transport have also been identified, with transport able to be driven by kinesin and dynein motors along microtubules (MTs) as well as by myosin along F-actin. Much remains to be elucidated about the complex mechanisms of the axonal transport of mitochondria. Shroom2 is a member of the Shroom family of proteins, which has been shown to coordinate both MT and F-actin assembly and to interact with myosin. We seek to explore the role that Shroom2 plays in trafficking mitochondria in axons. Here we show that Shroom2 knockdown leads to faster mitochondrial transport speeds in both retrograde and anterograde directions in embryonic Xenopus laevis neurons, with both fast-moving and slow-moving transport rates displaying a significant increase. Mitochondria in both dissociated neurons and neural tube explants displayed this pattern in response to knockdown. In the future, we hope to determine how Shroom2 functions to inhibit mitochondrial trafficking in axons by exploring its interactions with both F-actin and MT cytoskeletons and its link with myosin in axons. The results demonstrate that Shroom2 plays an important role in modulating the essential process of axonal mitochondrial transport.

α-Synuclein is a glycan binding protein, conferred by its N-terminal acetylation.

M. Birol1;

1Chemistry, University of Pennsylvania, Philadelphia, PA

Melissa Birol, Siobhan Toal, and Elizabeth Rhoades

Fibrillar deposits of the protein α-synuclein (αS) are the defining pathological feature of Parkinson’s disease, the second most common neurodegenerative disorder. αS is abundant in the brain, where its localization to presynaptic termini and ability to stabilise curved membranes support a role in synaptic vesicle exocytosis/endocytosis, although its precise role is not known. N-terminal acetylation is universally present on αS in vivo, in samples derived from both healthy persons and Parkinson’s disease patients. Prior work from our group and others have demonstrated that N-terminal acetylation impacts the fundamental biophysical properties of αS. Here, using cell-derived proteolipid vesicles, we find that αSacetyl binds specifically to neuronal-lineage cell membranes. Cleavage of surface proteo-glycans dramatically decreases binding by αSacetyl while having a negligible impact on binding by the unmodified protein, αSunmod. An array-based screen confirms that αSacetyl interacts specifically with complex, N-linked glycans. Monomer αSacetyl selectively binds to glycans cleaved from cultured neuronal cells and removal of cell-surface glycans dramatically reduces its cellular uptake. Based on these findings we propose that N-terminal acetylation confers glycan recognition and binding to αS and that it is a crucial modification for functional interactions with cellular protein binding partners. Moreover, understanding the basis of this interaction may have critical implications in obtaining a clearer understanding in the function of monomeric αSacetyl.

Molecular interaction between 440kDa ankyrin-B and L1CAM: a proposed mechanism for high-functioning autism.

K.K. Walder1, D. Lorenzo2, R. Yang3, D. Wu3, V. Bennett3;

1Cell Biology, Duke University, Durham, NC, 2Cell Biology and Physiology, University of North Carolina Chapel Hill, Chapel Hill, NC, 3Biochemistry, HHMI/ Duke University, Durham, NC

High functioning autism, also referred to as Asperger’s syndrome is characterized by normal or above normal intellectual ability combined with impaired social interactions. Genome-wide exome sequencing has identified de novo mutations in ANK2 associated with autism in the absence of seizures or intellectual impairment. These de novo mutations in ANK2 all result in either haploinsufficiency or mutation of the 440 kDa ankyrin-B polypeptide, which contains a 6.8kb giant exon expressed only in neurons. We have generated a mouse model where the floxed giant exon is conditionally removed by Cre-recombinase expressed under a Nestin promoter. These mice lose over 90 percent of 440 kDa ankyrin-B, but retain 220 kDa ankyrin-B. We report here, using the proximity ligation assay, that adult 440 kDa ankyrin-B-deficient mice exhibit nearly complete loss of ankyrin-B interaction with L1CAM, a cell adhesion molecule which requires ankyrin-binding activity to promote normal axon pathfinding. These results were unanticipated, since 220 kDa ankyrin-B is the predominant ankyrin-B polypeptide in adult brain and 220 kDa ankyrin-B contains a binding site for L1CAM. The L1CAM gene is located on the X chromosome and its mutation in human males results in a severe neurodevelopmental syndrome. Moreover, a Y1229H L1CAM mutation that eliminates ankyrin-binding results in a full L1CAM syndrome in humans as well as axon pathfinding defects in mice. We find that cultured hippocampal neurons from 440 kDa ankyrin-B-deficient mice as well as L1CAM Y1229H mutant mice both exhibit increased axon
branching. Thus, we propose a molecular interaction between 440 kDa ankyrin-B and L1CAM on axonal plasma membranes that is necessary for normal axon function, and is impaired in high functioning autism.

Synaptic vesicle clusters in nerve terminals: an example of liquid-liquid phase separation.
D. Milovanovic1, P. De Camilli1;
1Departments of Neuroscience and Cell Biology, Yale University School of Medicine, New Haven, CT

Neurotransmitter containing synaptic vesicles (SVs) form tight clusters at chemical synapses. These clusters act as a reservoir from which SVs are drawn for exocytosis during strong and prolonged activity. Several components associated with synaptic vesicles and likely form such clusters, including synapsin 1, have been identified. However, it remains unclear how SV clustering is compatible with their motility, so that release sites can be rapidly replenished after vesicle fusion events. Recently, liquid-liquid phase separation was shown to be a mechanism through which components of the cytoplasm (protein and RNA) can assemble themselves into distinct compartments without a limiting membrane. A key feature of proteins that can undergo liquid-liquid phase separation is their ability for engaging in multivalent interactions through protein-protein interacting domains and/or low complexity amino acid regions. We are exploring the possibility that SV clusters may represent an example of liquid-liquid phase separation in which one component of the phase are SVs and the other component is represented by proteins of the intervening matrix, synapsin 1 in particular. Synapsin 1 is highly abundant proteins at the nerve terminals, it binds membranes, and it contains an extended low complexity region: all of these properties make synapsin 1 an ideal candidate for mediating the phase separation.

Bulk degradation of short-lived dendritic membrane proteins requires Rab7 and transport to somatic lysosomes.
C. Yap1, L. Digilio1, L. McMahon1, B. Winckler1;
1Cell Biology, University of Virginia, Charlottesville, VA

Regulation of protein homeostasis (“proteostasis”) is necessary for maintaining healthy cells, and disturbances in proteostasis lead to aggregates, cellular stress and can result in toxicity. There is thus great interest in where proteins are degraded in cells. Neurons are very large as well as very long-lived, creating unusually high needs for effective regulation of protein turnover in time and space. We previously discovered that several dendritic membrane proteins are short-lived and have half-lives of less than two hours. These observations raised the question of whether short-lived dendritic membrane proteins are degraded by local degradative pathways in dendrites. In this work, we analyzed the spatial distribution of early endosomes, late endosomes and degradative lysosomes in neuronal dendrites, using staining against endogenous proteins residing in these compartments, as well as functional markers for acidified and degradative compartments. First, somatic compartments differ in composition from dendritic compartments further away from the soma: whereas most somatic Rab7- and LAMP1-positive compartments are degradative, few of the dendritic Rab7- and LAMP1-containing compartments are. We thus designate these Rab7-positive compartments as “post-early endosome/pre-degradative” endosomes. Secondly, inhibition of Rab7 activity impairs both retrograde transport and subsequent degradation of short-lived dendritic proteins. Rab7 activity is thus required to mobilize these
Rab7-positive dendritic endosomes for transport to the soma where they encounter degradative compartments. We thus discovered a Rab7-positive, LAMP1-positive, cathepsin-negative pre-degradative endosome in more distal portion of dendrites which might not have a clear correlate in fibroblasts.

**Axonal endoplasmic reticulum is very narrow.**  
M. Terasaki¹;  
¹Cell Biology, University of Connecticut Health Center, Farmington, CT

The endoplasmic reticulum (ER) is an interconnected network of tubules and sheets. In most mammalian tissues, ER tubules have a diameter of ~60 nm. Using new methods for serial section electron microscopy, a distinct class of very narrow, 20-30 nm diameter tubules were found in neurons of both the central and peripheral nervous system. The narrow tubules are the most abundant form of ER in axons, and are also found interspersed in the cell bodies and dendrites. At the site of branch points in axons, there is a small sheet which has a similarly narrow lumen. Free ends of narrow tubules are relatively common. The abundance of branch points and free ends was determined as a first step in analyzing how the ER network in axons is maintained at a relatively constant density down the length of the axon.

Incorporation of an excess of curvature inducing proteins such as reticulon into artificial bilayers gives rise to the formation of similarly narrow tubules (Hu et al., 2008), suggesting that the axonal ER narrowness is due to high density of curvature inducing proteins. Knockdown of reticulons in Drosophila results in widened ER tubules in axons (Yalcin et al., 2017). Since mutations in several curvature inducing proteins cause Hereditary Spastic Paraplegia, the narrowness of the ER is likely to be important for the as yet poorly characterised functions of the axonal ER.

**Elucidating the Pathophysiology of Membrin/GOSR2-mediated Progressive Myoclonus Epilepsy from Molecule to Neuron.**  
R. Praschberger¹, S.A. Lowe², N.T. Malintant³, C.N. Giachello³, N. Patel¹, H. Houlden⁴, D.M. Kullmann¹, R.A. Baines³, M.M. Usowicz³, S.S. Krishnakumar³, J.J. Hodge², J.E. Rothman¹, J.E. Jepson¹;  
¹Department of Clinical and Experimental Epilepsy, UCL Institute of Neurology, London, United Kingdom, ²School of Physiology, Pharmacology and Neuroscience, University of Bristol, Bristol, United Kingdom, ³Faculty of Biology, Medicine and Health; Division of Neuroscience Experimental Psychology, University of Manchester, Manchester, United Kingdom, ⁴Department of Molecular Neuroscience, UCL Institute of Neurology, London, United Kingdom, ⁵Department of Cell Biology, Yale School of Medicine, New Haven, CT

Mutations in the Golgi SNARE protein Membrin (encoded by GOSR2) cause progressive myoclonus epilepsy (PME). Patients with this form of PME typically present with ataxia around the age of three, followed by cortical myoclonus and generalized tonic-clonic seizures. However, despite Membrin’s known role in mediating ER to Golgi and intra-Golgi membrane fusion, it is still unclear how Membrin mutations result in a selective neuronal phenotype with the clinical hallmarks of severe ataxia and hyperexcitability.
We are utilising an array of complementary approaches to elucidate the disease mechanism of GOSR2-PME. As components of this strategy, SNARE dysfunction is being experimentally assessed in liposome fusion assays; mutant Membrin localisation and Golgi trafficking investigated in patient fibroblasts; and the impact of the disease mutations upon nervous system development and function studied in a novel in vivo model of GOSR2-PME.

Liposome fusion studies revealed reduced membrane fusion rates due to the pathogenic GOSR2-PME mutations. This finding implies that anterograde cargo transport might be impaired due to the formation of fewer fusogenic cis-Golgi SNARE complexes. The seeming paradox of how a global trafficking defect might eventually cause a selective neurological disorder is being investigated in Drosophila models of this disease - the first in vivo GOSR2-PME models to date. Given the critical importance of Golgi trafficking in dendrite development, we hypothesized that dendritic growth might be impaired. Indeed, we found profoundly shortened dendritic arbors with a total length reduction of up to two thirds in normally highly elaborate larval sensory neurons. This finding may explain one key feature of this disorder – ataxia – since cerebellar Purkinje cells with their highly elaborate dendritic trees would likely be most profoundly affected by such a dendritic growth deficit. In addition, we found that motoneuron synapses in our disease models exhibit gross morphological abnormalities and synaptic retraction, combined with hyperactivity.

From our experiments a mechanistic framework emerges which understands GOSR2-PME as a neurodevelopmental disorder with dendritic arborisation defects and morphologically abnormal, hyperactive excitatory synapses. Together, these multifaceted defects may simultaneously cause ataxia and shift circuit excitation-inhibition balance towards hyperexcitation. Besides having provided a multi-level insight into GOSR2-PME’s pathophysiology, this study reiterates the importance of the early secretory pathway in dendritic development and suggests a critical role of the Golgi apparatus in presynaptic development and function.

**A microtubule-associated septin maintains neuronal polarity by directing motor-cargo traffic in dendrites.**

E.P. Karasmanis¹, C. Phan¹, D. Angelis¹, I. Kesisova¹, C.C. Hoogenraad², R.J. McKenney³, E.T. Spiliotis¹; ¹Biology, Drexel University, Philadelphia, PA, ²Cell Biology, Utrecht University, Utrecht, Netherlands, ³Molecular and Cellular Biology, University of California Davis, Davis, CA

Neuronal function requires axon-dendritic membrane polarity, which depends on sorting of membrane traffic during entry into axons. Dendrites receive vesicles from the axon and cell body without apparent capacity for directional sorting due to a microtubule network of mixed polarity. Here, we found that a microtubule-associated septin (SEPT9), which localizes specifically in dendrites, impedes and reverses the entry of axonally-directed cargo of the microtubule motor kinesin-1/KIF5 such as the amyloid precursor protein (APP) and Bassoon. In contrast, SEPT9 promotes anterograde transport of kinesin-3/KIF1 cargo (e.g., low density lipoprotein receptor; postsynaptic density protein 95) from proximal to distal dendrites. In live neurons and single molecule cell-free motility assays, microtubule-associated SEPT9 suppresses kinesin-1/KIF5 motility and enhances kinesin-3/KIF1 specifically, regulating the trafficking and localization of their cargo to axons-dendrites. We show that this traffic control is critical for the growth of axons and dendrites in developing neurons. Thus, membrane traffic is spatially sorted and directed in dendrites by a septin-mediated mechanism, which maintains neuronal polarity and growth.

Determining the localization and function of schizophrenia-linked protein tSNARE1b in the endolysosomal system of developing neurons.

M. Plooster¹, G. Rossi², M.S. Farrell³, P.F. Sullivan⁴, S.L. Gupton⁵,⁶, P. Brennwald²;
¹Cell Biology and Physiology Curriculum, University of North Carolina, Chapel Hill, NC, ²Department of Cell Biology and Physiology, University of North Carolina, Chapel Hill, NC, ³Department of Genetics, University of North Carolina, Chapel Hill, NC, ⁴Department of Psychiatry, University of North Carolina, Chapel Hill, NC, ⁵Neuroscience Center, University of North Carolina, Chapel Hill, NC, ⁶Lineberger Comprehensive Cancer Center, University of North Carolina, Chapel Hill, NC

Schizophrenia is a severe neuropsychiatric disorder characterized by delusions and hallucinations, which lacks effective, targeted therapies, likely due in part to its polygenic etiology. Recently, the largest genome wide association study on schizophrenia to date identified 108 loci associated with the occurrence of schizophrenia. The fifth most significant hit mapped to a locus containing the gene TSNARE1, which encodes the previously unstudied protein t-SNARE domain containing 1 (tSNARE1). tSNARE1 contains a N-terminal c-Myb DNA binding domain and a C-terminal Qa SNARE domain that shares closest homology to Syntaxin 12 (Stx12), an endosomal SNARE protein. Rare variant mutations identified from patients with either schizophrenia or autism spectrum disorder suggest that the SNARE domain is critical to tSNARE1 function. Unlike canonical Qa SNARE proteins, the primary neuronal isoform of tSNARE1, tSNARE1b, lacks a transmembrane domain as well as any other predicted site for membrane attachment, which is thought to be necessary for membrane fusion. Therefore, our central hypothesis is that tSNARE1b acts as an inhibitory SNARE (i-SNARE) of specific membrane trafficking events. This hypothesis is supported by biochemical pull-down assays with recombinant proteins and embryonic brain lysates, which demonstrate that GST-tSNARE1 can replace Stx12 and assemble with the endosomal SNARE proteins Vti1a, Stx6, and VAMP4 into SNARE complexes. Because tSNARE1 shares its closest homology with Stx12, we hypothesized that tSNARE1 functions within the endosomal pathway. High resolution, live-cell confocal microscopy of tSNARE1b-GFP and a battery of spectrally distinct organelle markers in embryonic murine cortical neurons determined to which endocytic compartments tSNARE1b localizes. Colocalization of tSNARE1b and each marker was quantified using a semi-automated, quantitative image-analysis pipeline that robustly identifies colocalization based on two different measurements. Preliminary evidence suggests that tSNARE1 colocalizes the strongest with late endosome marker Rab7 and lysosome marker LAMP1, suggesting tSNARE1b may regulate trafficking between these organelles. Ongoing studies are exploring how tSNARE1b functions at the membrane trafficking between late endosomes, lysosomes, and autophagosomes with three-color, live-cell imaging.

Dynamic Spatiotemporal Organization of Exocytosis During Neuronal Morphogenesis.

F.L. Urbina¹, S.L. Gupton¹, S. Gomez²;
¹Cell Biology and Physiology, University of North Carolina: Chapel Hill, Chapel Hill, NC, ²Biomedical Engineering, University of North Carolina: Chapel Hill, Chapel Hill, NC

During development, neurons acquire a unique, highly polarized morphology, which establishes a high surface-to-volume ratio of plasma membrane-to-cytoplasm. Developing this elongated morphology requires significant plasma membrane expansion, primarily considered to occur via exocytic vesicle
fusion. We hypothesized that the location and timing of exocytosis in the developing neuron are both spatially and temporally non-random and that developing neurons and non-neuronal motile cells at steady state size exhibit distinct spatiotemporal organization and distribution of exocytosis. A pH-sensitive variant of GFP (pHluorin) fused to the luminal end of a vesicle-SNARE protein, such as VAMP2, provides a fluorescent intensity readout of fusion pore opening and the subsequent fate of VAMP2. Here, we exploited TIRF microscopy to image VAMP-pHluorin in embryonic cortical neurons and interphase melanoma cells, and developed computer-vision based software and statistical tools to detect and analyze exocytic events. We reveal distinct spatiotemporal distribution and organization of exocytosis in the soma and neurites that is modulated by both the developmental stage of the neuron as well as exposure to the extracellular guidance cue netrin-1. The netrin-1 dependent changes in exocytic frequency and organization in neurites are dependent on the brain-enriched E3 ubiquitin ligase, TRIM9, whereas netrin-dependent changes to exocytosis in the soma occur independently of TRIM9. Mathematical modeling of empirical data indicated that VAMP2-mediated vesicle fusion supplied excess material needed for developmental plasma membrane expansion. TIRF imaging of clathrin-light chain and additional modeling suggests that this excess delivery of membrane was balanced by clathrin-mediated endocytosis. In melanoma cells, exocytosis occurred less frequently, with distinct spatial clustering, specific to the vesicle type. This study reveals system-wide insights into spatiotemporal aspects of exocytosis in neurons that differ substantially from non-neuronal cells.

The Retromer Complex Regulates Presynaptic and Exosomal APP Trafficking at the Drosophila NMJ.
R.B. Walsh¹, M.J. Zunitch¹, A.N. Becalska¹, K. Narayanan¹, A.A. Rodal¹;
¹Biology, Brandeis University, Waltham, MA

In neurons, endosomal cargo sorting both intracellularly and between cells via endosomally-derived secreted exosomes, is necessary for growth, development, and survival, and defective cargo sorting is associated with devastating neurodegenerative diseases, including Alzheimer’s Disease (AD) and Parkinson’s Disease (PD). However, much remains unknown about the factors influencing how protein cargoes are transported and sorted within and between neurons and their associated cells. The Retromer is a membrane-associated heteromeric protein complex that is critical for endosomal cargo sorting, and loss of its activities has been heavily implicated as a cause of both AD and PD. Here, we identify Retromer as a key regulator of APP trafficking at the Drosophila neuromuscular junction (NMJ). Surprisingly, we found that APP traffic is heavily directed to exosomes in the postsynaptic muscle. Retromer loss causes an accumulation of APP presynaptically as well as in exosomes. Both retention of APP in endosomes as well as propagation of APP and its cleavage products between neurons via exosomes have been implicated in AD pathology, suggesting that these may be points where Retromer defects contribute to disease. We also show that Retromer’s effect on presynaptic protein accumulation and incorporation of cargo into exosomes extrapolates to other cargoes as well, including Synaptotagmin-4 and the antigen recognized by anti-HRP antibodies, indicating a general function for Retromer in regulating presynaptic trafficking and suggesting a novel role in regulating neuronal exosomes. Further, we demonstrate that a loss-of-function PD-causing point mutant in the Vps35 subunit of Retromer disrupts endosomal and exosomal APP trafficking, suggesting that the role of Retromer in endosomal and exosomal cargo traffic is important in PD as well as AD. Finally, we use tissue-specific manipulations of Retromer to demonstrate that Retromer’s pre- and postsynaptic cargo regulatory functions appear to be at least partially non-neuron-autonomous; depleting Retromer in the
muscle alone is sufficient to cause pre and postsynaptic accumulation of neuron-derived HRP. Taken together, our data implicate Retromer as a key regulator of both neuronal and exosomal APP, and suggests that Retromer may act in multiple tissue types to orchestrate neuronal cargo sorting.

Disruption of the epileptic encephalopathy gene DENND5A causes Golgi fragmentation and apoptotic cell death via altered TrkB signaling.

C. Han\(^1\), M. Fotouhi\(^1\), P.S. McPherson\(^1\);

\(^1\)Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, QC

Epileptic encephalopathies are a catastrophic group of epilepsies characterized by refractory seizures and cognitive arrest. We recently demonstrated that recessive loss-of-function mutations in DENND5A result in an epileptic encephalopathy characterized by massive alterations in neuronal development and survival. We now demonstrate that loss of DENND5A function leads to upregulation of the neurotrophin receptor TrkB, which becomes concentrated in the Golgi where it undergoes abnormal signaling leading to Golgi fragmentation and apoptotic cell death. DENND5A contains a DENN domain, an enzymatic module conferring guanine-nucleotide exchange factor (GEF) activity to multiple proteins serving as GEFs for Rabs. Interestingly, we find that DENND5A functions to activate Arf4, a member of a distinct class of small GTPases involved in membrane trafficking in the endosomal and secretory pathways. Alterations in TrkB signaling, Golgi fragmentation and neuronal development caused by DENND5A loss-of-function are phenocopied by Arf4 knockdown. Thus, we identify a novel link between an Arf GTPase, neurotrophin function and neuronal development, dysfunction of which is responsible for a new subform of epileptic encephalopathy.

Chondroitin Sulfate Proteoglycans Negatively Regulate the Positioning of Mitochondria and Endoplasmic Reticulum to Distal Axons.

R. Sainath\(^1\), L. Armijo Weingart\(^1\), A. Ketschek\(^1\), Z. Xu\(^1\), S. Li\(^1\), G. Gallo\(^1\);

\(^1\)Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA

Chondroitin sulfate proteoglycans (CSPGs) are components of the extracellular matrix that inhibit the extension and regeneration of axons. However, the underlying mechanism of action remains poorly understood. Mitochondria and endoplasmic reticulum (ER) are functionally inter-linked organelles important to axon development and maintenance. We report that CSPGs impair the targeting of mitochondria and ER to the growth cones of chicken embryonic sensory axons. The effect of CSPGs on the targeting of mitochondria is blocked by inhibition of the LAR receptor for CSPGs. The regulation of the targeting of mitochondria and ER to the growth cone by CSPGs is due to attenuation of PI3K signaling, which is known to be downstream of LAR receptor activation. Dynactin is a required component of the dynein motor complex that drives the normally occurring retrograde evacuation of mitochondria from growth cones. CSPGs elevate the levels of p150-Glued dynactin found in distal axons and inhibition of the interaction of dynactin with dynein increased axon lengths on CSPGs. CSPGs also decreased the membrane potential of mitochondria and inhibition of mitochondria respiration at the growth cone impaired axon extension. Combined inhibition of dynactin and potentiation of mitochondria respiration further increased axon lengths. These data reveal that the regulation of the
localization of mitochondria and ER to growth cones is a previously unappreciated aspect of the effects of CSPGs on embryonic axons.

KIF2A Regulates the Development of Dentate Granule Cells and Postnatal Hippocampal Wiring. N. Homma1,2, R. Zhou2, M.I. Naseer1, A.G. Chaudhary3, M.H. Al-Qahtani3, N. Hirokawa2; 1Life Science, National College of Nursing, Tokyo, Japan, 2Cell Biology and Anatomy, Graduate School of Medicine, Tokyo, Japan, 3Center of Excellence in Genomic Medicine Research, King Abdulaziz University, Jeddah, Saudi Arabia

Kinesin super family protein 2A (KIF2A), an ATP-dependent microtubule (MT) destabilizer, regulates cell migration, axon elongation, and pruning in the developing nervous system. KIF2A mutations have recently been identified in patients with malformed cortical development. However, postnatal KIF2A is continuously expressed in restricted brain regions, such as the hippocampus and the olfactory bulb, in which new neurons are generated throughout an individual’s life in established neuronal circuits. In this study, we investigated KIF2A function in the postnatal hippocampus by using tamoxifen-inducible conditional knockout (cKO) mice. Despite showing no significant defects in neuronal proliferation or migration, 3w-Kif2a-cKO mice showed signs of an epileptic hippocampus. In addition to mossy fiber sprouting, the 3w-Kif2a-cKO dentate granule cells (DGCs) developed many aberrant overextended dendrites, which eventually had axonal properties. These results suggested that postnatal KIF2A is a key length regulator of the developing neurites of DGCs and is involved in establishing postnatal hippocampal wiring.

ER-shaping proteins form functionally distinct microdomains in the ER membrane of neurons. J. Nixon-Abell1,2, C.J. Obara2, J. Lippincott-Schwartz2, C. Blackstone1; 1NINDS, National Institutes of Health, Bethesda, MD, 2Janelia Research Campus, Ashburn, VA

The endoplasmic reticulum (ER) is a complex membranous structure present in all eukaryotic cells, stretching from the nuclear envelope to the plasma membrane. This remarkably versatile network plays crucial roles in numerous cellular functions while simultaneously orchestrating interactions with, and between, almost every other subcellular organelle. The regulation of ER structure and function appears to be of particular importance in neuronal tissue, as almost all neurodegenerative pathways converge on ER-associated processes. The complex structural arrangement of the ER is thought to be governed, in part, by a subset of ER-shaping proteins (ERSPs). Mutations in genes encoding many of these proteins result in abnormal ER morphologies and underlie various neurodegenerative disorders. While many of these proteins are conserved throughout eukaryotes and ubiquitously expressed across tissue types, disease phenotypes are primarily restricted to neurons. For this reason, ERSPs provide a compelling model to better understand the role ER structure plays in influencing neuronal function in health and pathogenesis.

We employed a variety of superresolution imaging techniques in conjunction with gene editing technology to study the localization and function(s) of ERSPs at endogenous levels in human iPSC-derived neurons. A single iPSC line was CRISPR-edited to target multiple representative ERSPs with small-epitope tags. Multiplexed single molecule localization microscopy (SMLM) subsequently demonstrated the existence of ERSP microdomains that correlate not only with specific structural
components of the ER, but also coincide with distinct biological processes. We suspect that these
signature microdomain localizations are disturbed in the presence of pathogenic ERSP mutations which
in turn leads to the disruption of ER-affiliated cellular processes and consequential pathogenesis. This is
a particularly appealing model as it might help to explain why such a wide range of cellular phenotypes
are observed in many neurodegenerative diseases. Studying the differentiation cascade from iPSC
through to motor neuron, we further describe a morphogenic role of ERSPs in contributing towards the
ability of a cell to generate neuronal morphology. Using a combination of correlative RNA-seq,
quantitative proteomics, and SMLM we show which ERSP-containing microdomains are important for
the differentiation process at different stages.
Here we provide the first evidence that ERSPs, at endogenous levels, exist in microdomains throughout
the ER membrane and correlate with specific biological processes. Further, our data suggests that ERSP
microdomains play a crucial role in supporting the growth, development and function of neurons.

Roles for VPS13 Family Members in the Drosophila Nervous System.
D. Lozano1, R. Insolera1, C.A. Collins1;
1 Molecular, Cellular Developmental Biology, University of Michigan, Ann Arbor, MI

Mutations in the human vacuolar protein sorting 13 (VPS13) gene family, VPS13 A-D, have been shown
to contribute to a range of neurological disorders. These include Parkinson’s disease (VPS13C), Chorea-
Acanthocytosis (VPS13A), Cohen’s Syndrome (VPS13B) and, recently ataxia (VPS13D). The cellular
function of these family members in the nervous system is largely unknown. Also unknown is whether
the different family members have distinct cellular functions that account for the diverse disease
phenotypes in humans. To characterize and compare the cellular function of VPS13 family members, we
are using Drosophila melanogaster as a model organism. This study focuses upon VPS13A (known as
dVPS13 in Drosophila) and VPS13D (dVPS13), and has two aims: 1) compare neuronal phenotypes in
mutant lines for the dVPS13 and dVPS13D, and 2) determine whether the VPS13A and D orthologues
can functionally substitute for each other in rescue experiments. Deletion of dVPS13 leads to a
shortened lifespan, and build-up of poly-ubiquitin containing aggregates in the brain. In contrast,
mutations in dVPS13D cause lethality in early larval stages. In preliminary studies we have noticed poly-
ubiquitin aggregates accumulate more severely dVPS13D mutants. We have also discovered severe
defects in the morphology of mitochondria in the brain for both dVPS13 and dVPS13D, however these
defects appear localized to glia for dVPS13, in contrast to both neurons and glia for dVPS13D. Our
ongoing studies will determine whether human VPS13A can rescue any of these defects when driven in
different cell types using the Gal4/UAS system, and will provide further characterization of the
mitochondrial defects. Ultimately this work may illuminate cellular functions for the VPS13 family
members and give insight into mechanisms of disease pathology.

Investigating mechanisms of STRIPAK complex regulation in neuronal transport.
A.L. Neisch1, T.S. Hays1;
1Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN

The maintenance of neural circuits is essential for cognitive function and motor system coordination. At
the cellular level, neurons are polarized, elongated cells that need to transport signals and cargoes
across vast distances. At the molecular level these cargoes and signals are transported along the microtubule cytoskeleton by molecular motor proteins. Impairment of this intracellular transport in neurons contributes to compromised synaptic and dendritic functions, which can lead to neuronal cell death, a hallmark of neurodegenerative disorders. To better understand the mechanisms that regulate motor protein function we carried out an RNAi screen in Drosophila motoneurons focusing on the transport of the retrograde specific cargo, autophagosomes. From this screen we identified the STRIPAK complex as a regulator of autophagosome and dense core vesicle transport (Neisch et al., 2017). The STRIPAK complex is a highly conserved multi-protein complex that contains kinases, the phosphatase PP2A, and other proteins. We have demonstrated that the core STRIPAK components Cka, Mob4 and Strip are required for transport regulations, as is PP2A activity within the complex. Our model suggests that the balance between PP2A and kinase activities regulate transport. Currently we are investigating the mechanism of kinase association within the complex. In mammalian culture cells, the association of kinase within the Striatin homolog of CKA is proposed to be modulated by calcium signaling (Gordon et al., 2011). We are conducting molecular genetic experiments in Drosophila to address the role of calcium signaling in regulation of vesicle transport in neurons in vivo. Moreover, targeted mutagenesis and in vivo motility assays will test the importance of phospho-binding by Mob4, a member of a family of proteins known to function as adaptors in the recruitment of protein kinases (Couzens et al., 2017).

Ubiquitin-dependent regulation of filopodia during axon guidance and branching.
N. Boyer¹, C. Monkiewicz², S. Menon³, S.L. Gupton¹,²,³;
¹Neurobiology Curriculum, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC, ²Cell Biology and Physiology, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC, ³Neuroscience Center, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC

During development, neurons extend axons across long distances to find postsynaptic partners and create neuronal networks. Upon reaching target regions, axons branch to increase network complexity. At the distal end of an extending axon, a dynamic filopodia-rich growth cone senses extracellular guidance cues and facilitates directional extension and branching of the axon. This requires tight spatial and temporal modulation of the F-actin cytoskeleton, which is reorganized rapidly in response to extracellular guidance cues. We found that lower concentrations of the extracellular guidance cue netrin-1 increases growth cone filopodial stability and density and induces attractive axon turning and axon branching, whereas higher netrin concentrations collapse and repulse the growth cone. The mechanisms by which netrin and its receptor DCC alter cytoskeletal machinery in these distinct responses however have not been fully elucidated. Here we show that TRIM67, a brain-enriched member of the tripartite motif family of E3 ubiquitin ligases, interacts with DCC and is required for both attractive and repulsive responses to netrin. Using murine embryonic cortical neurons, we find that growth cones of Trim67⁻/⁻ axons fail to increase in size or number of filopodia in response to a low concentration of netrin, and fail to collapse in response to a high concentration of netrin. However, Trim67⁻/⁻ axons respond appropriately to other guidance cues. We find that TRIM67 regulates filopodia stability and localizes to the tips of filopodia, where it colocalizes and cotransports with the barbed end actin polymerase VASP. We show that TRIM67 and VASP interact and that TRIM67 is required to increase the dynamics of VASP at filopodial tips in response to netrin-1. We previously found that a
closely related E3 ligase TRIM9 reduces VASP dynamics and filopodial stability via ubiquitination of VASP. Surprisingly TRIM67 negatively regulates this VASP ubiquitination, potentially via ubiquitination of TRIM9. Together with investigations of Trim9<sup>−/−</sup>:Trim67<sup>−/−</sup> neurons, our results suggest that TRIM67 and TRIM9 coordinate to promote cytoskeletal reorganization in response to netrin-1 downstream of DCC. This regulation is likely critical to appropriate neuronal morphogenesis: Netrin-dependent axon branching and axon turning is absent in Trim67<sup>−/−</sup> neurons in vitro, and the netrin-dependent cortical corpus callosum projection is thinner in Trim67<sup>−/−</sup> mice in vivo.

A requirement for Mena, an actin regulator, in local mRNA translation in developing neurons.
M. Vidaki<sup>1</sup>, F.B. Gertler<sup>1</sup>;
<sup>1</sup>Koch Institute for Integrative Cancer Research, Massachusetts Institute of Technology, Cambridge, MA

During development, the exquisitely regulated process of axon guidance establishes the circuitry necessary for a properly functioning nervous system (NS) in the adult. Aberrant axonal navigation results in defective connectivity and multiple neurodevelopmental disorders including, among others, epilepsy, intellectual disabilities, autism and schizophrenia. One key mechanism required for proper axon growth, guidance and maintenance is local mRNA translation. Although local protein synthesis has been extensively studied in synapse formation and plasticity, its regulation during axon development remains poorly understood. Here, we uncover a novel role for the actin-regulatory protein Mena in the formation of a ribonucleoprotein complex (RNP) that involves translational inhibitors (HnrnpK, PCBP1), and regulates local translation of specific mRNAs in developing axons. We find that translation of dyrk1a, a Down Syndrome- and Autism Spectrum Disorders- related gene, is dependent on Mena, both in steady state conditions as well as upon BDNF stimulation. In particular, after BDNF stimulation we find that the Mena-RNP dissociates, releasing the mRNA of dyrk1a for translation in the axon/growth cone. We identify hundreds of additional mRNAs that associate with the Mena-complex, suggesting it plays broader role(s) in post-transcriptional gene regulation. Interestingly, this function is Mena-specific, as we could not detect any of the other Enah/VASP family members (VASP and EVL) being associated with mRNAs in the brain. Our work establishes a dual role for Mena in neurons, raising the intriguing possibility that it could act as a regulatory node that coordinates and balances actin polymerization and local protein synthesis in response to specific cues during neuronal development and, potentially, in adult neuroplasticity.

Novel functions of LIM and SH3 domain proteins in regulating dendritic development and synapse formation.
K.R. Myers<sup>1</sup>, J.Q. Zheng<sup>1</sup>;
<sup>1</sup>Cell Biology, Emory University, Atlanta, GA

In the central nervous system, each neuron elaborates a dendritic arbor of varying complexity that receives and integrates thousands of synaptic inputs. The development of dendritic arbors and their postsynaptic spines depend on the actin cytoskeleton and its dynamic remodeling. However, our understanding of the mechanisms underlying actin remodeling and its regulation by synaptic activity remains limited. Here, we report that the F-actin binding LIM and SH3 domain proteins, LASP1 and LASP2, exert distinct functions on dendritic development and synapse formation. LASP proteins have
previously been shown to play a role in cell migration and tumor metastasis, but very little is known about their function in the nervous system. Here, we show that both LASP proteins are present in the dendritic compartment of cultured hippocampal neurons and, importantly, highly enriched in dendritic spines. Furthermore, we have identified the molecular domains of LASP proteins responsible for their subcellular localization in spines. Moreover, we have obtained evidence that LASP proteins exhibit isoform-specific effects on dendritic arbor, dendritic spine, and synaptic development. Down regulation of LASP proteins causes defects in dendritic arbor and dendritic spine motility and stabilization. These findings demonstrate a previously unknown role for LASP proteins in neuronal development, and suggest a function in actin-based modifications of synaptic structure and function.

Arginyltransferase ATE1 is targeted to the neuronal growth cones and regulates neurite outgrowth during brain development.
J. Wang\(^1\), I. Pavlyk\(^1\), P. Vedula\(^1\), S. Sterling\(^1\), N.A. Leu\(^1\), D.W. Dong\(^1\), A.S. Kashina\(^1\);
\(^1\)Biomedical Sciences, University of Pennsylvania, Philadelphia, PA

Arginylation is an emerging protein modification mediated by arginyltransferase ATE1, shown to regulate embryogenesis and actin cytoskeleton, however its functions in different physiological systems are not well understood. Here we analyzed the role of ATE1 in brain development and neuronal growth by producing a conditional mouse knockout with Ate1 deletion in the nervous system driven by Nestin promoter (Nes-Ate1 mice). These mice were weaker than wild type, resulting in low postnatal survival rates, and had abnormalities in the brain that suggested defects in neuronal migration. Cultured Ate1 knockout neurons showed a reduction in the neurite outgrowth and the levels of doublecortin and F-actin in the growth cones. In wild type, ATE1 prominently localized to the growth cones, in addition to the cell bodies. Examination of the Ate1 mRNA sequence reveals the existence of putative zipcode-binding sequences involved in mRNA targeting to the cell periphery and local translation at the growth cones. Fluorescence in situ hybridization showed that Ate1 mRNA localized to the tips of the growth cones, likely due to zipcode-mediated targeting, and this localization coincided with spots of localization of arginylated β-actin, which disappeared in the presence of protein synthesis inhibitors. We propose that zipcode-mediated co-targeting of Ate1 and β-actin mRNA leads to localized co-translational arginylation of β-actin that drives the growth cone migration and neurite outgrowth.

\(^1\)BMB, The Pennsylvania State University, University Park, PA

Mature neurons contain non-centrosomal microtubule arrays with different arrangements of microtubules in axons and dendrites. In Drosophila dendrites microtubule nucleation sites are concentrated at dendrite branch points, and local nucleation contributes to minus-end-out microtubule polarity. Golgi outposts have been suggested to house nucleation sites (Ori-Mckenney, Jan and Jan, Neuron 2012), however, we found that removal of the Golgi from dendrites did not reduce targeting of gamma-tubulin, the core microtubule nucleator, to dendrite branch points (Nguyen et al, MBoC 2014).
To generate an alternative hypothesis about what might localize nucleation sites to branch points, we started with the clue that another microtubule regulator, Apc2, is also concentrated at dendrite branch points. Apc2 recruits Apc so it can link the plus-tip protein EB1 to kinesin-2 and steer growing microtubules along stable ones at branch points. As Apc2 is a scaffolding protein with many known interaction partners, we performed a candidate screen to identify proteins required to position Apc2-GFP. We found that mitochondrial energy production, ankyrin2 and its membrane partner neuroglian, branched actin, heterotrimeric G proteins and axin were all required for Apc2 targeting. We next tested whether any of these proteins were also required to localized gamma-tubulin to branch points. Surprisingly we found that the membrane proteins frizzled and frizzled2 act with the heterotrimeric G protein GalphaO to localize axin to branch points, and in turn axin is required to localized gamma-tubulin. Thus a modified wnt signaling pathway is an essential regulator of gamma-tubulin localization in dendrites. To determine the functional consequences of these wnt pathway members on microtubule organization in dendrites, we performed two additional assays. First, we assayed microtubule polarity and found that these pathway members are required to maintain minus-end-out polarity. Second, we assayed the increase in microtubule nucleation triggered by axon severing, and again found that frizzleds, G proteins and axin were required for this response. Thus this alternate wnt signaling pathway acts as a master regulator to localize both Apc2 and gamma-tubulin, and is required to control local microtubule nucleation in dendrites.

Patterns of microtubule organization and dynamics determine neuronal cargo distribution.

S. Yogev\(^1\), C. Maeder\(^2,3\), R. Cooper\(^4\), K. Shen\(^2,3\);

\(^1\)Neuroscience, Yale University, New Haven, CT, \(^2\)Biology, Stanford University, Stanford, CA, \(^3\)HHMI, Stanford, United States, \(^4\)Electrical Engineering, Stanford university, Stanford, CA

Microtubules (MTs) are the main cytoskeletal substrate on which axonal transport progresses. How the architecture and dynamics of the MT network are set up and how they affect the overlying transport of neuronal cargo is poorly understood. Conversely, molecular motors can also regulate MT behaviour, but the in vivo role for such modulation is not clear. We developed a rapid, fluorescence-based method for analyzing neuronal MT length, abundance and dynamics in C.elegans, and used it to explore how neuronal MTs are patterned, and how these patterns affect cargo transport. We identified roles for conserved MAPs and signalling pathways in determining microtubule length, spacing and abundance. In turn, these parameters impinge on axonal transport progression: cargo pauses at polymer termini, suggestive that switching MT tracks is rate limiting for efficient transport. Cargo run length is set by MT length, and higher MT coverage correlates with shorter pauses. We also detected a surprising role for dynein heavy chain (DHC-1) in maintaining the correct distribution and dynamics of MT polymers in the dendrite. In dhc-1 mutants, MTs shifted distally and displayed excessive growth and shrinkage, which hampered cargo transport, trapping mitochondria and synaptic vesicle precursors and depleting them from their endogenous locations. Live imaging, mutant analysis and single molecule in-vitro assays suggest a model where an anchored dynein pool at the tip of the dendrite interacts with plus-end-out MTs to stabilize them and allow efficient retrograde transport. Collectively, these results uncover the principles and mechanisms that pattern neuronal MTs to promote efficient cargo transport.

Molecular Pathogenesis of Tubulin Disorders During Neural Development.
J.E. Aiken1,2, J.K. Moore1; E.A. Bates2;  
1Department of Cell and Developmental Biology, University of Colorado Anschutz Medical Campus, Aurora, CO; 2Department of Pediatrics, University of Colorado Anschutz Medical Campus, Aurora, CO

‘Tubulopathies’ are severe human brain malformations associated with missense mutations in the tubulin genes. Despite the identification of many tubulin mutations in patients, we do not understand how these mutations impact the microtubule cytoskeleton, how the changes to microtubule function lead to brain malformations, or how different tubulin isotypes regulate microtubules to support normal neurodevelopment. TUBA1A α-tubulin is the most commonly affected tubulin isotype, with mutations linked to diverse cortical malformations including microlissencephaly, lissencephaly, pachygyria, and polymicrogyria. We hypothesize that TUBA1A α-tubulin uniquely contributes to neuronal maturation, and distinct TUBA1A mutations may disrupt specific microtubule functions during development. Therefore, tubulopathy mutations may provide a unique window into the role of microtubules, and specifically TUBA1A, in young neurons. Here we focus on mutations affecting the conserved arginine at position 402 (R402), which is a hotspot accounting for 30% of all reported TUBA1A mutations in patients. Using yeast mutants to mimic R402C and R402H substitutions found in patients, we show that the mutant α-tubulins incorporate into microtubules but cause a dominant disruption of the microtubule motor dynein that scales with abundance of mutant α-tubulin in the cell. In addition, our preliminary experiments in cortical neurons suggest that ectopic expression of R402C/H TUBA1A mutants is sufficient to disrupt microtubule function in a manner consistent with dynein impairment. Together, our results indicate that tubulopathy mutations at R402 poison the microtubule network in young neurons by creating defective binding sites for dynein at the microtubule surface.

Tau is not a stabilizer of microtubules in the axon but rather enables axonal microtubules to have labile domains of substantial length.
L. Qiang1; X. Sun1; T.O. Austin1, H. Muralidharan1, W. Yu1, D.C. Jean1, P.W. Baas1; 1Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Hundreds of research papers claim that the main function of tau in the axon is to stabilize its microtubules (MTs). This claim is mainly based on findings that tau can stabilize MTs in the test tube, and that tau overexpression in cells leads to increased MT stabilization. Many researchers are so invested in the idea of tau as a MT stabilizer that they are seeking to use MT-stabilizing drugs to treat neurodegenerative diseases in which tau loses its association with MTs. However, there are reasons to be skeptical. Individual MTs in the axon consist of a stable domain and a labile domain toward the minus and plus end of the MT, respectively. On average, roughly half the microtubule mass in the axon is labile, which means that labile domains can achieve substantial lengths without being stabilized. MT stability becomes more complex in adult axons compared to developing axons, but the importance of the labile domains persists throughout life. If tau were responsible for stabilizing the stable domains, there should be relatively less MT-bound tau in the distal region of the axon (where labile domains are enriched) compared to the rest of the axon, but the opposite is true. Here we used siRNA to deplete tau from cultured fetal rat cortical neurons, and found that, over a period of four days, the MT mass in the axon diminishes by roughly 20%. In tau-depleted axons, roughly 85% of the MT mass is stable and only 15% is
labile, indicating that, not only is the lost MT mass labile, but a portion of the remaining MT mass that was labile becomes stable. Functional consequences are indicated by defects in growth cone turning, which requires labile MTs extending into the distal axon. We found that MAP6 (also called stable tubule only peptide), which is normally enriched on the stable domains of MTs, redistributes along the length of the MT after tau depletion, providing an explanation for why a higher portion of the MT mass is stable after tau depletion. When MAP6 is depleted from neurons, the portion of the MT mass that is stable drops to less than 30%, indicating that MAP6 is a genuine stabilizer of MTs in the axon. MT-bound tau becomes more evenly distributed after MAP6 depletion, further indicating that the two proteins have complementary distributions. We conclude that tau is enriched on labile domains of MTs to limit the binding to them of MAP6, thus enabling the labile domains to obtain great lengths without being stabilized by MAP6. We speculate that the process of microtubule stabilization, specifically the conversion of labile domains into stable domains, involves a switch in the proportions of tau and MAP6 bound to the MT. (LQ, XS and TOA are co-first authors. TOA is supported by an NSF GRFP. The work was funded by NIH and DOD grants to PWB and LQ.)

**Novel concepts of microtubule regulation during neuronal growth, maintenance and degeneration.**

I. Hahn¹, Y. Qu¹, A. Voelzmann¹, J. Parkin¹, M. Lees¹, A. Prokop¹;
¹Faculty of Biology, Medicine and Health, University of Manchester, Manchester, United Kingdom

Axons are the slender, often meter-long processes of neurons which electrically wire the brain, and these delicate structures need to be maintained for decades. Parallel bundles of microtubules (MTs) form their structural backbones and life-sustaining transport highways. We study axon biology through deciphering the MT regulating machinery composed of different classes of MT-binding proteins as well as actin networks. For this, we use an unprecedentedly comprehensive approach capitalising on combinatorial fly genetics. We recently proposed a model in which spectraplakins (large actin-microtubule linkers) guide the extension of polymerising microtubules along cortical F-actin, thus directly laying axonal MTs out into parallel bundles. Here we propose two further novel mechanisms promoting the bundle organisation of axonal MTs: Firstly, we identified a membrane-anchored cortical collapse factor which serves as a check point by eliminating "off track" MTs that have escaped the guidance mechanism. When artificially detached from the membrane, this factor is able to deplete entire MT networks. In the absence of this factor, more MTs persist in the periphery of growth cones and looped MTs accumulate in axons. Secondly, combining super-resolution microscopy with systematic genetics, we found that evolutionary conserved periodic cortical actin rings in axons sustain MT polymerisation, hence MT bundles. To understand this phenomenon, we study the machinery of axonal MT polymerisation which is of enormous complexity. We will report about three key factors acting as a "ménage à trois" to promote MT polymerisation. So far, all our data support a model of local homeostasis in axons which provides a novel concept providing explanations for axon longevity and degeneration.

NEK7 regulates dendrite morphogenesis in neurons via Eg5-dependent microtubule stabilization.  
F. Freixo¹, P. Martinez Delgado², Y. Manso³, C. Sánchez-Huertas¹, C. Lacasa¹, E. Soriano³, J. Roig², J. Luders¹;  
¹Cell and Developmental Biology, Institute for Research in Biomedicine (IRB Barcelona), Barcelona, Spain, ²Molecular Biology Institute of Barcelona (IBMB-CSIC), Barcelona, Spain, ³Department of Cell Biology, Physiology and Immunology, Faculty of Biology, University of Barcelona, Barcelona, Spain

Organization of microtubules into ordered arrays is best understood in mitotic systems, but remains poorly characterized in postmitotic cells such as neurons. By analyzing the cycling cell microtubule cytoskeleton proteome through expression profiling and targeted RNAi screening for candidates with roles in neurons, we have identified the mitotic kinase NEK7. We show that NEK7 regulates dendrite morphogenesis in vitro and in vivo. NEK7 kinase activity is required for dendrite growth and branching, as well as spine formation and morphology. NEK7 regulates these processes in part through phosphorylation of the kinesin Eg5/KIF11, promoting its accumulation on microtubules in distal dendrites. Here Eg5 limits retrograde microtubule polymerization, which is inhibitory to dendrite growth and branching. Eg5 exerts this effect through microtubule stabilization, independent of its motor activity. This work establishes NEK7 as a general regulator of the microtubule cytoskeleton, controlling essential processes in both mitotic cells and postmitotic neurons.

Interplay between microtubule depolymerizing kinesin KLP-7 and Wnt signaling establishes microtubule polarity in C. elegans touch neuron.  
D. Puri¹, P. Thyagarajan¹, K. Biswas¹, A. Ghosh Roy¹;  
¹National Brain Research Centre, Gurgaon, India

In the nervous system, directional flow of information depends on the polarized architecture of neuron. Neuron has a unique structure – many dendrites and one axon. Microtubule (MT) polymers are the building blocks of the polarized architecture of neuronal cell. Although MT protofilaments give stability in axon, they themselves are dynamic - undergoing polymerization and depolymerization. The dynamics of the microtubule network needs to be regulated in a context-dependent manner during polarization, maintenance or other remodeling processes. Using C. elegans touch neuron as a model, we have asked how polarity of microtubules is established and maintained in neuron. Both anterior and posterior touch receptor neurons are unipolar with a long anterior process, which, connects to its post-synaptic cell, and a short posterior process. Loss of kinesin-13 family microtubule depolymerizing enzyme klp-7 (kinesin-like posterior) leads to excess stabilization of microtubules leading to overgrowth of the short posterior process (1). We found that this phenotype in klp-7(0) can be reversed by a microtubule-stabilizing drug Colchicine or in backgrounds lacking either alpha or beta tubulin. In vivo imaging of microtubules with EBP-2:GFP reporter reveals that the short process of PLM has mixed polarity of MTs, whereas the long anterior process has all plus end unipolar MTs. The MTs in the ectopically extended posterior process in klp-7(0) becomes plus end out. Therefore, activity of KLP-7 is important to maintain the MTs with mixed polarity in the short posterior neurites. Previous study indicated that loss of Wnt signaling reverses the polarity of touch neurons in that short posterior process becomes axon and makes synapse (2, 3). We asked whether Wnt signaling through KLP-7 can establish axonal polarity.
We found that loss of klp-7 suppresses the phenotype displayed either by loss of Wnt receptor lin-17 or its ligand lin-44. This further indicates that the activation of Wnt signaling during development might directly or indirectly regulate KLP-7 to establish microtubule polarity during neuronal polarization. We will be further investigating how KLP-7 is regulated during the establishment of neuronal polarity.

Role of Formin-2 in actin-microtubule coordination during axonal pathfinding.
T. Kundu1, A. Sahasrabudhe1, A. Jacob1, A. Ghose1;
1Biology, IISER Pune, Pune, India

Neural circuits are formed by directed translocation of axonal growth cones to their synaptic targets. This growth cone mediated movement occurs through active and coordinated remodeling of the underlying cytoskeletal components. Recent studies from our lab have implicated Formin-2 (an actin nucleator) in this growth cone migration. The speed and directionality of growth cone movement and filopodial force generation was found to be compromised. Guidance defects were also observed in spinal commissural neurons which stalled and did not cross midline (Sahasrabudhe et. al., 2016). Growth cone steering and guidance also involve microtubules. Hence, this study examines the role of Formin-2 in mediating actin-microtubule crosstalk. Knockdown of Formin-2 reduced microtubule presence in the filopodia. Directionality of filopodal initiation was also affected due to skewed innervation of microtubules in filopodia. In addition to this, even though the area occupied by microtubules in the growth cone remains unaffected, the overall microtubule morphology is altered. These preliminary results suggest that Formin-2 might be involved in co-ordination of actin and microtubule dynamics and further studies are in motion to elucidate the nature of this interaction.

Nicotine Exposure Alters Neuronal Cytoskeleton by the Gβγ/pGSK3β Mediated Pathway.
C.M. Palacios1, K. Castaneda1, M.N. Ramirez2, J.A. Pipkin2, B. Cruz2, M. Miranda-Arango1, L.E. O’Dell2, S. Roychowdhury1;
1Biology, University of Texas at El Paso, El Paso, TX, 2Psychology, University of Texas at El Paso, El Paso, TX

Background: Tobacco use is a major public health concern. Nicotine is the main addictive agent in tobacco and it is well established that nicotine interferes with the ability of neurons to send, receive, and process information. However, the underlying molecular mechanisms by which nicotine alters neuronal pathways in the brain are not well understood. It is believed that changes in the neuronal cytoskeleton may provide a mechanism by which long-lasting behavioral changes occur during chronic nicotine exposure. Goal: The present study examined key molecular targets that modulate microtubules (MTs), a major cytoskeletal filament in neurons in response to nicotine exposure. Since Gβγ, an important component of GPCR pathway, and pGSK3β (phosphorylated GSK3β), a downstream effector
of tyrosine kinase receptor Trk A, coordinate to regulate MT modulation in neurons, our hypothesis is that nicotine exposure alters/disrupts microtubule structure in neurons through the Gβγ/pGSK3β pathway. Methods: We utilized a transdisciplinary approach involving an animal model of nicotine dependence and in-vitro cell culture systems to address this emerging problem. Wistar rats were exposed to chronic nicotine via osmotic pump for fourteen days (3.2 mg/kg/day). Control rats received sham surgery. Brains from control and nicotine-exposed rats were subjected to immunoblot, immunohistochemical and confocal microscopic analysis using antibodies specific for tubulin, Gβ, and pGSK3β. In addition, PC12 cells were used to conduct the study because they respond to nerve-growth-factor (NGF) with growth arrest and exhibits typical phenotype of neuronal cells. NGF differentiated PC12 cells were treated with 5 μM nicotine for 24h followed by immunoblot and confocal microscopic analysis. Results and Conclusion: We found that the nicotine exposure in rat brain altered tubulin/MTs organization in neurons located in the nucleus accumbens (NAcc), a brain region known to be associated with nicotine addictions. Immunoblot analysis reveals that chronic nicotine exposure inhibited the expression of Gβγ and subsequent phosphorylation of GSK3β by 22% and 42% respectively in NAcc. Using cultured PC12 cells, we observed that in vitro nicotine exposure significantly reduced neurite formation, altered MTs, and increased the co-localization of Gβγ, GSK3β and MTs in NGF-differentiated PC12 cells. These studies suggest that alteration of neuronal cytoskeleton by Gβγ/pGSK3β may contribute to nicotine abuse and addiction.

Dynamic microtubules specify local delivery and capture of presynaptic cargo at en passant synapses.
P. Guedes-Dias1, J.J. Nirschl1, N. Abreu1, M. Tokito1, E.L. Holzbaur1;
1Department of Physiology, University of Pennsylvania, Philadelphia, PA

The formation and maintenance of presynaptic sites are critical for proper neuronal transmission. Presynaptic function requires the active transport and specific delivery of presynaptic cargo, including dense-core vesicles and synaptic vesicle precursors. In contrast to the classical terminal synapse at the distal end of the axon, the vast majority of synapses in the central nervous system are established along axonal processes, juxtaposed to the uniformly polarized axonal microtubule arrays ("en passant synapses"). Presynaptic cargo are generated in the soma and are transported along microtubules by KIF1A and dynein motors, however, the mechanisms specifying the targeting of transiting presynaptic cargo to en passant synapses are not well understood. Here, we investigate the role of local cytoskeletal determinants and vesicular motors in this process using rat primary hippocampal neurons, live-cell fluorescence microscopy and in vitro single-molecule approaches. We found that transiting presynaptic vesicles are preferentially retained at presynaptic sites when moving in the anterograde direction. We found that presynaptic regions are hotspots of high microtubule dynamicity, and anterogradely moving presynaptic vesicles pause preferentially at these sites. Dampening microtubule dynamics with low-dose nocodazole was sufficient to abolish the preferential retention of anterograde-moving vesicles at presynaptic sites. In contrast, sites of lysosome pausing were stochastically distributed along the axon, with low rates of capture at synaptic regions. This difference suggests that the high dynamicity of presynaptic microtubules particularly affects presynaptic cargo transport, potentially acting as a cue to halt KIF1A processivity. Using single-molecule assays, we found that kinesin-1 binds equally well to either dynamic (GTP-like) or stable (GDP-like) microtubules. In contrast, the presynaptic vesicle motor KIF1A has a significantly lower affinity to dynamic microtubules, thus revealing a mechanistic basis for the high vesicle pausing and retention rates observed at presynaptic sites in live neurons. Together, our
results unveil a model whereby the interplay between local microtubule cues and cargo-specific motors allows precise delivery of appropriate cargo to the presynapse.

**Regulation of axon initial segment cytoskeletal architecture and function by βIV-spectrin.**
S.L. Jones¹, T.M. Svitkina²;
¹Biology, University of Pennsylvania, Philadelphia, PA

The axon initial segment (AIS) of polarized neurons is a specialized structure that, in addition to initiating action potentials, helps maintain neuron polarity by preventing the mixing of axonal and somatodendritic components. This latter function depends, in part, on a submembrane cytoskeletal network comprising ankryinG, actin filaments, and βIV-spectrin. While ankryinG functions as the master organizer of the AIS, βIV-spectrin is thought to contribute to AIS maintenance. The role of βIV-spectrin in AIS function and structure is poorly understood. AIS structure has been shown by platinum replica electron microscopy (PREM) to contain a dense mixture of fibrils and globules that coat microtubule bundles. We have proposed that this fibrillar-globular coat functions as a selective diffusion barrier that contributes to AIS polarity function. Here we investigate the structural and functional consequences of βIV-spectrin knockdown in hippocampal neurons in vitro using two independent lentiviral shRNAs, compared with scrambled and luciferase shRNA controls. βIV-spectrin depletion caused dramatic increase in AIS lengths (as determined by ankryinG immunofluorescence) and extensive spreading of AIS membrane proteins (including voltage-gated ion channels and cell adhesion molecules) throughout the axon. These data are consistent with a role for βIV-spectrin in AIS maintenance. We also examined the polarized distribution of several somatodendritic proteins and found that while many of them (e.g., PSD95, transferrin receptor, and MAP2) remained localized to dendrites, the potassium/chloride co-transporter KCC2 re-distributed to axons/AISs of neurons lacking βIV-spectrin. Interestingly, similar results were obtained following treatment with the actin depolymerizing drug latrunculin B. To determine the effects of βIV-spectrin knockdown on AIS structure, we examined AISs by PREM and discovered a fibrillar phenotype characterized by the presence of dense fibrillar bundles that (1) contain fibrils of ~100 nm in length, (2) align parallel to the AIS shaft, (3) contain globular structures at their ends, and (4) appear to repeat periodically along the AS. These fibrillar bundles likely represent ankryinG molecules since they stain positive by ankryinG immunogold and other likely candidates (e.g., all-spectrin, βII-spectrin, βIII-spectrin, septin7, and myosin II) failed to accumulate substantially in the AIS following βIV-spectrin depletion. Efforts are underway to confirm the identity of the fibrillar bundles. Together, these data indicate that βIV-spectrin is an important component of the AIS cytoskeleton that contributes to maintenance of overall AIS structure and its role in neuron polarity.

**Utilizing microtubule polarity as a tool for characterizing neuronal processes in the nerve net of an early metazoan: Nematostella vectensis.**
M.C. Stone¹, J.M. Eason¹,², G.O. Kothe², M.M. Rolls¹, T.J. Jegla²;
¹Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA, ²Biology, The Pennsylvania State University, University Park, PA

Functionally polar neurons with separate axons and dendrites have been found in all bilaterian model organisms examined to date, and thus neuronal polarity appears to be a universal feature of bilaterian
nervous systems. The evolutionary origins of neuronal polarity have not been examined, so it is unclear if neuronal polarity evolved in concert with nervous system centralization in early bilaterians or was already present in the diffuse nerve nets of early metazoans. We addressed this question by looking for distinct axons and dendrites in the nerve net of a cnidarian, the starlet sea anemone Nematostella vectensis. Cnidaria is a sister lineage to Bilateria that is believed to have separated prior to the evolution of centralization. The nervous system of anthozoan cnidarians, including Nematostella, is a diffuse net that is likely similar to the nervous system of the cnidarian/bilaterian ancestor. Microtubule orientation differentiates axons (+ end out) and dendrites (- end out or mixed) in polar bilaterian neurons, and is believed to underlie trafficking differences that contribute to functional specialization of neurites. We therefore developed a live imaging strategy to examine microtubule polarity in Nematostella neurons and cnidocytes using an EB1-GFP + tip marker. Two characteristic types of neurons we identified were bipolar and tripolar neurons with unbranched neurites. These cells are non-polar with respect to the microtubule cytoskeleton because all neurites contain identical axon-like + end out microtubules. Cnidocytes, which are nervous system cells specialize for stinging, also appear non-polar but, in contrast, have branched neurites with dendrite-like mixed microtubule orientation. Cnidarians can thus make two types of neurites with axon-like and dendrite-like microtubule orientation, a prerequisite for bilaterian-style neuronal polarity. However, further studies will be needed to determine whether these cnidarian neurites are functionally unique and orthologous to axons or dendrites, or whether there are additionally polar neurons within the nerve net.

Microtubule-associated protein Tau (MAPT) is involved in the stability of microtubules, which maintain the cell shape. Tau protein is predominantly expressed in neurons, where it has a role in microtubule assembly and stability, axonal transport, and neurite outgrowth. In neurodegenerative diseases known as tauopathies, such as Alzheimer’s disease (AD), Tau function is compromised. Tau expression is developmentally regulated by alternative splicing, giving rise to 6 different isoforms in the human adult brain. Alternative splicing of exon 10 gives rise to two protein isoforms with either three or four microtubule-binding repeats in the 3R Tau (exon 10 exclusion) and 4R Tau (exon 10 inclusion) splice variant, respectively. Expression of both isoforms is developmentally regulated, and upon adulthood they are characterized by region- and cell type-specific neuroanatomic distribution. In this study we sought to identify the spatio-temporal pattern of Tau variant expression during postnatal mouse brain development. To achieve this we utilized a highly specific and sensitive single-molecule RNA in situ hybridization assay, BaseScope, to evaluate the age-dependent neuroanatomic expression of 3R and 4R Tau splice variants in the mouse brain at postnatal days P1, P10, P30, and P56. BaseScope probes designed to uniquely identify the exon junctions of E9/E10 (4R Tau) and E9/E11 (3R Tau) were able to specifically detect expression of the Tau variants at the single cell level within the morphological tissue context. Quantification of the 3R and 4R Tau expression levels revealed changes in the 3R:4R Tau ratio over the course of development. In addition, we found distinct subregional and layer-specific differences in the expression patterns of both isoforms. The observed layer-specific expression patterns may provide novel insight into how the two Tau isoforms differ biologically. Taken together, these results demonstrate the ability of the BaseScope assay to characterize the specific spatio-temporal expression
pattern of 3R and 4R Tau variants during mouse brain development at the single cell level. This is the first study of MAPT exon 10 alternative splicing by in situ detection which enables expression mapping of Tau variants in the morphological and spatial context, and a similar assay strategy can also be used to study Tau isoforms in relation to AD and other tauopathies.

Proteomic Insights into Cytoskeletal Mechanisms of Neurodegeneration.
C. Carreon1, M. Aguilera-Flores1, I. Almeida1, S. Roychowdhury1;
1Department of Biological Sciences, University of Texas at El Paso, El Paso, TX

Cytoskeletal defects are hallmark of several neurodegenerative diseases. Results from our laboratory indicate that Gbeta-gamma, a major component of G protein-coupled receptor (GPCR) signaling pathway, interacts with microtubules (MTs) and plays an important role in the neuronal differentiation of PC12 cells. Inhibitors of Gbeta-gamma disrupted MTs, blocked neurite outgrowth, and induced neuronal damage, suggesting a role of Gbeta-gamma in neurodegenerative processes. Gbeta-gamma has been shown earlier to promote MT assembly in vitro and in cultured PC12 and NIH3T3 cells. In an effort to understand the mechanism of cytoskeletal disruption and neurodegeneration, we carried out a high-resolution proteomic analysis of cytoskeletal fractions (CSKs) of NGF-differentiated PC12 cells treated with agent known to trigger CSK disruption and block neuronal differentiation. Using Scaffold perSPECTives software to analyze the proteomic data, we found that neuronal differentiation of PC12 cells dramatically altered the proteomic landscape of CSK. 4-Nonylphenol (4-NP), an endocrine disruptor likely to cause neuronal damage, significantly affected the protein composition/pattern of CSK, including the association with Gbeta-gamma. String Link and Gene Ontology enrichment analysis indicated that several biological pathways are affected by 4-NP, including pathways related to Alzheimer’s disease, Parkinson’s disease, and Huntington disease. This study has potential to identify new biomarkers and/or pathways involved in disruption of CSK and the development of neurodegenerative disorders.

Identification of genes that control the formation of membrane-less organelles.
D. Berchtold1, N. Battich1, L. Pelkmans1;
1Institute of Molecular Life Sciences, University of Zurich, Zurich, Switzerland

Membrane-less organelles (MLOs) are subcellular compartments in eukaryotic cells that form through phase separation of proteins and RNAs from the surrounding milieu. The molecular composition of different types of MLOs is dynamic yet specific and determines their functional identity and biophysical properties. In human cells, almost all MLOs form de-novo after cell division. The number and size of MLOs change along the cell cycle and according to the physiological state of the cell. MLO formation is driven by many factors, such as the concentration and multivalency of organelle components. However, the mechanisms by which cells control the assembly and dissolution of MLOs remain largely unknown. Altering protein multivalency by posttranslational modifications might be key to regulating MLO formation. For instance, we recently showed that DYRK3 kinase activity is required for the dissolution of stress granules. Here, we present the results of three parallel high-resolution image-based siRNA screens that enabled us to identify kinases and phosphatases that control the formation and dissolution

Sunday-324
of six major MLOs in human cells: Nucleoli, Cajal bodies, splicing speckles and PML bodies in the nucleus, as well as P-bodies and stress granules in the cytoplasm. As part of our automated image analysis pipelines we employed a pixel-based classifier to segment individual MLOs in more than 12 million single cells and extracted their phenotypic features. A self-organizing map algorithm was used to assign each cell to a distinct position in the dimensionality reduced feature space according to the phenotype of two multiplexed MLO markers each. Using this powerful single cell clustering approach we were able to exclude indirect hits that only perturb the cell cycle but to detect genes with partial penetrant phenotypes on MLO formation. Computational multiplexing of all screens allowed us to identify genes with pleiotropic effects and to assess co-regulation between the six measured MLOs. We will present evidence for novel regulators of MLOs and show that perturbation of organelle homeostasis affects previously unlinked physiological processes. Together, our dataset will contribute to deciphering the regulation and biological functions of non membrane-bound organelles.

The endoplasmic reticulum (ER) is a complex membranous organelle that samples the majority of the cellular volume over very short time scales. Physically, this is achieved by a system of interconnected and highly dynamic tubes of liquid lumen enclosed in a fluid bilayer. Despite this remarkable liquid-in-a-liquid system, the diffusive properties of many membrane and luminal proteins in the ER have not been fully characterized. We thus examined three classes of membrane proteins with distinct insertion topologies: single-pass transmembrane (TM) proteins (e.g. Sec61b), hairpin shaping proteins (e.g. reticulons), and luminal spacing proteins (e.g. CLIMP63). To assess how these proteins behave within the ER membrane, we coupled fluorescence recovery after photobleaching (FRAP) to study their ensemble migration, with a single-particle tracking (SPT) approach to understand the motion of individual molecules. Each class of shaping protein exhibited differential diffusional characteristics on both the ensemble (FRAP) and single molecule (SPT) scale dependent on their membrane topology. Fascinatingly, overexpression of hairpin proteins, not TM or luminal spacing proteins, was also sufficient to dramatically decrease recovery of a luminal marker following photobleaching. This was the case for all studied hairpins, implying a unique property of this topogenic class of protein in influencing luminal diffusion. Hairpin proteins localize primarily to ER tubules and have been previously demonstrated to decrease tubular diameter in vitro and in S. cerevisiae. Thus, we proposed that a similar mechanism may be at play in mammalian cells, where a decrease in cross-sectional area limits diffusion of a luminal cargo through tubular regions of the ER. In support of this hypothesis, transmission electron microscopy reveals a dramatic and significant reduction in tubular diameter in cells overexpressing hairpin proteins, and reveals the presence of large luminal ‘sacs’ close to the nucleus, presumably where the lumen is

Sunday-325
“squeezed” into in order to accommodate the decreased luminal capacity of tubules. Crucially, this luminal redistribution has dramatic effects on the overall dynamics of the ER, massively proliferating the number of new tubule extensions present independent of the hairpin protein used. Additionally, when thin tubes are generated within the ER using a pharmacological treatment, hairpin proteins selectively localize to and stabilize these structures. In conclusion, we demonstrate that specific topologies of proteins inserted in the ER membrane influence diffusional properties of both membrane and luminal cargo and subsequently cause dramatic alterations in both the morphology and dynamicity of the ER.

On the Mechanism of Protein Targeting from the Endoplasmic Reticulum to Lipid Droplets.

M. Olarte\(^1\), R.V. Farese, Jr.\(^2,3\), T.C. Walther\(^2,3,4\);  
\(^1\)Department of Cell Biology, Yale School of Medicine, New Haven, CT, \(^2\)Department of Genetics and Complex Diseases, Harvard T.H. Chan School of Public Health, Boston, MA, \(^3\)Department of Cell Biology, Harvard Medical School, Boston, MA, \(^4\)Broad Institute of Harvard and MIT, Cambridge, MA, \(^5\)Howard Hughes Medical Institute, Boston, MA

Lipid droplets (LDs) are organelles that possess a unique structure, consisting of an oil-phase bound by a monolayer of phospholipids. Proteins specifically target to the surface of LDs, however, our understanding of how this happens is incomplete. One class of LD proteins, including glycerol-3-phosphate O-acyltransferase 4 (GPAT4), which catalyzes the rate-limiting step of triacylglycerol (TG) synthesis, targets LDs from the endoplasmic reticulum (ER). GPAT4 re-localizes and accumulates on mature LDs through ER-LD membrane bridges. Here, we investigated the re-localization mechanism that allows for the accumulation of GPAT4 on LDs. We find that a membrane-embedded motif of GPAT4 (amino acids 160–216) forms oligomers and is sufficient to mediate protein accumulation on LDs. The amino acid sequence of this segment plays a key role in LD targeting. Specifically, mutational analysis of this sequence showed that large hydrophobic residues, in particular several tryptophans, are required for LD targeting. Conversely, several positively charged residues in the membrane-embedded sequence were not required. Our results suggest a model in which large hydrophobic residues mediate ER-LD protein targeting by detecting and binding LD surface properties, such as phospholipid packing defects resulting from the exposure of the underlying oil at the LD monolayer. These findings shed light on the mechanism of GPAT4 targeting to LDs as a model protein and suggest the critical role that the physical surface features of LDs play in the general mechanism of protein targeting from the ER to LDs.

Caveolae are abundant flask-shaped invaginations of plasma membranes that buffer membrane tension through their disassembly. Few quantitative studies on the deformation of caveolae have been reported. Each caveola contains approximately 150 caveolin-1 proteins. In this study, we estimated the extent of caveolar deformation by measuring the density of caveolin-1 projected onto a two-
dimensional (2D) plane. The caveolin-1 in a flattened caveola is assumed to have approximately one-quarter the density of the caveolin-1 in a flask-shaped caveola. The one-quarter-density caveolin-1 increased after increasing the tension of the plasma membrane through hypo-osmotic treatment. The one-quarter-density caveolin-1 was soluble in detergent and formed a continuous population with the caveolin-1 in the caveolae of cells under isotonic culture. The distinct, dispersed lower-density caveolin-1 was soluble in detergent and increased after the application of tension, suggesting that the hypo-osmotic tension induced the dispersion of caveolin-1 from the caveolae possibly through flattened caveolar intermediates.

DYRK3 kinase regulates dissolution and condensation of membrane-less organelles during mitosis.
A.K. Rai¹, J. Chen², M. Selbach², L. Pelkmans¹;
¹IMLS, University of Zurich, Zurich, Switzerland, ²MDC, Max Delbruck Center, Berlin, Germany

Cell undergoes many biochemical reactions in compartments that are not surrounded by any lipid membranes called membrane-less organelles. Recently, it has been proposed that the mechanism of condensation of such compartments relies on a physical principle called phase separation, which is driven by weak molecular interactions between low-complexity domains (LCDs) within proteins and RNA. However, the cellular mechanisms regulating the dynamic condensation and dissolution of these compartments remains poorly understood. Interestingly during early mitosis, concomitant with nuclear envelope breakdown, multiple membrane-less organelles undergo dissolution, and then re-condense towards the end of mitosis. We show that the dual-specificity kinase DYRK3 interacts with, and localizes to multiple membrane-less organelles like stress granules, splicing speckles and pericentriolar satellites. Inhibition of DYRK3 kinase activity during mitosis results in co-condensation of multiple proteins from these compartments, and poly-adenylated RNA into aberrant hybrid structures. The formation of such aberrant structures in mitotic cells results in mitotic delay because of extended metaphase. We have been able to demonstrate that DYRK3 acts as a dissolvase during mitosis and increase in DYRK3 kinase to its substrate concentration ratio as a consequence of nucleo-cytoplasmic dilution post nuclear envelope breakdown allows cells to undergo rapid dissolution of organelles during early mitosis. Further, the re-condensation of organelles during late mitosis can be explained by our observation that the APC/C-CDH1 driven ubiquitination degrades DYRK3 during late mitosis, decreasing DYRK3 to substrate ratio. Thus, changes in relative concentration of the dissolvase (DYRK3) to the phase separating proteins (DYRK3 substrate) can explain the phenomenon of complete dissolution of multiple organelles during early mitosis and their re-condensation later in mitosis.

Light-dissociable membrane-less organelles maintain spatial patterns over long periods of time.
E.A. Dine¹, A.A. Gil¹, G.A. Uribe¹, E.M. Zhao², J.E. Toettcher¹²;
¹Molecular Biology, Princeton University, Princeton, NJ, ²Chemical and Biological Engineering, Princeton University, Princeton, NJ

Recent studies have shown the prevalence of membrane-less organelles inside cells, but understanding how these organelles form and dissociate remains a challenge. To better understand these issues, optogenetic tools controlling the assembly of membrane-less organelles have been developed.
However, existing optogenetic tools are only able to induce assembly upon light stimulation. Here, we report a tool for light-induced disassembly of membrane-less organelles. Our tool allows for the generation of protein droplets in the dark that dissociate upon blue light stimulation; droplets that we refer to as Reverse OptoDrops or RODs. Light-dependent assembly and disassembly of RODs are fast and reversible processes, leading to precise temporal control over protein phase separation. Moreover, we find that the spatial distribution of RODs can be tightly controlled with patterned light inputs, and that these patterns are retained for long periods of time, even after the removal of the light stimulus. Together, these results add another tool for precise spatiotemporal control over membrane-less organelles and suggest how long-term spatial information can be stored by the cell simply by the fundamental biophysics controlling protein clustering.

Members of the UDP-GalNAc:polypeptide N-acetylgalactosaminytransferase family of enzymes use different Golgi targeting signals.  
J.L. Becker¹, D.T. Tran¹, L.A. Tabak¹;  
¹Section on Biological Chemistry, NIDCR, National Institutes of Health, Bethesda, MD

Mucin-type O-glycosylation is an evolutionarily conserved protein modification in which N-Acetylgalactosamine (GalNAc) is added to the hydroxyl group of serine or threonine residues within the Golgi apparatus. This reaction is initiated by the UDP-GalNAc:polypeptide N-acetylgalactosaminytransferase (GalNAc-T) family of enzymes, with 20 family members in humans. Conceptual translation indicates that GalNAc-Ts are type II transmembrane proteins, though it is unclear how they localize to the Golgi or how their in vivo localization may affect substrate specificity. To address these questions, we sought to determine the Golgi targeting signals utilized by GalNAc-Ts. We began by identifying the minimum amino acids required for proper localization in human foreskin fibroblast (HFF) cells. We generated and transiently expressed plasmids encoding GFP fusions of various protein regions of the representative family members GalNAc-T1, -T2, -T7, and -T10. Immunofluorescence and confocal microscopy showed that -T1, -T2, and -T7 require at minimum both the cytoplasmic tail and transmembrane domain to colocalize with Giantin, a cis/medial Golgi protein, while -T10 requires the transmembrane domain and luminal stem region. These data suggest that GalNAc-Ts employ at least two distinct modes of Golgi localization—one defined by the amino acid sequence of the cytoplasmic tail and another encoded in the luminal stem. To further characterize the localization signal in the tail, we found that the -T10 tail includes a single glutamic acid while -T1, -T2, and -T7 tails lack negatively charged residues. When the glutamic acid in the -T10 tail was substituted with a lysine or alanine, the -T10 tail and transmembrane domain was directed to the Golgi, suggesting that the glutamic acid may prevent tail-directed Golgi targeting. We next performed pulldown assays using the combined tail and transmembrane domains of -T1 and -T10 and identified two Golgi-associated proteins that may interact with -T1 but not -T10: ARF1 and TIP47. Affinity purification using peptides of the -T1 and -T10 tails and subsequent western blots confirmed the interaction of TIP47 with the -T1 tail but not with the -T10 tail. Future experiments will determine if TIP47 depletion affects GalNAc-T localization. We will also attempt to identify putative binding partners for the -T10 stem and determine their importance for stem-dependent Golgi targeting. In summary, our data demonstrate that multiple Golgi targeting strategies exist in the GalNAc-T family. These studies will help determine the significance of these distinct targeting signals in GalNAc-T localization and function.

Pathogenic mechanism of human centronuclear myopathy resulted from nonsense mutations of Amphiphysin-2/Bin1.
J. Loh1, Y. Liu1;
1Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

Centronuclear myopathy (CNM) is a genetic disorder characterized by muscle weakness that is debilitating at an early age. Autosomal recessive CNM is caused by mutations in Amphiphysin-2 (Bin1), a protein important for membrane curvature generation and critical for the formation of highly curved plasma membrane invagination in muscle cells, the T-tubules. Most of the CNM-related Bin1 mutations are located at its membrane curvature generation or membrane binding domains thus resulting in defects in T-tubule formation. Two mutations, Q434X and K436X, which result in truncated SH3 domains without membrane curvature generation perturbation, have not been well-characterized for their pathogenic mechanism. The phenotypes of these Bin1 mutants were illustrated in relation to their effects on Dynamin 2 (Dnm2) activity in our study. Dnm2 is a Bin1 interacting protein and is well-known for its membrane scission activity to release vesicles from the plasma membrane. We found the binding affinity of Dnm2 and Q434X and K436X was decreased in comparison to full-length BIN1, suggesting a diminished interaction between Bin1 and Dnm2. Surprisingly, fission activity of Dnm2 in vitro was enhanced, which was further supported by increased fission activity in vivo by co-transfection of the Bin1 mutants with Dnm2 in myoblast cells. In conclusion, we discovered the hyperactivity quality of Dnm2 membrane fission to be a key characteristic of the pathogenic mechanism of autosomal recessive CNM leading to defects in T-tubule formation. We will further investigate the effect of mutant Bin1 on Dnm2 membrane binding and assembly with electron microscopy analysis.

Cell size determines nuclear shape in Saccharomyces cerevisiae.
K. Amoateng1, A.D. Walters1, R. Wang2, J. Chen3,4, G. McDermott3,4, C.A. Larabel3,4, O. Gadal2, O. Cohen-Fix1;
1Laboratory of Molecular and Cellular Biology, National Institutes of Health, Bethesda, MD, 2Laboratoire de Biologie Moléculaire Eucaryote (CBI), Université de Toulouse, Toulouse, France, 3Department of Anatomy, University of California San Francisco, San Francisco, CA, 4Molecular Biophysics and Integrated Bioimaging, Lawrence Berkeley National Laboratory, Berkeley, CA

Nuclei are typically round or oval, and under normal growth conditions cells maintain a constant ratio between nuclear and cell volume (N:C volume ratio). However, what aspect of nuclear size is linked to cell growth is not known. To address this, we inhibited cell growth and examined the consequences to nuclear size and shape in the yeast Saccharomyces cerevisiae. Two methods were used to inhibit cell growth: inhibition of secretion using temperature sensitive mutants in the secretory pathway, and inhibition of protein synthesis using cycloheximide. In both cases, inhibition of cell growth led to a striking nuclear phenotype, where the nucleus became bilobed with the bulk of the DNA in one lobe and the nucleolus in the other. Formation and maintenance of the bilobed nucleus was dependent on fatty acid synthesis, as the addition of a fatty acid synthesis inhibitor, cerulenin, abolished the bilobed nuclear phenotype. Thus, bilobe formation was likely a result of continued nuclear membrane expansion despite the inhibition to cell growth. Indeed, in the case of secretion mutants, the formation of the bilobe phenotype occurred predominantly in later stages of the cell cycle, when the nuclear envelope...
would have normally expanded to accommodate chromosome segregation. Importantly, the N:C volume ratio in cells containing bilobed nuclei was the same as in wild type cells as determined by three different methods. Based on this we conclude that while nuclear volume is linked to cell growth, nuclear surface area expansion is not. Therefore, in yeast under certain conditions the maintenance of a constant N:C volume ratio can come at a cost of nuclear deformation. Given that the constant N:C ratio is conserved, nuclear deformation in other systems may be caused by unregulated nuclear membrane expansion under the constraint of a nuclear volume that is linked to cell size.

Deciphering the cisternal localization of GalNAc-Ts using super-resolution imaging.
G.G. Herbome1, D.T. Tran3, G.H. Patterson3, L.A. Tabak3;
1NIDCR / Biological Chemistry Section, National Institutes of Health, Bethesda, MD, 2NIBIB / Section on Biophotonics, National Institutes of Health, Bethesda, MD

The acquisition of mucin-type O-glycans in the Golgi is catalyzed by the family of 20 UDP-GalNAc:polypeptide N-Acetylgalactosaminyltransferases (GalNAc-Ts) which transfer N-Acetylgalactosamine (GalNAc) to selected Thr/Ser residues in substrates. The addition of GalNAc onto a substrate appears to occur in an ordered, hierarchical, manner. In vitro studies have shown two classes of GalNAcTs, the “early” GalNAc-Ts, that can modify un-glycosylated peptides (e.g. T1 and T2), and the “late” GalNAc-Ts, that can modify peptides already decorated with GalNAc (such as T7 and T10).

Conventional, diffusion limited, fluorescent imaging approaches cannot resolve the cisternal localization of Golgi proteins. Thus, to determine if the hierarchical acquisition of GalNAc is influenced by a unique spatial organization of the initiating enzymes within the Golgi we employed super-resolution microscopy approaches to localize endogenous GalNAcTs. First, STimulated Emission Depletion microscopy (STED) was used to compare the localization of GalNAc-Ts to the cis Golgi marker GM 130 and trans Golgi marker TGN 46 and to compare the localization of GalNAc-T2 with other GalNAc-Ts (T1, T5 and T7). STED imaging revealed that the four GalNAc-Ts co-localized more with GM130 than TGN 46, suggesting that they all reside close to the cis region of the Golgi. However, because the achievable resolution of STED is around 100 nm, which correspond to the size of a single Golgi cisterna, we sought to confirm these results using an additional approach. To this end, we are currently evaluating GalNAc-T localization using STochastic Optical Reconstruction Microscopy (STORM), which can achieve resolutions of up to 20nm.

Our data indicate that all four GalNAc-Ts studied, appear so far to be located in the same cis region inside the Golgi indicating that the substrate specificity of individual enzymes might be the main contributor to the hierarchical acquisition of O-glycans.

This research was supported by the Intramural Research Program of the NIH.

Sunday-330
The endoplasmic reticulum (ER) is a closed network of tubes and membranous sacs. Live cell imaging shows that this network is very dynamic. ER tubules routinely branch, elongate and fuse with other tubules or sacs. Elongation occurs along microtubules and fusion is mediated by the dynamin-related GTPase Atlastin. Frequent fusion events must be balanced by similarly frequent fission events or else the ER will form a continually tightening network that eventually collapses into a densely woven fabric. Mechanisms for ER fission are, however, as of yet unknown. Here, we show that Dynamin-2 (Dnm2), which severs endocytic vesicles from the plasma membrane, can also be recruited to the ER under stress-inducing conditions, coincident with the severing of ER membrane. Dnm2 knockout cells have more tightly woven ER networks and they show significant delays in ER fragmentation induced by calcium ionophores. These results suggest that Dnm2 contributes to ER scission. We also observe increased colocalization of Dnm2 with Endophilin B1 (EndoB1) and other ER markers when cells are treated with calcium ionophores or with autophagy inducing chemicals. Increased interactions are detected with immunofluorescence and proximity ligation assays for endogenous proteins and with transiently transfected fluorescent proteins. EndoB1 is a BAR domain and SH3 domain containing protein, closely related to Endophilin A1, which interacts with Dnm2 at the plasma membrane during clathrin-independent endocytosis. Although EndoB1 interacts with Dnm2 when autophagy is induced, these proteins unexpectedly have opposite effects on the progression of autophagy. Loss of EndoB1 through CRISPR knockout inhibits autophagy, but this inhibition is fully suppressed in EndoB1 - Dnm2 double knockout cells. These results suggest that Dnm2 can interfere with autophagy but this interference is relieved through binding interactions with EndoB1. We have thus uncovered novel interactions between Dnm2 and ER membrane proteins that control ER scission and autophagy.

Asymmetric cell division is the primary mechanism to generate cellular diversity, and it relies on the correct partitioning of cell fate determinants. However, the mechanism by which these determinants are delivered and positioned is poorly understood, and the upstream signal to initiate asymmetric cell division is unknown. Here we report that the endoplasmic reticulum (ER) is asymmetrically partitioned during mitosis in epithelial cells just before delamination and selection of a proneural cell fate in the early Drosophila embryo. At the start of gastrulation, the ER divides asymmetrically into a population of asynchronously dividing cells at the anterior end of the embryo. We found that this asymmetric division of the ER depends on the highly conserved ER membrane protein Jagunal (Jagn). RNA inhibition of jagn just before the start of gastrulation disrupts this asymmetric division of the ER. In addition, jagn-deficient embryos display defects in apical-basal spindle orientation in delaminated embryonic neuroblasts. Our results describe a model in which an organelle is partitioned asymmetrically in an otherwise symmetrically dividing cell population just upstream of cell fate determination and updates previous models of spindle-based selection of cell fate during mitosis.

A new pathway for membrane protein insertion at the ER.
A. Guna1, N. Volkmar2, J.C. Christianson2, R.S. Hegde1;
1MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, 2Ludwig Institute for Cancer Research, University of Oxford, Oxford, United Kingdom

Membrane protein insertion is an essential cellular process. The broad biophysical and topological range of membrane proteins necessitates multiple insertion pathways, which remain incompletely defined. Here, we have discovered a new membrane protein insertion pathway, identified the class of substrates it handles, explained why other known pathways do not work for these substrates and reconstituted the pathway using purified components. We show that tail-anchored proteins with low to moderate transmembrane domain hydrophobicity fail to engage TRC40, the previously known targeting factor for this class of membrane proteins. Instead, these proteins are kept soluble in the cytosol by calmodulin. Dynamic release from calmodulin allowed sampling of the endoplasmic reticulum (ER). At the ER, the conserved ER membrane protein complex (EMC), a broadly conserved ten-subunit complex of unknown function, was shown to be essential for efficient insertion in vitro and in cells. In the absence of an intact EMC, these proteins were shown to mislocalize, aggregate, and get degraded. Purified EMC in synthetic liposomes was sufficient to catalyse insertion of its substrates in a reconstituted system. Therefore, the EMC is a transmembrane domain insertase that is necessary and sufficient for the insertion of roughly half of all tail-anchored proteins that don’t have access to the TRC40-dependent pathway.

SAC1 degrades its lipid substrate PtdIns4P in the ER to maintain a steep electrochemical gradient on donor membranes.
J.P. Zewe1, S.J. Sangappa1, R.C. Wills1, B. Goulden1, G.R. Hammond1;
1Department of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Phosphatidylinositol 4-phosphate (PtdIns4P) is one of the most functionally diverse molecules utilized by eukaryotic cells. It is both a metabolic hub for other crucial signaling lipids such as PtdIns(4,5)P2 and PtdInsP3, and a key molecule for recruitment of membrane and lipid transport proteins in its own right. Most recently, it has been proposed to form a “phosphoinositide-motive force”, whereby transport of PtdIns4P molecules down their concentration gradient from the plasma membrane (PM) or Golgi to the ER drives counter transport of other lipids up their own concentration gradients. A critical requirement for this model is that the main PtdIns4P degrading enzyme, the integral ER phosphatase SAC1, hydrolyzes PtdIns4P in the ER in a “cis” configuration. Alternatively, it has been suggested that other functions of PtdIns4P are regulated by SAC1 hydrolyzing PtdIns4P directly in the PM in a “trans” configuration at membrane contact sites (MCS). However, such activity would surely disrupt lipid counter transport. Therefore, we sought to determine whether SAC1 acts in “cis”, “trans”, or both in mammalian cells. Acute chemical ablation of SAC1 activity drives ectopic accumulation of PtdIns4P in the ER, revealing “cis” activity. Furthermore, endogenous or ectopically expressed SAC1 localizes to the ER and Golgi, but does not constitutively or dynamically enrich at ER-PM MCS. Forced recruitment of SAC1 to experimentally induced MCS does not produce robust “trans” activity on PM PtdIns4P. However, “trans” activity can be induced by adding an approximately 6 nm long helical linker between the ER anchor and the catalytic domain. Together, our results reveal that SAC1 operates in a “cis” configuration. This ensures a “phosphoinositide-motive force” for lipid transport is effective, and also
implies regulation of PM phosphoinositide signaling is tightly linked to non-vesicular traffic of PtdIns4P at ER-PM MCS.

An image-based subcellular map of the human proteome.
P.J. Thul1, L. Åkesson1, D. Mahdessian1, A. Bäckström1, F. Danielsson1, C. Gnann1, M. Hjelmar1, R. Schutten1, C. Stadler1, D.P. Sullivan1, C.F. Winsnes1, M. Uhlén1, E. Lundberg1;
1Science for Life Laboratory, Royal Institute of technology (KTH), Stockholm, Sweden

Compartmentalization of biological reactions is an important mechanism to allow multiple cellular reactions to occur in parallel. Resolving the spatial distribution of the human proteome at a subcellular level increases our understanding of human biology and disease. A high-resolution map of the human cell has been generated, the Cell Atlas (1), part of the open access Human Protein Atlas database (2,3). Using an antibody and imaging-based approach 12,003 proteins have been localized to 32 subcellular structures, enabling the definition of 13 major organelle proteomes. The high spatial resolution allowed identification of novel protein components of fine structures such as the midbody, nuclear bodies as well as rods & rings. An integrative approach was used including strict antibody validation criteria using gene silencing, paired antibodies, and fluorescently tagged proteins (4,5). Deep learning approaches and a citizen science approach was employed for refined pattern recognition in images, the mini-game “Project Discovery” integrated into an massively-multiplayer online game that has engaged more than 200,000 players world-wide (6).

We show that half of all proteins localize to multiple compartments. On one level, it can be a spatial confinement to control the timing of the molecular function in one compartment. On another level, such proteins may have context specific functions and ‘moonlight’ in different parts of the cell, thus increasing the functionality of the proteome and the complexity of the cell from a systems perspective. We further reveal 16% of the proteome to show single cell expression variation in terms of protein abundance or spatial distribution. Finally we show that current protein-protein network models benefit from integration of the Cell Atlas localization data as spatial boundaries.

Here we present the most comprehensive subcellular map of the human proteome and discuss the importance of spatial proteomics for single cell biology.

Proper positioning of organelles by cytoskeleton-based motor proteins underlies cellular events such as signalling, polarization and growth. For many organelles, however, the precise connection between position and function has remained unclear, because strategies to control intracellular organelle positioning with spatiotemporal precision are lacking. We previously established optical control of intracellular transport by using blue light-sensitive heterodimerization to recruit specific cytoskeletal motor proteins (kinesin, dynein or myosin) to selected cargoes using LOV domains. To increase spatiotemporal control of such assays we engineered phytochrome B domains into photoswitches for intracellular transport that enable the reversible interaction between organelles and motor proteins by exposure to red and far-red light. Using patterned illumination and live-cell imaging, we demonstrate that this system provides unprecedented spatiotemporal control. We also demonstrate that it can be used in combination with a blue-light dependent system to independently control the positioning of two different organelles. Our strategy for optogenetic control of organelle positioning will be widely applicable to explore site-specific organelle functions in different model systems.

INPP5K, a member of the inositol 5-phosphatase family, consists of the phosphatase domain followed by a SKICH domain. Partial loss of function mutations of INPP5K were recently reported to result in congenital muscular dystrophy. How INPP5K localizes and functions in the ER remains unknown. Here we report that recruitment of INPP5K to the ER relies on ARL6IP1, an ER membrane protein which shares features of ER shaping proteins and whose dysfunction results in hereditary spastic paraplegia. The interaction of INPP5K with ARL6IP1 requires a cooperation of both its phosphatase and SKICH domains. Both INPP5K and ARL6IP1 are localized throughout the tubular ER network, but are not present in ER sheets. In addition, they are more concentrated, relative to generic ER proteins (e.g. Sec61b, VAPB), in newly formed tubules that undergo rapid extension along microtubule tracks. Depletion of either INPP5K or ARL6IP1 results in decreased abundance of ER tubules and in the expansion of ER sheets, possibly due to impaired formation of new ER tubules. Supporting these findings, a forward genetic screen aimed at the identification of genes controlling the ER architecture in PVD neurons of C. elegans, led to the isolation of cil-1 mutants, which are deficient in the function of the INPP5K orthologue. In these mutants, the complexity of ER tubule network and the extension of ER tubules into dendritic branches was impaired. These defects were rescued by expression of WT CIL-1, but not of catalytically inactive CIL-1 or SKICH domain-deleted CIL-1. Our results implicate an ER localized inositol-5-phosphatase in the control of the ER architecture.
Targeting of tail-anchored proteins by GET3B in Arabidopsis chloroplasts.
S.A. Anderson, D.E. Fernandez; 1Botany, University of Wisconsin - Madison, Madison, WI

Tail-anchored proteins, which have a cytosolic N-terminus, a single transmembrane domain, and a very short C-terminal tail, present a special challenge for membrane targeting. Targeting information has been shown to be primarily associated with the transmembrane domain and tail. Because these are still in the ribosome tunnel when translation stops, these proteins must be targeted post-translationally. To manage this, most eukaryotes have a dedicated system called GET (Guided Entry of Tail-anchored proteins), which includes SGT2 and GET1-5 in yeast. The central player is the targeting factor GET3, which receives the substrate protein from SGT2, GET4, and GET5 and delivers it to GET1 and 2 at the ER. This system is fairly conserved across eukaryotic lineages.

Recently, three GET3 homologs have been identified in Arabidopsis thaliana, with one, GET3B, predicted to contain a chloroplast transit peptide. However, the remaining components of the pathway do not appear to be present in chloroplasts. Chloroplasts contain multiple tail-anchored proteins, which are products of both the plastid and nuclear genomes, and play important roles in the photosystems and Sec translocases. Does GET3B play a role in targeting of these proteins? We are testing this hypothesis through a combination of genetic analysis, microscopy, and biochemistry. We will present data showing that GET3B binds to at least one tail-anchored protein in the stroma (the main aqueous space of chloroplasts) and forms a homodimer. The results from other on-going experiments will be presented. Supported by NSF DGE-1256259 and the UW-Madison Graduate School.

The AFF-1 exoplasmic fusogen is required for endocytic scission and seamless tube elongation.
F. Soulavie, D. Hall, M. Sundaram; 1Department of Genetics, University of Pennsylvania, Philadelphia, PA, 2Department of Neuroscience, Albert Einstein College of Medicine, New-York, NY

Many membranes merge during cellular trafficking, but some mechanisms involved in fusion and fission events initiating at exoplasmic (non-cytosolic) membrane surfaces are not well understood. Here we show that the C. elegans exoplasmic fusogen AFF-1 is required for endocytic scission and trafficking events during development of the intracellular lumen of a seamless unicellular tube. One proposed mechanism for intracellular lumen formation involves endocytosis to internalize basal membrane, followed by vesicle merging or exocytosis to form a lumen. An alternative mechanism involves cell wrapping to form a lumen lined by an autocellular junction, followed by membrane auto-fusion to remove that junction and become a seamless toroid. Using the C. elegans excretory duct tube as a model, we provide evidence that both mechanisms contribute to intracellular lumen formation and growth in vivo, and that both require the exoplasmic fusogen AFF-1. EGF-Ras-ERK signaling promotes duct cell fate and upregulates AFF-1 expression. AFF-1 is both necessary and sufficient to induce duct auto-fusion, and is necessary but not sufficient to promote subsequent tube elongation. Duct-specific removal of AFF-1 reduces lumen elongation independently of effects on junction removal. aff-1 mutants have an expanded apical domain and accumulate large basal inclusions with convoluted membranes, and experiments with the membrane-binding dye FM4-64 suggest that these basal inclusions correspond to a blocked endocytic intermediate. AFF-1 is an exoplasmic fusogen that localizes at or near
The basal plasma membrane during duct lumen growth, and therefore could be suitably positioned to mediate vesicle scission during endocytosis. We propose that EGF-Ras-ERK signaling stimulates both AFF-1 expression and basal endocytosis, and that AFF-1 is required for scission of basal endocytic compartments and for apically-directed exocytosis that ultimately contribute apical membrane to drive lumen growth.

Investigating the phospho-regulation of ER shaping protein RTN1A (Reticulon-1A) by the Calcineurin phosphatase.
S. Ei Cho¹, J. Roy¹, Y. Ivarsson², M.S. Cyert¹;
¹Biology, Stanford University, Stanford, CA, ²Chemistry - BMC, Uppsala University, Uppsala, Sweden

The endoplasmic reticulum is a dynamic organelle that performs multiple functions including intracellular Ca2+ regulation. Its structure is maintained by membrane shaping proteins such as reticulons, a group of proteins highly expressed in brain. The C-termini of reticulons are highly conserved with long hydrophobic domains while their N-termini are variable and believed to bring specific function to each protein. Interestingly, one of the reticulon family members, RTN1A, has a unique N-terminus that is highly phosphorylated, especially in serine residues. However, the functional consequence of this phosphorylation is unknown. Recent work from our lab has identified a calcineurin-binding motif in the unique N-terminus of RTN1A, suggesting that calcineurin may regulate this protein. Calcineurin (CN) is a Ca2+/calmodulin-activated serine threonine phosphatase that has been implicated in many ER-related functions including ER stress regulation. The substrates of CN that mediate these functions have remained unknown. Using a proximity-based interaction assay, we showed that RTN1A associates with CN in vivo, with the interaction being mediated by the CN-binding motif. Further, we showed that RTN1A is dephosphorylated by CN in vitro, suggesting that RTN1A is a direct substrate of CN. Recently, it was shown that the N-terminus of RTN1A is necessary and sufficient to induce ER-mitochondria contacts, which are sites for Ca2+ transfer between the ER and mitochondria. Additionally, the level of RTN1A was elevated in kidney disease and induced ER stress and apoptosis2, which increase CN activity. We are currently investigating a role for CN-dependent dephosphorylation in regulating RTN1A functions. Supported by T32GM007276. 1. Cho, I.-T., Adelmant, G., Lim, Y., Marto, J. PI(4,5)P2 controls the level of its precursor, PI4P, in the plasma membrane by regulating PI4P/PS transport at ER-plasma membrane contact sites.
M. Sohn\(^1\), M. Korzeniowski\(^2\), G. Hammond\(^2\), E. Boura\(^3\), T. Balla\(^4\);
\(^1\)National Institute of Child Health and Human Development, NIH, Bethesda, MD, \(^2\)Department of Cell Biology, University of Pittsburgh, Pittsburgh, PA, \(^3\)Institute of Organic Chemistry and Biochemistry, Czech Academy of Sciences, Prague, Czech Republic

Phosphatidylinositol 4,5-bisphosphate [PI(4,5)P2] is a minor but critical regulatory phospholipid playing a role in signal transduction, endocytosis, exocytosis, actin dynamics as well as ion channel activity in the plasma membrane (PM). Little is known about how cells keep PI(4,5)P2 levels within normal range. Here we found that PM PI(4,5)P2 controls its own precursor supply at the PM by regulating the activities of the oxysterol-binding protein related proteins (ORP) 5 and ORP8 at ER-PM contact sites. ORP5/8 was previously known to transfer PI4P from the PM to the ER in exchange for phosphatidylserine (PS) which is transported in the reverse direction. We found that while ORP5 is already active at basal levels of PI4P and PI(4,5)P2, ORP8 shows little activity due to its poor membrane interaction. This difference is caused by the different membrane binding affinities of the N-terminal PH domains of ORP5/8. Importantly, interaction of ORP5 with the PM was found to depend both on PI4P and PI(4,5)P2 and decreases in either phosphoinositides levels caused dissociation of ORP5 from the PM. In contrast, PM interaction of ORP8 was strongly enhanced by expression of a PIP-5-kinase (PIP5K), which synthesizes PI(4,5)P2 in the PM. PIP5K overexpression also caused a massive reduction in PM PI4P and PS levels and only moderately increased the level of PI(4,5)P2. Thus, enhanced PI(4,5)P2 production facilitates the PI4P/PS exchange to the point where PM PI4P levels are depleted and no more able to support PS transport to the PM. This regulatory mechanism helps cells maintain PI(4,5)P2 levels by controlling the PI4P flux between PI4P/PS transfer and PI(4,5)P2 generation.

Cells undergoing glucose restriction start to catabolize fat molecules to produce ATP through mitochondrial oxidative phosphorylation (OXPHOS). At the same time, autophagy (a conserved lysosome-mediated self-eating process) is triggered to support cellular lipid catabolic activity via redistributing stored fatty acids in lipid-droplets (LDs) to fat-metabolizing organelles such as mitochondria. However, how mitochondria and LD-specific autophagy (i.e, micro-lipophagy) interplay in starved cells for their long-term survival remains unknown. Here, we demonstrate that a regulatory feedback mechanism exists between mitochondria and micro-lipophagy in budding yeasts. We find that in response to acute glucose restriction, cells rapidly induce mitochondrial OXPHOS, followed by the upregulation of genes that control mitochondrial fusion activity. This leads to mitochondrial tubulation and prevents loss of mitochondrial DNA and respiratory capacity by protecting the organelles from being targeted to bulk autophagy during starvation. Our analysis reveals that mitochondrial respiratory activity is the key trigger for remodeling vacuolar membrane to form a micro-scale liquid-ordered (Lo)
membrane domain. We show that vacuolar Lo domain forms by the redistribution of Atg14p (a component of class III phosphatidylinositol-3-kinase (PI3K) complex I) to the vacuole surface upon the induction of mitochondrial OXPHOS. Through stabilizing other PI3K components (e.g., Atg6p) on the vacuole, Atg14p further differentiates the Lo domains to recruit LDs onto the vacuole surface for triggering micro-lipophagy. Cells lacking mitochondrial fusion activity or incapable of boosting aerobic respiration due to genetic/pharmacological stresses fail to develop vacuolar Lo domains, completely block micro-lipophagy induction, and display significantly diminished ATP production with shortened lifespans during glucose starvation. Thus, our data suggests that mitochondrial fusion plays a key role in micro-lipophagy by modulating mitochondrial aerobic respiration and vacuolar Lo domain differentiation in starved cells. This additional interplay between mitochondria and LD-specific autophagy may allow cells to operate a precise regulation of LD-stored lipid recycling in response to cellular energy demand and would help drive effective cell survival program during metabolic stress.

Reduction in the ER-mitochondria contact site plays an important role in palmitic acid-induced insulin resistance.
S. Shinjo1,2, S. Jiang3, M. Nameta4, S. Minamisawa1, N. Goda2;
1Department of Cell Physiology, The Jikei University School of Medicine, Tokyo, Japan, 2Department of Life Science and Medical Bioscience, Waseda University, School of Advanced Science and Engineering, Tokyo, Japan, 3Niigata College of Medical Technology, Niigata, Japan, 4Department of Electron Microscope Core Facility, Niigata University, Niigata, Japan

Endoplasmic reticulum (ER) has physical contacts with mitochondria in its subdomain referred as mitochondria-associated ER membrane (MAM). Although reduction in crosstalk between ER and mitochondria through the MAM affects cellular homeostasis, its pathological significance in insulin resistance in type 2 diabetes mellitus remains elusive. Here, we disclosed the importance of impaired MAM formation in the fatty acid-elicited insulin resistance in hepatocytes. Palmitic acid (PA) suppressed insulin-stimulated phosphorylation of Akt in HepG2 cells within 12 hours. Neither ER stress response nor mitochondrial ROS is implicated in the repression of Akt phosphorylation as demonstrated by pharmacological inhibition. Even 3-hour-treatment of PA reduced the calcium flux from ER to mitochondria, followed by a significant decrease in MAM contact area, suggesting that PA suppressed the functional and structural interaction between ER and mitochondria. Overexpression of mitofusin2, a critical component of the MAM, substantially restored MAM contact area and partially ameliorated the PA-induced suppression of insulin sensitivity with Ser473 phosphorylation of Akt selectively improved.
These results suggest that the decline of the contact site between the ER and mitochondria, but not perturbation of homeostasis in the ER and mitochondria, plays important roles in PA-elicited Akt inactivation in hepatic insulin resistance.

STED super-resolution microscopy reveals CLIMP63-dependent domain segregation of lumenal and membrane proteins in ER tubules.
G. Gao1, C. Zhu1, I.R. Nabi1;
1Cellular and Physiological Sciences, The University of British Columbia, Vancouver, BC

The endoplasmic reticulum (ER) is an expansive, membrane-enclosed organelle. It plays crucial roles in numerous cellular processes including protein synthesis, stress response, calcium storage, and lipid metabolism and is classically divided between rough, ribosome-studded ER sheets and smooth, peripheral ER tubules. The spatiotemporal limitations of diffraction limited fluorescent microscopy have hindered efforts to understand microdomain organization and protein distribution within ER tubules and sheets. Here, we apply STED (stimulated emission depletion) super-resolution microscopy to characterize the morphology and microdomains of ER tubules. Live and glutaraldehyde fixed cell imaging with STED reveals that peripheral ER tubules are highly periodic, containing blobs and constrictions not observable by diffraction-limited microscopy. Lumenal (KDELmoxGFP) or membrane (Sec61β-GFP) ER reporters showed different periodicity patterns within the same ER tubule. Triple labeling 3D STED imaging of fixed cells localized endogenous ER protein (Derlin-1, Calnexin) clusters to periodic constrictions of lumenal KDELmoxGFP but not membrane Sec61β-GFP reporter in both isolated peripheral tubules and dense tubular matrices. ER lumenal periodicity and protein localization to periodic ER constrictions were disrupted by siRNA knockdown of the lumenal spacer CLIMP63. CLIMP63 localizes with lumenal KDELmoxGFP and is segregated away from Calnexin and Derlin-1 protein clusters. This suggests that ER tubules are composed of regions of dense ER membrane protein complexes that exclude lumenal ER proteins localized to CLIMP63 microdomains. These results have significant implications for our understanding of ER organization, dynamics and function in normal and diseased conditions.

Membrane binding of PACSIN2 dependent on the characteristics of the membrane.
A.G. Amir1, S. Suetsugu1;
1Biological science, Nara Institute of Science and Technology, Nara, Japan

Cell membrane tension is essential in several phenomena such as cell polarity and motility, exocytosis and endocytosis, adipogenic differentiation and so on. One of mechanisms of how cells adapt for membrane tension is mediated by flattening and disassembly of caveolae, that are small flask-shaped plasma membrane invaginations. Several membrane proteins have been identified to play important roles in caveolae formation. One of those is F-BAR domain protein PACSIN2. PACSIN2 has been reported to be colocalized in and sculpt caveolae. Under tension, PACSIN2 is released from caveolae. Mechanism of the release of PACSIN2 is not fully understood. Here we examined PACSIN2 binding to membrane phospholipids by liposome co-sedimentation assay, using liposomes of various compositions. PACSIN2 strongly binds to liposome made of bovine brain Folch fraction, which mostly contains large amount of phosphatidylserine (PS), a negatively charged phospholipid abundant in caveolae. Because the membrane tension is related to the generation of the packing defects of the membrane, we then examined the binding of PACSIN2 to saturated or unsaturated lipids, which are thought to have different
levels of packing defects. The liposomes were made of phosphatidylcholine with PS, and the two fatty acids of phospholipids was unified as 16:0-16:0, 16:0-18:1, and 18:1-18:1. Among 16:0-16:0 PC/16:0-16:0 PS (DPPC/DPPS), 16:0-18:1 PC/16:0-18:1 PS (POPC/POPS), and 18:1-18:1 PC/ 18:1-18:1 PS (DOPC/DOPS) liposomes, we found that PACSIN2 most strongly bind to DOPC/DOPS, which contain two mono-unsaturated fatty acids, suggesting that packing defects promote the membrane binding of PACSIN2. Then, we investigated the effect of tension to the PACSIN2 binding. We used NaCl buffer to create osmotically-induced tension on liposome surface made of bovine Folch fraction lipids. When concentration of solute is higher inside than outside liposome, tension occurs. However, this induced the rupture of the liposome. By performing osmotically-induced leakage assay, we show that the 0-40mM NaCl concentration differences between the inside and the outside of liposome induced negligible amount of membrane ruptures. However, PACSIN2 binding affinity under 0-40mM NaCl concentration difference remains stable. These results indicate that tension in this range is not sufficient to induce packing defects for alteration of PACSIN2 binding, or tension might not directly affect PACSIN2 binding affinity to membrane, suggesting the other mechanisms for the release of PACSIN2 from the membrane upon membrane tension.

Single molecule and ensemble dynamics of the endoplasmic reticulum.
C.J. Obara1,2, J. Nixon-Abell1,3, C. Blackstone1,3, J. Lippincott-Schwartz1,2; 1Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA, 2Cell Biology and Metabolism Program, National Institute of Child Health and Human Development, Bethesda, MD, 3Cell Biology Section, National Institute of Neurological Disorder and Stroke, Bethesda, MD

The endoplasmic reticulum (ER) is an expasive, membrane-enclosed organelle that plays crucial roles in numerous cellular processes. Besides its clearly defined roles as the major site of cellular translation, the master regulator of calcium homeostasis, and origin of the secretory pathway; it makes contacts with and signals to control the behavior of many other cellular organelles. Despite this diverse set of functions, the spatial location of these processes within the ER network remain poorly characterized due to the highly intricate and dynamic nature of the organelle. Here, we utilize a variety of emerging superresolution imaging technologies to characterize the fine structure and the distribution of ER proteins within the organelle membrane and lumen. We have previously shown that the peripheral ER contains many intricate tubular clusters that cannot be distinguished from continuous sheets by diffraction-limited imaging; we further show that these structures contain diverse biological processes and proteins that are consistent with their complex structure. In fact, the ER is not as homogeneous of a structure as appears with traditional imaging approaches, instead containing a multitude of highly dynamic microdomains throughout the membrane and lumen which carry out individualized biological functions. By performing high speed, simultaneous structured illumination microscopy (SIM) and single particle tracking-photoactivation localization microscopy (sptPALM), we track the behavior of individual proteins within the dynamic membranous network of the ER. We show for the first time a strong effect of organelle structure on the behavior of single ER proteins and protein complexes, suggesting a correlation between the structure of the organelle and the localization of biological functions at the level of individual protein molecules.

Snx14 is a novel lipid metabolism protein at the Endoplasmic Reticulum.  
S. Datta¹, Y. Liu¹, H. Hariri², M. Henne³;  
¹Cell Biology, University of Texas Southwestern Medical Center, Dallas, TX

Cells store high-energy lipids in the form of lipid droplets (LDs), which are harvested during starvation. Although it is recognized that cells also produce LDs when facing imminent starvation, how cells sense this starvation, and coordinate LD biogenesis and turnover, is unknown. Defects in this general adaptive metabolic response are associated with metabolic, cardiovascular, and neurodegenerative diseases. Here, we investigate the role of an uncharacterized protein, Snx14, in lipid metabolism and nutrient stress response. Recent studies from our lab have shown that yeast utilize the nuclear Endoplasmic Reticulum (ER)-vacuole junctions (NVJs) as dynamic metabolic platforms to coordinate LD biogenesis and turnover in response to nutritional stress. NVJ-resident protein Mdm1 localizes to distinct subdomains flanking the NVJ where LDs bud, and its loss perturbs LD biogenesis. Mdm1 has four mammalian homologs (Snx13, Snx14, Snx19 and Snx25), all of which share conserved protein architecture with Mdm1. Among them, Snx14 is associated with neuropathology characterized by cerebellar ataxia. Here, we show that Snx14 localizes to the ER in mammalian cells, where it regulates fatty acid metabolism. Indeed, we observe a significant increase in the LD number and triglyceride (TAG) levels in Snx14 overexpressed cells pulsed with oleate. Moreover, we observe a dramatic redistribution of Snx14 from the ER to LDs following oleate treatment, implying a role for Snx14 in fatty acid-to-TAG conversion. Consistent with this, global RNAseq data indicates a role for SNX14 in metabolism and cellular nutrient stress response. Current and future studies aim to understand the underlying mechanisms by which Snx14 regulates lipid metabolism and adaptive cellular responses to stress.

Evaluation of sterol transport from the endoplasmic reticulum to mitochondria in Saccharomyces cerevisiae.  
S. Tian¹, A. Ohta², H. Horiuchi³, R. Fukuda⁴;  
¹Department of Biotechnology, The University of Tokyo, Tokyo, Japan, ²Department of Biological Chemistry, College of Bioscience and Biotechnology, Chubu University, Aichi, Japan

Sterols are primary components of eukaryotic biological membranes and are included in plasma membranes and organelles at specific ratios. Mitochondrial membranes also contain sterols, and sterol synthesis has been shown to be critical for mitochondria morphogenesis in Saccharomyces cerevisiae. However, it remains unclear how sterol synthesized in the endoplasmic reticulum (ER) is transported to the mitochondria. In this study, we constructed a system to quantitatively measure sterol transport from the ER to mitochondria in S. cerevisiae, and explored its mechanism. In this system, sterol transport was evaluated by sterol esterification using a recombinant bacterial sterol acyltransferase SatA targeted to mitochondria (mito-SatA-EGFP) in a mutant defective in the intrinsic sterol acyltransferases Are1 and Are2 in the ER. When the are1Δare2Δ strain expressing mito-SatA-EGFP was incubated in the presence of [3H]methionine, radiolabeled sterol was converted to steryl ester by mito-SatA-EGFP in the are1Δare2Δ strain. In addition, when the ER membrane containing radiolabeled sterols were incubated with purified mitochondria containing mito-SatA-EGFP in vitro, sterol esterification was observed in a
time-dependent manner. These results suggest that this system will contribute to the elucidation of the mechanism of inter-membrane sterol transport.

Proteomics identifies organelle specific phosphorylation and reveals major subcellular reorganization in the progression of NAFLD.
N. Krahmer1, B. Najafi2, F. Quagliariini3, N.H. Uhlenhaut3, A. Zeigerer2, G.H. Borner1, M. Mann1,4; 1Proteomics and Signal Transduction, Max-Planck Institute of Biochemistry, Martinsried, Germany, 2Institute for Diabetes and Cancer, Helmholtz Zentrum München, München, Germany, 3Helmholtz Diabetes Center (HDC) and German Center for Diabetes Research, Helmholtz Zentrum München, München, Germany, 4NNF Center for Protein Research, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark

Obesity induced non-alcoholic fatty liver disease (NAFLD) is associated with the development of type 2 diabetes and constitutes a major health problem. A hallmark of the diseases is extensive lipid droplet (LD) formation and accumulation of toxic lipid species interfering with cellular signaling and functions. However, the cellular mechanisms during disease progression and cellular lipid overflow are poorly understood. Here, we develop a novel workflow for label free mass spectrometry based protein and phosphopeptide correlation profiling to systematically monitor the level and cellular distribution of ~6000 liver proteins and ~16,000 phosphosites during the development of dietary induced steatosis in mice. We see a redistribution of the secretory apparatus including a mislocalization of the COPI complex, and targeting of all analyzed Golgi apparatus proteins to LDs what leads to a general reduction of hepatic protein secretion. Further, we identify targeting of several organelle contact site proteins to LDs, accompanied by increased contacts between LDs and other organelles. Our resource provides the first systematic in vivo analysis of subcellular re-arrangements and organelle specific phosphorylation during disease development.

EHD proteins cooperate to generate caveolar clusters and to maintain caveolae during repeated mechanical stress.
I. Yeow1, G. Howard1, J. Chadwick1, C. Mendoza-Topaz1, C.G. Hansen1,2, B.J. Nichols1, E. Shvets1,3; 1MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, 2MRC Centre for Inflammation Research, Edinburgh, United Kingdom, 3Sphere Fluidics Limited, Cambridge, United Kingdom

Caveolae introduce flask-shaped convolutions into the plasma membrane, and help to protect the plasma membrane from damage under stretch forces. The protein components that form the bulb of caveolae are increasingly well characterised, but less is known about the contribution of proteins that localise to the constricted neck. Here we make extensive use of multiple CRISPR/Cas9-generated gene knockout and knock-in cell lines to investigate the role of EHD (Eps15 Homology Domain) proteins at the neck of caveolae. We show that EHD1, EHD2 and EHD4 are recruited to caveolae. Recruitment of the other EHDs increases markedly when EHD2, which has been previously detected at caveolae, is absent. Construction of knockout cell lines lacking EHDs 1, 2 and 4 confirms this apparent functional redundancy. Two striking sets of phenotypes are observed in EHD1,2,4 knockout cells: 1. The
characteristic clustering of caveolae into higher order assemblies is absent. When the EHD1,2,4 knockout cells are subjected to prolonged cycles of stretch forces, caveolae are destabilised and the plasma membrane is much more likely to rupture. Our data identify the first molecular components that act to cluster caveolae into a membrane ultrastructure with the potential to extend stretch buffering capacity, and support a revised model for the function of EHDs at the caveolar neck.

Cholesterol remodeling may protect cells from pore-forming toxins by enhancing membrane repair.
R. Thapa¹, M. Romero¹, P.A. Keyel¹;
¹Biological Sciences, Texas Tech University, Lubbock, TX

Necrotizing fasciitis and gas gangrene are caused by Streptococcus pyogenes and Clostridium perfringens, respectively. Both organisms produce virulence factors including cholesterol dependent cytolysins (CDCs), which bind to cholesterol on mammalian membranes and form lytic pores. The lethal threat these pores pose is countered by membrane repair. One mechanism of membrane repair is intrinsic repair, the sequestration and shedding of CDCs on cholesterol-enriched microvesicles. How cells sequester and shed CDCs is unknown. Toxin oligomerization, is sufficient to promote shedding, suggesting that intrinsic repair relies on membrane remodeling or the alteration of lipid domains. We hypothesize that cholesterol accessibility and cholesterol microdomain architecture drive sequestration and shedding during intrinsic repair. We tested this hypothesis by controlling the membrane cholesterol during CDC challenge in three ways: addition of hydroxypropyl-β-cyclodextrin (HPCD) to remove cholesterol, addition of monomeric, pore-deficient CDCs to sequester cholesterol, or addition of oligomeric, pore-deficient CDCs that enhance intrinsic repair. First, we carried competitive cytotoxicity assays using active (wild-type) and inactive CDCs alone or together. We found that treatment with excess inactive toxins did not impair wild-type toxin binding, but these inactive toxins protected multiple cell lines from CDCs. When we treated cells with HPCD, we found that low doses of HPCD decreased toxin activity without impairing toxin. These results suggest that cholesterol availability may regulate toxin activity to protect cells from CDCs. Thus, cholesterol remodeling may play a key role in promoting host survival during necrotizing fasciitis or gas gangrene.

Dietary fatty acids direct differentiation of mesenchymal stem cells through lipidomic remodeling, microdomain stabilization, and enhancement of Akt signaling.
K.R. Levental¹, J.H. Lorent¹, Y. Zhou¹, J.F. Hancock¹, L. Levental¹;
¹Integrative Biology and Pharmacology, McGovern Medical School at the University of Texas Health Science Center Houston, Houston, TX

The plasma membrane is the interface between a cell and its environment and conducts the majority of extracellular signaling. These functions are strictly dependent on both membrane lipid compositions and the biophysical phenotypes (e.g. membrane fluidity and lateral organization arising from collective lipid behavior). Dietary perturbations of lipid profiles can have severe deleterious consequences (e.g. hypercholesterolemia) or be broadly therapeutic, as with -3 polyunsaturated fatty acids (PUFAs). The molecular mechanisms underlying these effects are not clear; however, an intriguing possibility is that dietary fats integrate into membrane lipids, change membrane properties, and thereby affect cell signal
transduction. We have observed extensive, cell-autonomous remodeling of both cellular and plasma membrane (PM) lipidomes during human mesenchymal stem cell (MSC) differentiation into adipocytes and osteoblasts. Lipidomic differentiation results in unique, cell-specific membrane compositions, with osteoblasts containing longer and more polyunsaturated lipids, which result in more ordered membranes and more stable raft microdomains. The distinct features of osteoblast membranes enabled rational remodeling of membrane phenotypes to direct lineage specification in MSCs. Specifically, supplementation with a lipid component characteristic to osteoblasts (the -3 PUFA docosahexaenoic acid, DHA) induces broad lipidomic remodeling in MSCs, reproducing features of an osteoblastic membrane phenotype. Specifically, DHA robustly incorporated into specific membrane lipids, eliciting compensatory lipidomic responses in the cells. Together, these lipidomic changes reproduced osteoblast membrane biophysical phenotypes, namely stabilized membrane microdomains. These changes to the membrane phenotypes in MSCs affected PM signaling, most notably resulting in Akt recruitment and activation at the plasma membrane. Finally, this DHA-mediated induction of the osteoblastic membrane phenotype significantly affected differentiation of MSCs, specifically potentiating osteogenic differentiation. These results demonstrate that membrane phenotypes are central drivers of cell function and are susceptible to remodeling by exogenous fatty acids, suggesting a novel mechanism wherein dietary fats affect cellular physiology through remodeling of membrane lipidomes, biophysical properties, and signaling.

**Phosphoinositide diffusion in the plasma membrane reveals distinct populations in COS-7 cells.**
J.E. Pacheco1, G.R. Hammond1; 1Department of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Polyphosphoinositides (PPIns) are key regulatory lipids that coordinate diverse cellular functions. PtdIns(4,5)P2 in particular is a pivotal lipid that regulates many plasma membrane functions, including signaling, endo/exocytosis, modulation of ion channels and the formation of cellular junctions, to name just a few. This wide range of function demands a tightly controlled spatial and temporal PtdIns(4,5)P2 distribution, to prevent cross-talk in the activation of distinct cellular processes. PtdIns(4,5)P2 has been shown to form clusters at specialized cellular structures, like phagosomes or synaptic terminals. These cellular structures are also enriched in phosphatidylinositol 4-phosphate 5-kinase (PIPSK), the enzyme that predominantly synthesizes PtdIns(4,5)P2. In addition to these structures, there are great number of potential membrane domains with important physiological functions where PtdIns(4,5)P2 is involved, but nothing is known about the dynamic of PtdIns(4,5)P2 in these domains. Here, by using genetically encoded sensors of PtdIns(4,5)P2 fused to photoconvertible fluorescent protein mEos2, we tracked individual molecules of PtdIns(4,5)P2 in the plasma membrane of living cells. The lateral mobility of PtdIns(4,5)P2 yielded an apparent diffusion coefficient of 0.15 μm² /s. To extract fine information of single molecule trajectories, we computed radial displacement distributions, which allowed the identification of two populations with different mobility. Both populations showed Brownian motion, but diffusion coefficients displayed significant differences. For the fast population the diffusion coefficient was of 0.2 μm² /s and represented a 68% of all trajectories, meanwhile for the slow population the diffusion coefficient was 0.03 μm² /s. We are attempting to correlate the spatial distribution of these populations with respect to membrane domains specialized for function, such as clathrin-coated structures and focal adhesions. These results shows that PtdIns(4,5)P2 exhibits heterogeneous motion and suggest the presence of nanodomains in the plasma membrane, which could harbor relevant physiological functions.

*Plasma membrane wounding and repair occurs during BCR-antigen interaction and promotes B cell activation.*  
F.Y. Maeda¹, J. Van Haaren¹, N.W. Andrews¹, W. Song¹;  
¹Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

B lymphocytes survey antigen through the B cell receptor (BCR), which activates B cells to mount antibody responses against infectious agents. We previously showed that plasma membrane wounding and repair caused by bacterial pore-forming toxins interferes with BCR activation due to competition for lipid rafts (1). This study addresses whether the plasma membrane wounding occurs when B cells engage antigen, and if repair of such wounds impacts B cell activation. Using live cell imaging, flow cytometry and a membrane impermeable dye we found that pseudo and bone fide antigen but not transferrin, when immobilized to beads, wound the plasma membrane of B cells in an antigen dose-dependent manner. The wounding triggers lysosome exocytosis and production of ceramide at the junction between B cells and antigen-coated beads. Inhibition of lysosomal exocytosis and secretion of the lysosomal enzyme acidic sphingomyelinase, which generates ceramide at the outer leaflet of the plasma membrane, increases the number of wounded B cells. Wounded B cells show enhanced polarization of surface BCR, ceramide, and phosphorylated tyrosine toward the antigen-bead binding sites as well as internalization of the immobilized antigen, when compared to non-wounded B cells. Collectively, these results suggest that immobilized antigen can wound the plasma membrane of B cells at the antigen binding sites, and that repair of the wounds can enhance B cell activation by facilitating surface BCR/lipid raft polarization and antigen uptake.

*Crosstalk between membrane lipid unsaturation and inter-organelle lipid transport.*  
M. Renne¹, M. Hokken¹, D. Bierhuizen¹, X. Ma¹, X. Bao¹, T. de Kroon¹;  
¹Membrane Biochemistry Biophysics, Utrecht University, Utrecht, Netherlands

Membrane lipids are synthesized in different organelles, requiring transport of lipids between organelles. Mitochondria contain enzymes for producing phosphatidylethanolamine and cardiolipin. Their precursors, phosphatidylserine (PS) and phosphatidic acid, respectively, are synthesized in the endoplasmic reticulum (ER) and transported to mitochondria. Transport is thought to occur at regions of close contact between these organelles. In the yeast S. cerevisiae two protein complexes that tether ER and mitochondria have been identified: the ER–mitochondria encounter structure (ERMES) [1], and the ER membrane complex (EMC) [2] that are both proposed to be involved in lipid transport, however, the molecular mechanism is not known. Furthermore, a protein complex that clamps the vacuole to the mitochondria, the vacuole mitochondria patch (vCLAMP) was identified and implicated in mitochondrial lipid import [3,4].  
The efficiency of transport of newly synthesized PS into mitochondria was previously shown to be inversely related to molecular hydrophobicity, with less hydrophobic molecular species (with shorter and/or more unsaturated acyl chains) transported more efficiently into mitochondria than more hydrophobic species [5].
Recently, our lab showed that the yeast glycerol-3-phosphate acyltransferase Sct1p affects membrane lipid unsaturation by competing with the desaturase Ole1p for their shared substrate palmitoyl (C16:0)-CoA [6]. Overexpression of SCT1 decreases membrane lipid unsaturation and causes a growth phenotype. Loss of Psd1p, the mitochondrial enzyme that decarboxylates PS to PE, exacerbates the SCT1-overexpression growth phenotype and further decreases lipid unsaturation upon SCT1-overexpression, consistent with mitochondria serving as a sink for lipids with unsaturated acyl chains. This growth phenotype was recapitulated in ERMES- and vCLAMP- but not in EMC single deletion mutants, supporting a role for the ERMES and vCLAMP complexes in lipid transport. Currently we are studying the effect of inactivating ERMES- and EMC components on lipid acyl chain composition. We propose manipulation of lipid composition by overexpression of SCT1 as a tool for increasing the resolution in monitoring lipid metabolism and transport.

Spatial organization of ER–PM junctions revealed by super- and high-resolution imaging.
T. Hsieh, Y. Chen, C. Chang, W. Lee, J. Liou;
1Department of Physiology, University of Texas Southwestern Medical Center, Dallas, TX

The endoplasmic reticulum (ER) extends widely and forms junctions with virtually all the other membrane-bound organelles in eukaryotic cells. These ER–organelle junctions enable direct interactions and transfer of molecules between the ER and its apposing organelles to fulfill various cellular functions. Particularly, ER–plasma membrane (PM) junctions mediate crucial activities ranging from Ca\(^{2+}\) signaling to lipid metabolism. The location and extent of these cellular activities may be modulated by spatial organization of ER–PM junctions in the cell cortex. Nevertheless, the morphology and distribution of ER–PM junctions are not well characterized. Using photoactivated localization microscopy (PALM), we reveal ER–PM junctions are main ablong with the dimensions at 100-nm scale. Using total internal reflection fluorescence microscopy (TIRFM) and structure illumination microscopy (SIM), we show that F-actin contributes to spatial distribution and stability of ER–PM junctions. Further functional assays suggest that intact F-actin architecture is required for phosphatidylinositol 4,5-bisphosphate [PI(4,5)P\(_2\)] homeostasis mediated by ER–PM junctions. Taken together, our study provides quantitative information about spatial organization of ER–PM junctions that is in part regulated by F-actin. We envision functions of ER–PM junctions can be differentially regulated through dynamic actin architecture during cellular processes.

Involvement of membrane rafts in acrosome reaction of avian sperm via cAMP-dependent pathway.
C. Priyadarshana1, N. Ishikawa2, A. Tajima2, A. Asano2;
1Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan, 2Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan

Membrane rafts are specific membrane regions enriched in sterols and functional proteins, and play important roles in diverse cellular processes. Transcriptionally and translationally inactive, sperm need these membrane domains pre-assembled into specific cellular compartments where function needs later. Recently, we demonstrated in chicken sperm that membrane rafts exist in the plasma membrane overlaying sperm head region. This, combined with our previous finding of functional importance of membrane rafts in acrosome reaction (AR) in mammalian sperm, led us to investigate roles of membrane rafts in signaling pathways leading to AR in chicken sperm. Using 2-hydroxypropyl-beta-cyclodextrin (2OHCD), we showed that disruption of membrane rafts inhibited protein phosphorylation of PKA substrate and acrosome reaction in response to physiological stimulation although intra-cellular Ca2+ was increased. Furthermore, cytosolic cAMP level was decreased in 2OHCD-treated sperm. However, those inhibitions were abolished by treatment with dibutylryl cAMP, suggesting a role of membrane rafts in regulation of PKA pathway in chicken sperm. To seek an upstream cascade, we examined the involvement of soluble AC (sAC) and transmembrane AC (tmAC) in the inhibition of PKA substrate phosphorylation and AR using specific AC stimulators (NaHCO3- and Forskolin) and inhibitors (KH7 and MDL-12,330A). The results showed that both stimulators and inhibitors were effective for regulation of PKA substrate phosphorylation, suggesting presence of both proteins in chicken sperm. Furthermore, treatments with both sAC and tmAC stimulators rescued 2OHCD-induced inhibition of PKA substrate phosphorylation and AR. Conclusively, our results demonstrated that membrane rafts play an important role in acrosome reaction via regulating cAMP dependent pathway involving PKA.

Plasmodesmata defects observed in UDP-glucose:sterol glucosyltransferase B1 mutants.
V.G. Pook1, M. Nair1, S. DeBolt1;
1Horticulture, University of Kentucky, Lexington, KY

Sterol glucosides are found ubiquitously in higher plants but their biological function remains elusive. Though it is clear that the presence of these glycosylated sterol derivatives alters the biophysical properties of the membrane, how it affects membrane function is still under investigation. Here, we use transmission electron microscopy (TEM) to explore the morphology of plasmodesmata (PD) in lines of Arabidopsis thaliana carrying insertions in the UDP-Glc:sterol glucosyltransferase gene, UGT80B1. We show that the PD of the mutant line differ from those of wild-type plants. Firstly, we observed a significantly higher frequency of branched PD in ugt80B1 mutants. In addition, while the simple linear PD of wild-type plants were often dilated, those of the mutant line were not. We postulate that the altered membrane lipid profile found in ugt80B1 mutants leads to aberrant PD morphology.
The eukaryotic plasma membrane is compartmentalized into nano- and microscale domains enriched in particular lipids and proteins. However, our understanding of the molecular bases and biological roles of this partitioning remains incomplete. Here we report that clustering of the yeast Can1 permease in eisosome domains requires complex sphingolipids, is dictated by its conformation, and controls its ubiquitin-dependent turnover. In its substrate-free outward-open conformation, Can1 accumulates in eisosomes, while a substrate-induced shift to an inward-facing conformation promotes its cell surface dissipation and accessibility to the ubiquitylation machinery. Furthermore, under starvation conditions an Lsp1-dependent expansion of eisosomes provides protection for Can1 and other transporters from bulk endocytosis parallel with autophagy. Our results illustrate that the highly dynamic lateral segregation of membrane transporters is governed by the combined effects of their conformation and sphingolipids. They also highlight regulated protection from ubiquitylation and endocytosis as a novel role for protein partitioning into membrane domains.

Kinases and Phosphatases 1

The allosteric regulation of protein function plays important roles in many cellular signaling pathways, including cell metabolism, growth, division and programmed cell death. Allosteric proteins typically show a modular organization that results in segregated functional domains. Often, the communication between domains is triggered by external stimuli like ligand binding, and results in high-order functions such a cooperativity and allostery. How the protein's communication is modulated by ligand binding to enable the propagation of signals from one domain to another remains poorly understood. Here, we investigate the communication between the two cAMP binding domains (CBD) in the regulatory subunit of Protein Kinase A. We use optical tweezers to mechanically unfold each CBD alone or as part of the regulatory subunit, with and without cAMP. We find that cAMP stabilizes each individual CBD, but the magnitude of stabilization is markedly different. This result highlights that conservation in structure does not entail conservation in structural stability. The selective unfolding of each CBD within the regulatory subunit shows that cAMP triggers networks of communication that involve direct, interfacial interactions between the two CBDs as well as long-range interactions between non-contiguous structural motifs. The mutant R241A, a hotspot residue position for allosteric interaction, severely disrupts the interaction between two CBD domains. This study allows us to dissect how a ligand turns on
and off domain communication in allosteric proteins. Moreover, this study enabled the identification and characterization of aberrant allosteric events associated with mutations observed in the disease state.

Impact of Phosphorylation by Met on FAK Activation.
H. Gessessew¹, L. O'Connor¹, J.E. Hall¹;
¹Biology, Bucknell University, Lewisburg, PA

Focal adhesion kinase (FAK) is a non receptor tyrosine kinase that plays a role in development, homeostasis and progression of human diseases. FAK has three structured domains; FERM, kinase, and FAT (focal adhesion targeting domain). The FERM domain covers the catalytic domain in an autoinhibited conformation, which must be released for full catalytic activity. FAK responds to multiple stimuli such as growth factor receptors and integrins. The met receptor is an example of one of the diverse activation stimuli. It relieves FAK autoinhibition in response to hepatocyte growth factor (HGF) stimulation. This stimulation leads to phosphorylation of the activation loop of FAK, which blocks the FERM domain from binding to the catalytic domain. Additional studies have shown the met receptor phosphorylates FAK on Y194 in this interaction. The effect of this phosphorylation is what we sought to investigate. A FRET-based biosensor was used to detect the conformational change of FAK upon activation. MDCK cells transfected with FAK biosensor were used to measure basal FRET levels and upon HGF stimulation. HGF binds to and activates the met receptor which in turn binds to and activates FAK. In order to study the effect of Y194 phosphorylation, two mutants were made using site directed mutagenesis. The Y194E mutation mimics the phosphorylated state of FAK. The Y194F mutation prevents phosphorylation at this site. The effects of these mutations will be observed using FRET-based and biochemical assays. This study gives a more complete understanding of FAK activation via the met receptor.

Encoding optical control in LCK kinase to study its function and effect of coreceptor binding in live cells.
A. Liaunardy-Jopeace¹, B.L. Murton¹, M. Mahesh², J.W. Chin², J.R. James¹;
¹Department of Medicine, University of Cambridge, Cambridge, United Kingdom, ²Medical Research Council Laboratory of Molecular Biology, Cambridge, United Kingdom

LCK is a tyrosine kinase essential for initiating T-cell antigen receptor (TCR) signaling. A complete understanding of LCK function is constrained by a paucity of methods to quantitatively investigate its activity within live cells. To address this limitation, we generated LCK*, in which a key active site lysine is replaced by a photo-caged equivalent, using genetic code expansion. This enabled fine temporal and spatial control over kinase activity, allowing us to measure phosphorylation kinetics in situ using biochemical and imaging approaches. We find that auto-phosphorylation of the active site loop of LCK is indispensable for its catalytic activity. Furthermore, LCK kinase can stimulate its own activation by adopting a more open conformation, which can be modulated by point mutations. We then show that CD4 and CD8, the T cell co-receptors, can enhance LCK activity, explaining their effect in physiological TCR signaling. Our approach also provides general insights into SRC-family kinase dynamics.

Engineered Allosteric Regulation of Protein Kinases by Light.
M. Shaaya1, V. Huyot1, V. Natarajan1, A.V. Karginov1;
1Cellular and Molecular Pharmacology, University of Illinois at Chicago, Chicago, IL

A single protein kinase can initiate very distinct physiological and pathological processes depending on the timing and the location of its activation in the cell. However, interrogation of kinase-mediated processes remains challenging due to the paucity of tools that precisely regulate kinases in space and time. To overcome existing limitations, we developed a novel approach for light-mediated regulation of kinases. We engineered a light-regulated allosteric switch (LightR), a small domain based on Vivid (VVD) photoreceptor, that undergoes conformational changes upon illumination with blue light. Insertion of LightR at a specific location in the catalytic domain of Src kinase enables light-mediated control of its activity. In the dark, engineered LightR-Src is inactive. Illumination of cells with blue light leads to robust activation of the kinase. Activation of LightR-Src is specific, fast, and reversible. This allows us to mimic transient activation of the kinase in living cells. The level of activation can be controlled by changing light intensity. Specific modifications of the LightR domain allow us to modulate the activation/inactivation kinetics and the level of activity of LightR-Src, enabling additional “tuning” of the engineered kinase and its optimization for different applications. Activation of LightR-Src in living cells induces robust cell spreading and protrusive activity, which are known Src-induced phenotypes described in previous studies. Importantly, the morphological changes stop as soon as the kinase is inactivated, demonstrating reversibility of the manipulated signaling. Repeated activation/inactivation of LightR-Src induces cycles of morphodynamic activity of the cells, showing the capability of this tool to mimic oscillation of kinase signaling in living cells. Localized illumination of cells induces local formation of protrusions demonstrating spatial regulation of LightR-Src. Insertion of LightR domain at a homologous position in Abl kinase also enabled light-mediated regulation of its activity. These results, and the high structural similarity among catalytic domains of kinases, suggest broad applicability of this tool for regulation of different kinases. Furthermore, this approach could be potentially employed to control the activity of other enzymes in time and space.

Polymerization of the mitochondrial phosphatase PGAM5 underlies its biological activity.
K. Ruiz1, T.M. Thaker1, L. Miller-Vedam2, C. Agnew1, A. Frost2, N. Jura13;
1Cardiovascular Research Institute, University of California San Francisco, San Francisco, CA,
2Department of Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA,
3Department of Cellular and Molecular Pharmacology, University of California San Francisco, San Francisco, CA

Phosphoglycerate mutase family member 5 (PGAM5) is an atypical protein phosphatase localized to the mitochondrial membranes through a transmembrane domain tether. PGAM5 is involved in regulation of mitochondrial fission, and has been shown to promote cell death in response to oxidative stress or mitochondrial damage. The cell death response is believed to be triggered when PGAM5 is cleaved from mitochondrial membranes and relocated to the cytosol. The physiological importance of PGAM5 is underscored by genetic studies in mice, which revealed that PGAM5 deficiency causes a Parkinson’s Disease-like disorder. The mechanism for regulation of the PGAM5 phosphatase domain activity has been poorly understood, and as a result the tools for understanding biological functions of PGAM5 or
demonstrates immunosuppressants, we evidence mitochondrial cryo approaches these predicted microscopy, identified contains select developing into phosphatases. 

Electron microscopy, we demonstrate that PGAM5 adopts the dodecameric structure also in solution and we show, for the first time, that this assembly is critical for PGAM5 phosphatase activity and its role in mitochondrial homeostasis. Our new high resolution crystal structure of the PGAM5 dodecamer demonstrates that the multimerization motif serves as an allosteric activation domain. Furthermore, our electron microscopy analysis of the purified PGAM5 reveals that the cleaved form of PGAM5 organizes into long filaments composed of the dodecameric PGAM5 rings. Using super resolution fluorescence microscopy, we demonstrate presence of these filaments in the cytoplasm of intact cells and provide evidence that PGAM5 oligomerization is necessary for function of PGAM5 as activator of cell death. In summary, our work uncovers novel structures of the multimeric PGAM5 assemblies and demonstrates their importance for PGAM5 signaling.

Mapping the human calcineurin phosphatase signaling network through global identification of short linear motifs that mediate substrate recognition.

J. Roy¹, C.P. Wigington¹, N.P. Damle¹, I. Ulengin-Talkish¹, S. Ei Cho¹, N.E. Davey², Y. Ivarsson³, C.J. Wong⁴, A. Gingras⁵, M.S. Cyert¹;
¹Biology, Stanford University, Stanford, CA, ²Conway Institute of Biomolecular and Biomedical Research, University College Dublin, Dublin, North Ireland, ³Chemistry - BMC, Uppsala University, Uppsala, Sweden, ⁴Lunenfeld-Tanenbaum Research Institute at Mount Sinai Hospital, University of Toronto, Toronto, Canada

Systems level analyses of phospho-signaling networks requires the understanding of both kinases and phosphatases. However, current knowledge of phosphatase functions is limited by the lack of global approaches for substrate identification. Recent work has shown that many phosphatases use short linear motifs (SLiMs), which are located in intrinsically disordered regions, to recognize their binding partners and achieve specificity in spite of considerable degeneracy at the phospho-sites on which they act. Calcineurin (CN), the conserved Ca2+/calmodulin-dependent protein phosphatase and target of immunosuppressants, FK506 and Cyclosporin A, recognizes substrates via two conserved SLiMs, ‘PxIxIT’ and ‘LxVP’. CN is ubiquitously expressed, and has identified roles in the immune system, heart, and brain, but many of its substrates and functions are as yet undiscovered. We defined the CN-signaling network by integrating experimental and computational approaches to identify proteins that interact with CN throughout the proteome. We used proteomic peptide phage display (ProP-PD) to directly select calcineurin-binding SLiMs from predicted disordered regions of the human proteome, and identified PxIxIT and LxVP sequences that define 41 new candidate substrates. After confirming that these peptides bind CN with specificity in vitro, we used them, along with known CN binding motifs, to develop a Position Specific Scoring Matrix (PSSM) and defined a set of 846 human proteins containing predicted PxIxIT and/or LxVP sequences that are highly likely to be CN substrates or regulators. Further, we used proximity based BioID/MS analyses to identify CN interacting partners in HEK293 cells, of which >40% are predicted to contain CN binding SLiMs using the PSSM. This combinatorial approach has allowed us to build a high confidence CN signaling network, which connects CN to several new cellular processes such as nuclear transport, cytoskeletal organization and mitosis, and to diseases such as schizophrenia, autism and myocardial ischemia. Additionally, we show that the signaling protein Notch1 contains a CN-interacting LxVP SLiM and is a novel CN target. CN interacts with Notch1 in vivo and
regulates its phosphorylation both in vivo and in vitro. We demonstrate that CN de-phosphorylates Notch1 and enhances its steady-state levels in vivo to positively impact Notch1 signaling. Thus our analyses not only expands the role of CN in known cellular pathways and disease processes but also uncovers new roles for this enzyme in novel signaling pathways.

*The Mutation of the PTPN11 Gene that Encodes SHP-2 Protein Promotes Tumorigenic Activity of the NF1-Deficient cells.*

Y. Arima¹, R. Harigai¹, H. Saya²;
¹Division of Gene Regulation, Institute for Advanced Medical Research, Keio University School of Medicine, Tokyo, Japan
²Department of Developmental Biology, Keio University

The NF1 tumor suppressor gene encodes neurofibromin and is a functional Ras GTPase-activating protein (RasGAP) involved in negatively regulating the Ras signals by accelerating the conversion of activated Ras-GTP to inactive Ras-GDP. NF1 gene germline mutations cause Neurofibromatosis type 1 (NF1, von Recklinghausen disease). We inoculated the GFP-labeled human NF1-deficient cell line sNF96.2-GFP into immunodeficient mice, and sub-clonal cell lines were established from developed tumors. To determine the additional genetic alterations that promote malignancy of NF1-associated tumors, we analyzed the genomic DNA by using the next-generation sequencing. We identified 18 heterozygous variants within the coding regions of 17 genes that were present in the tumor-derived cells. Because phosphorylations of Akt and MEK were increased in the tumor-derived cells, we focused on *BRAP* (c.1109G>C, p.Gly370Ala) and *PTPN11* (c.1508G>T, p.Gly503Val), which are thought to be associated with the Ras pathway. *BRAP* and *PTPN11* genes encode the BRCA1-associated protein and the tyrosine phosphatase SHP-2, respectively. To determine the role of those gene mutations in the malignant progression of NF1-associated tumors, we established three overexpressing cell lines, *BRAP*mut, *PTPN11*mut, and *BRAP*mut/PTPN11mut. We inoculated the parental sNF96.2-GFP cells and those overexpressing cells into nude mice, and found that the *PTPN11*mut cells show a much higher tumorigenic activity than the parental sNF96.2-GFP cells. However, *BRAP*mut and *BRAP*mut/PTPN11mut cells did not form tumors, thus indicating that *BRAP*mut suppresses *PTPN11*mut-mediated tumorigenic activity. Western blot analysis revealed that the phosphorylation of MEK was increased in the *PTPN11*mut cells, but in neither the *BRAP*mut cells nor in the *BRAP*mut/PTPN11mut cells. Our data indicates that this mutation in the *PTPN11* gene promotes the malignant characteristics of NF1-associated tumors, and that this tumor promotion is canceled by the *BRAP* gene mutation. The combination of *PTPN11* gene mutations and the NF1 gene mutations appears to induce a pathological activation of the Ras pathway.

*Active-site dependent and independent roles of the lipid phosphatase Fig4 in the activation of its opposing kinase, Fab1.*

B.S. Strunk¹,², N. Kumar³, N. Jin¹,², N. Steinfeld¹, K.M. Reinisch³, L.S. Weisman¹,²;
¹Life Sciences Institute, University of Michigan, Ann Arbor, MI, ²Department of Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, ³Department of Cell Biology, Yale School of Medicine, New Haven, CT

PI lipid phosphatases modulate signaling cascades through localized dephosphorylation of specific phosphoinositides (PI) on subcellular membranes. In addition, a number of these phosphatases likely
regulate cellular processes through lipid phosphatase independent functions. For example, it has been suggested that Fig4, a PI 5-phosphatase proposed to dephosphorylate PI3,5P2, also activates its opposing kinase, Fab1. Fig4 is required to form the Fab1-Vac14-Fig4 complex and this complex is required for elevation of PI3,5P2. Here we show that Fig4 dependent activation of Fab1 is largely, but not entirely, independent of Fig4 catalytic function. The catalytically inactive Fig4-C467S mutant supports 75% - 80% of stress induced elevation of PI3,5P2. Notably, when compared with wild-type Fig4, Fig4-C467S dramatically enhances association of Fig4 and Vac14 with Fab1. One possibility is that Fig4 acts as a protein phosphatase, and that tight binding to Fab1 occurs via a substrate trapping effect. Alternatively or in addition, there may be active site dependent conformational rearrangements within the Fab1-Vac14-Fig4 complex. We found that at least two sites on opposite sides of the Fig4 active site modulate Fig4 association with the Fab1-Vac14-Fig4 complex. The Fig4 C-terminal tail was known to contact the Fab1-Vac14-Fig4 complex through direct association with Vac14. Our studies reveal an N-terminal surface on the Fig4 phosphatase domain that influences both a newly identified interaction between the phosphatase domain and the C-terminal tail of Fig4 as well as the interaction of these domains with Vac14. This surface was identified through investigation of amino acids corresponding to human neurodegenerative disease related mutations. Notably, studies of other PI-phosphatases suggest that these enzymes regulate protein partners through both phosphatase-dependent and phosphatase-independent mechanisms. We propose that the ability to behave as active site-dependent conformational switches may be a common property of PI-phosphatases.

Non-Canonical Activation of p38 During Endoplasmic Reticulum Stress.
J.L. Brewster¹, D. Reynolds¹, J.G. Tolar¹;
¹Natural Science Division, Pepperdine University, Malibu, CA

In all eukaryotic cells, stress signaling from the endoplasmic reticulum (ER) plays a critical role in cellular adaptation and in the maintenance of homeostasis. Severe disruption of ER function can induce dramatic changes in cellular behavior or even apoptosis (cell suicide). This study evaluates stress signaling from the ER resident signaling kinase known as PKR-like ER kinase (PERK). Prior work in our lab has shown PERK to play an essential role in the activation of apoptosis during ER stress. Downstream of PERK activity is the stress-activated kinase, p38, whose activity is required for apoptosis activation during some forms of ER stress. The mechanism of PERK and p38 interaction is not well understood. Heat Shock Protein 90 (HSP90) is a cytosolic chaperone that binds to inactive p38. Release of p38 from HSP90 is known to enable autoactivation of this kinase. In this study, we used hamster kidney fibroblasts (BHK21 cells) in cell culture to evaluate ER stress signaling. Inhibition of HSP90 (17-AAG treatment) was sufficient to induce phosphorylation of p38 on threonine 180 (T180), a marker of p38 activation. When the timing of this activation was evaluated, 17-AAG was shown to induce p38 within 5 minutes of exposure and to continue for approximately 30 minutes. Tunicamycin, an activator of ER stress, caused an activation of p38 along a similar pattern of 5-30 minutes. To examine if ER stress was sufficient to induce p38 dissociation from HSP90, immunoprecipitation assays were used. Cells overexpressing p38 (FLAG-tagged) were lysed and an anti-FLAG antibody used to pull p38 down from the lysate. HSP90 co-immunoprecipitated with p38, and this association was diminished by either HSP90 inhibition or ER stress activation. Assessment of the dependence of PERK activity upon stimulation of p38 release is ongoing and will be discussed.

The Role of SIK1 in Regulating Apical NHERF1 and Ion Transporters.
M.L. Taub1, J. Mulkin1;
1Biochemistry, University at Buffalo, Buffalo, NY

Salt Inducible Kinase (SIK) is a Ser/Thr kinase that is activated (and induced) in response to increases in intracellular Na+ in a number of different tissues (including adrenal and kidney). SIK1 has been shown to play a role in regulating renal proximal tubule Na,KATPase, both transcriptionally and post-transcriptionally (activating basolateral Na,KATPase). In order to study the role of SIK1 in the renal proximal tubule further, we have examined the effect of a SIK1 knockdown on the expression of apical transporters in the renal proximal tubule. The laboratory of Dr. Rebecca Berdeaux (UT Houston) provided us with formalin-fixed kidneys from mice with expressing catalytically inactive SIK1 (KO SIK1), as well as from wildtype (WT) littermates. After paraffin embedding, sectioned kidney slices, we examined the sections by immunofluorescence microscopy to look at the effect of the SIK1 KO on several apical proximal tubule ion transporters (a Na+H+ antiporter, NHE3 and a Na+Pi cotransporter, NPT2a) and a regulatory protein, NHE Regulatory Factor 1 (NHERF1). NHE3 and NPT2a are essential for the reabsorption of Na+ and Pi, respectively, by the renal proximal tubule. NHERF1 plays an important role in regulating the level of NHE3 and NPT2a in the apical membrane. Thus, all of these membrane proteins are essential for Na+ and Pi homeostasis. Our results indicated that the SIK1 KO caused a reduction in the level of apical NHE3 and NPT2a, and this could be explained by a similar reduction in the level of NHERF1. These observations suggest that SIK1 likely plays a previously unknown role in regulating NHERF1 expression.

The A-kinase anchoring protein beta-synemin binds PKC epsilon.
B.C. Prudner1, M.J. Kuneli2, Y. Chen3, D.S. Damron4, M.A. Russell5;
1Internal Medicine - Medical Oncology, Washington University in St. Louis, St. Louis, MO, 2College of Nursing, Kent State University at Trumbull, Warren, OH, 3Department of Biological Sciences, Kent State University at Trumbull, Warren, OH, 4Department of Biological Sciences, Kent State University, Kent, OH

Synemin is a type IV intermediate filament protein. The two largest isoforms (alpha and beta) are usually co-expressed such as in muscle cells. Earlier we found that in muscle cells alpha-synemin preferentially localizes to the sarcolemma and intercalated disks while beta-synemin is concentrated at the Z-disks. Both isoforms also have an unusually long tail domain. This domain is a site for numerous protein interactions, some unique to each isoform and some common to both. For example, in the past we found that both bind protein kinase A (PKA) and are thus also classified as A-kinase anchoring proteins (AKAPs). AKAPs act to tether PKA to specific subcellular locations to maintain the specificity of the PKA signaling pathway. Excitingly, we have now found evidence that synemin also binds PKC epsilon. Specifically, co-immunoprecipitation studies show that PKC epsilon binds to beta-synemin only upon stimulation of the beta-adrenergic pathway with isoproterenol. Additionally, western analysis using cells expressing either wild type or mutant synemin indicates that, upon loss of beta-synemin anchored PKA, there is a decrease in phosphorylation of PKC substrates, including an ~22 kDa protein. Studies are ongoing to determine the identity of this protein. Based on molecular weight and known PKC epsilon substrates in muscle cells we predict this protein is either troponin I (TnI) or myosin regulatory light chain 2 (RLC2). In support of RLC2, yeast-two hybrid analysis revealed that protein-protein interaction
occurs between beta-synemin and RLC2. Thus, beta-synemin is proposed be a site of cross-talk between PKA and PKC epsilon and also may localize these kinases to the sarcomere near known PKA and PKC epsilon substrates.

Distinct mechanism of spleen tyrosine kinase activation by pITAM and Integrin cytoplasmic domain.

L. Antenucci¹; J. Yläne¹; L. Antenucci²

¹Department of Biological and Environmental Science and Nanoscience Center, University of Jyväskylä, Jyväskylä, Finland

Spleen tyrosine kinase (Syk) is involved in activation and development of hematopoietic cells, osteoblast differentiation, and, more generally in cellular adhesion [1]. Syk activation by genomic rearrangement is linked to certain T-cell lymphomas and Syk inhibitors have been shown to prolong survival of patients with B cell lineage malignancies [2]. Normal Syk activation is mediated either by the interaction with double-phosphorylated Immunoreceptor Tyrosine-based Activation Motif (pITAM) which induces structural rearrangements in Syk structure, or by the phosphorylation of specific tyrosine residues along the sequence [3]. Syk is activated downstream of integrin function and this is at least partially independent on pITAM. However it is not known whether integrins and pITAM directly activate Syk with the same mechanism [4]. Here we use purified Syk protein and fluorescence-based enzyme assay to study whether interaction of integrin beta3 cytoplasmic domain with the regulatory domain of Syk causes similar changes in enzyme activity as pITAM peptides. We observed no direct activation of Syk by soluble integrin peptide. Integrin did not compete with pITAM-induced activation, even though at high concentration integrin peptide was found to compete with the substrate. However, clustered integrin peptides were able to induce Syk activation, presumably via transphosphorylation mechanism. We observed a similar behaviour of integrin with Syk mutant (Y348F/Y352F), indicating that the multiple phosphorylation sites can be involved in integrin-induced activation. These studies provide valuable information about the interplay between cell adhesion and immune activation pathways.

Untangling kinase-based signalling interactions in endothelial cell migration and angiogenesis.

Y. Hsiao¹²; C. Tsai¹⁴; H. Lin⁵; L. Yu¹²; F. Tsai¹²;

¹Dept. of Pharmacology, National Taiwan University College of Medicine, Taipei City, Taiwan, ²Dept. of Internal Medicine, National Taiwan University Hospital, Taipei City, Taiwan, ³Ph.D. Program in Human Biology, School of Integrative and Global Majors, University of Tsukuba, Tsukuba, Japan, ⁴International Institute for Integrative Sleep Medicine (WPI-IIS), University of Tsukuba, Tsukuba, Japan, ⁵Dept. of Immunology, National Taiwan University College of Medicine, Taipei City, Taiwan

Cell migration is important for embryogenesis, wound healing, angiogenesis and cancer metastasis, but how cells control their migration for above functions has remained elusive. Recent large-scale genetic
explorations have identified important signalling molecules that control cell migration, but how these signalling pathways interact with each other for proper cell motility is also unknown. We therefore started a two-hit genetic-plus-pharmacological screen to identify the significance of signalling interactions in migrating human umbilical vein endothelial cells (HUVEC). The screen identified two kinases, protein kinase C eta (PRKCH) and STE20-like kinase (SLK), both of which interact with Rho-associated kinase (ROCK) during cell migration. Interestingly, ROCK inhibition antagonized the effect of PRKCH knockdown but synergistically enhanced the effect of SLK knockdown during HUVEC migration. Suppressing the expression of PRKCH or SLK also affected the capability of HUVECs to form branching tubes in the matrigel, indicating the importance of both kinases in angiogenesis. We are currently working on the molecular mechanisms how these kinases interact with ROCK. Since ROCK inhibition has been shown effective to relieve various retinopathies, our work will improve the current treatment of angiogenesis-related eye diseases.

**Eisosome-associated protein Slm1 regulates two downstream pathways for heat stress adaptation.**  
K. Hashii¹, K. Yae¹, R. Tsuda¹, N. Tanaka¹, M. Tabuchi¹;  
¹Graduate School of Agriculture, Kagawa University, Kagawa, Japan

*Saccharomyces cerevisiae* has three distinct plasma membrane domains that are not overlapped. One of them is called Membrane Compartment of Can1 (MCC) that corresponds to inner membrane furrows termed eisosome. Eisosome contains various membrane associated-proteins, transporters and tetraspanning membrane proteins, which are considered to contribute to normal eisosome structure and function. One of the eisosome-associated protein, Slm1 localizes to MCC/eisosome at the steady state. However, upon exposure to plasma membrane (PM) stress, such as high temperature stress or perturbation of sphingolipid metabolism, Slm1 translocates to another membrane domain called Membrane Compartment of TORC2 (MCT), where Slm1 recruits AGC kinase Ypk1, then Ypk1 is activated by TORC2. Activated Ypk1 regulates various downstream pathways, such as sphingolipid metabolism and actin organization for PM stress adaptation. In this study, we investigated how Slm1 regulates the downstream pathways during PM stress.

We found that overexpression of GFP-tagged Slm1 (GFP-Slm1 OP) causes high temperature sensitivity and hyper-phosphorylation of downstream Cell Wall Integrity (CWI) MAP kinase, Slt2. Intriguingly, deletion of SLT2 or Rho1 GEF, ROM2 in GFP-Slm1 OP cells exacerbated high temperature sensitivity, suggesting that activation of CWI pathway is indispensable for heat stress adaptation rather than the cause of high temperature sensitivity in GFP-Slm1 OP cells. Furthermore, localization of GFP-Slm1 was still observed in MCC even upon PM stress, indicating that Slm1 plays some important roles for stress adaptation in MCC that have not been well characterized. To explore it, we analyzed genetic interaction between GFP- SLM1 OP and MCC-related genes and discovered strong genetic interaction with *PIL1* that is a major MCC component. GFP-Slm1 OP in *PIL1* deletion mutant caused abnormal recycling of membrane proteins, such as v-SNARE, Snc1 and actin repolarization. We also found simultaneous deletion of both *PIL1* and *SLT2* causes PM integrity (PMI) defect upon heat stress. Taken together, we propose that Slm1 spatiotemporally regulates both PMI and CWI pathways by changing its distribution in membrane domain for heat stress adaptation.

Multi-protein Skb1 nodes control fission yeast mitotic entry.
J.O. Magliozi\textsuperscript{1};
\textsuperscript{1}Biochemistry and Cell Biology, Dartmouth College, Hanover, NH

Protein clusters provide input into signal transduction pathways in a variety of cell types. The fission yeast Schizosaccharomyces pombe regulates mitotic entry through distinct protein clusters at the plasma membrane known as “nodes”. Protein kinases Cdr2, Cdr1 and Wee1 form nodes at the medial cortex of the plasma membrane. Wee1 inhibits CDK1 activity while Cdr2 and Cdr1 inhibit Wee1 to allow entry into mitosis. Past studies have shown type II arginine methyltransferase Skb1 forms node structures at non-growing cell regions distinct from Cdr2 nodes. Genetic epistasis revealed that Skb1 functions as a mitotic inhibitor through the Wee1 pathway. Elimination of Skb1 nodes results in altered cell size at division, making these structures crucial for correct cell cycle timing.

Similar to Cdr2 nodes, Skb1 nodes contain multiple proteins to generate cortical structures. Through proteomics and candidate-based screens, we identified the peripheral membrane-binding protein Sfl1 and the Syntaxin-like t-SNARE protein Psy1 as additional components of Skb1 nodes. Psy1 is essential for vegetative growth and exocytosis in fission yeast. The function of Psy1 at these cortical nodes is unknown. We are currently investigating the physical interactions and functional consequences of assembling these three proteins into large, megadalton-sized structures.

Single Molecule Study of Wnt Signaling Pathway Activation.
W. Ma\textsuperscript{1}, M. Chen\textsuperscript{2}, X. He\textsuperscript{3}, S. Angers\textsuperscript{3}, M.W. Kirschner\textsuperscript{4};
\textsuperscript{1}Systems Biology, Harvard Medical School, Boston, MA, \textsuperscript{2}Neurology Research, Children’s Hospital, Boston, MA, \textsuperscript{3}Pharmacy Department of Biochemistry, University of Toronto, Toronto, ON

30 years of molecular biology study on Wnt signaling pathway has yield ample knowledge of the regulation details on the molecular level. Due to the complex nature of Wnt signaling pathway, there are still open questions on how receptors and scaffold proteins orchestra to activate the pathway. In this work, we studied the membrane dynamical behavior of several important scaffold proteins in Wnt signaling pathway like Axin1 and Dishevelled2 with both biochemical and single molecule approaches. In addition to quantification of the stoichiometry of Axin1 and Dishevelled2, our results also show interesting dynamics information of how the scaffold proteins and receptors work together responding to Wnt treatment. Based on the quantitative information, we improved the existing model of canonical Wnt pathway activation.

APC regulates Wnt signaling by inhibiting a constitutive clathrin-mediated activation pathway.
1Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN, 2Department of Molecular and Systems Biology, Dartmouth College, Hanover, NH, 3Department of Surgery, University of Miami, Miami, FL

The Wnt pathway is a conserved pathway that controls many developmental processes and is mutated in many human diseases (e.g., cancer). In the absence of Wnt ligand, cytoplasmic β-catenin is phosphorylated and targeted for degradation by a complex assembled by the scaffold protein Axin, and the tumor suppressor adenomatous polyposis coli (APC). When a Wnt ligand binds to the co-receptors Frizzled (Fz) and the low-density lipoprotein receptor-related protein 6 (LRP6), a receptor complex is assembled promoting LRP6 phosphorylation. Phosphorylated LRP6 binds to the β-catenin degradation complex in a process mediated by Dishevelled (Dvl), assembling the Wnt signalosome. The signalosome is internalized which blocks β-catenin degradation, leading to the activation of a Wnt-transcription program. Mutations in the APC gene leading to constitutive Wnt pathway activation occur in over 80% of human colorectal cancers (CRC). Our lab developed a monoclonal antibody (mAb7E5) that targets the co-receptor LRP6 and inhibits Wnt signaling in vitro and in vivo. Significantly, mAb7E5 inhibits Wnt signaling in APC mutant CRC cell lines. Similarly, LRP6 knockdown inhibits Wnt signaling in APC mutant cells. Consistent with these results, activation of the Wnt pathway by knockdown of APC in human cells can be inhibited by simultaneously knocking down LRP6, or by blocking Fz or Dvl function. These results indicate that loss of APC leads to constitutive ligand-independent Wnt signalosome formation. This mechanism is conserved in Drosophila, where intestinal stem cell proliferation by loss of APC is inhibited by depletion of the receptor Arrow/LRP6 or Dvl. Using an inducible degradable form of APC, we demonstrate that APC loss is rapidly followed by Wnt receptor activation and increased β-catenin levels. Finally, clathrin inhibition blocks activation of the Wnt pathway in APC mutant cells and in organoids derived from tumors obtained from APC mutant mice. Consistent with a role for clathrin in regulating Wnt signaling upon loss of APC, we show that APC co-immunoprecipitates with clathrin. These results suggest a model in which Wnt receptor activation can occur via a constitutive, ligand independent clathrin-mediated mechanism that is normally inhibited by APC.

Molecular delineation of MST4-elicited ACAP4 phosphorylation during histamine-stimulated gastric acid secretion.
M. Mullen3, X. Yao1, Y. Liu1, P. Gui1, X. Wang1;
1Physiology, Morehouse School of Medicine, Atlanta, GA

The digestion in the stomach depends on acidification of the lumen. Histamine-elicited acid secretion is triggered by activation of PKA cascade, which ultimately results in the insertion of gastric H,K-ATPases into the apical plasma membranes of parietal cells. Our recent study revealed the functional role of PKA-MST4-ezrin signaling axis in histamine-elicited acid secretion (Jiang et al, 2015. J. Biol. Chem.). However, it remains uncharacterized how PKA-MST4-ezrin signaling axis operates the insertion of H,K-ATPases into the apical plasma membranes of gastric parietal cells. Here we show MST4 phosphorylates ACAP4, an ARF6 GTPase-activating protein (Ding et al., 2010 J. Biol. Chem.) at Thr545. Histamine stimulation
activates MST4 and promotes MST4 interaction with ACAP4. ACAP4 physically interacts with MST4 and is a cognate substrate of MST4 during parietal cell activation. The phosphorylation site of ACAP4 by MST4 was mapped to Thr545 by mass spectrometric analyses. Importantly, phosphorylation of Thr545 is essential for acid secretion in parietal cells because either suppression of ACAP4 or over-expression of non-phosphorylatable ACAP4 prevents the apical membrane reorganization and proton pump translocation elicited by histamine stimulation. In addition, persistent over-expression of MST4 phosphorylation-deficient ACAP4 results in an inhibition of gastric acid secretion and a blockage of tubulovesicle fusion to the apical membranes. Significantly, phosphorylation of Thr545 enables ACAP4 to interact with ezrin. Given the location of Thr545 between the GAP domain and the first ankyrin repeat, we reason that MST4 phosphorylation elicits a conformational change which enables ezrin-ACAP4 interaction. Taken together, these results define a novel molecular mechanism linking PKA-MST4-ACAP4 signaling cascade to polarized acid secretion in gastric parietal cells. Current effort is directed to understand the mechanisms underlying homotypic tubulovesicle fusion during histamine-elicited apical trafficking.

The mAKAP complex orchestrates the dephosphorylation of MEF2D in muscle cells to stimulate its activity.

S.N. Aponte Paris¹, M.S. Kapiloff², K.L. Dodge-Kafka³;
¹Calhoun Cardiology Center, UConn Health, Farmington, CT, ²Medicine and Pediatrics, University of Miami, Miami, FL

Myocyte Enhancer Factor 2D (MEF2D) is a transcription factor required for the development of pathological remodeling as well as the induction of cardiac hypertrophy by pressure overload. However, little is known about how this transcription factor is regulated. Previous work showed that the scaffolding protein mAKAP (muscle A-Kinase Anchoring Protein) orchestrated the calcineurin (CaN)-mediated stimulation of MEF2D in skeletal muscle cells. CaN and mAKAP immunoprecipitate with MEF2D in skeletal muscle cells and primary neonatal cardiac myocytes (RNV); MEF2D and CaN association was dependent on mAKAP expression. Furthermore, expression of anchoring disrupting peptides, which displaced CaN binding to mAKAP, blocked the induction of MEF2D gene transcription in skeletal myoblasts as well as the induction of cardiac hypertrophy in RNV, demonstrating the importance of the mAKAP complex for stimulation of MEF2D activity. The goal of this study was to elucidate the molecular mechanism that underlies the regulation of MEF2D activity by mAKAP-bound CaN. We found that stimulation of C2C12 cells with differentiation media induced the binding of active CaN to mAKAP, resulting in the dephosphorylation of MEF2D at Serine 444, which led to its desumoylation. Our current focus is on determining if MEF2D post-transcriptional modifications allows for increased gene transcription. C2C12 skeletal muscle cells will be stimulated with differentiation media, luciferase assay will be used to measure MEF2D transcriptional activity and we will also look at the expression of MEF2D target genes Nppa (atrial natriuretic factor), Acta1 (skeletal muscle α-actin), and Actc1 (cardiac muscle α-actin). Overall, our data suggests that the mAKAP complex focuses the actions of CaN onto MEF2D, to promote regulation of its post-transcriptional modifications, which we propose will allow for increased transcriptional activity in both stimulated skeletal muscle myoblasts and stressed cardiac myocytes. Understanding the regulation and activity of the transcription factor MEF2D and its associated proteins is a crucial step towards the ability to block the development of cardiac hypertrophy.

Macropinosomes Coordinate the Activation of PI3Kβ by Gβγ and Rac.
Z. Erami1, B.D. Khalili1, G.K. Salloum1, Y. Yao1, A. Shymanets1, B. Nuernberg2, A.R. Bresnick1, J.M. Backer1;
1Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, 2Institute for Pharmacology and Toxicology, Eberhard-Karls-Universität Tübingen, Tubingen, Germany, 3Biochemistry, Albert Einstein College of Medicine, Bronx, NY

Phosphoinositide 3-kinases (PI3Ks) are regulated by a diverse range of upstream activators, including receptor tyrosine kinases (RTKs), G-protein-coupled receptors (GPCRs), and small GTPases from the Ras, Rho and Rab families. For the Class IA PI 3-kinase PI3Kβ, which regulates thrombosis, spermatogenesis, and tumorigenesis in vivo, two mechanisms for GPCR-mediated regulation have been described: direct binding of Gβγ dimers to the C2-helical domain linker of p110β, and Dock180/Elmo1-mediated activation of Rac1, which binds to the Ras-Binding Domain (RBD) of p110β. We now show that the integration of these dual pathways is unexpectedly complex. Gβγ and constitutively active Rac1 (CA-Rac1) additively activated PI3Kβ in breast cancer cells. GPCR-mediated activation of Akt was preserved in cells expressing a p110β RBD mutant that is deficient for Rac1 binding. However, CA-Rac1-mediated activation of PI3Kβ was blocked in cells expressing a PI3Kβ mutant that cannot bind Gβγ, and Rac1 activation of wild type PI3Kβ was inhibited by reagents that block endogenous Gβγ signaling. Moreover, Rac1 still activated PI3Kβ in cells expressing the p110β RBD mutant. These data suggest an alternative mechanism for CA-Rac1 activation of PI3Kβ that is independent of direct Rac-PI3Kβ binding. Notably, cells expressing CA-Rac1 exhibited a robust induction of macropinocytosis, which has been previously suggested to amplify signaling to PI3K by GPCRs. Consistent with this hypothesis, suppression of macropinocytosis by EIPA blocked Rac-mediated Akt activation in cells expressing wild type or Rac1-deficient p1110β. Our data suggest that Rac-stimulated macropinosomes serve as signaling platforms that enhances Gβγ coupling to PI3Kβ.

A novel YAP-binding protein Furry controls localization and activity of YAP.
K. Irie1, T. Nagai1, K. Mizuno1;
1Biomolecular Sciences, Graduate school of Life Sciences, Tohoku university, Sendai, Japan

The Hippo pathway is known as a signaling pathway that restricts cell proliferation and controls organ size. MST1/2 kinases bind to their adaptor protein Sav1 and phosphorylate and activate downstream kinases, NDR1/2 and LAT51/2. LAT51/2 kinases phosphorylate transcriptional co-activators, YAP and TAZ, to promote their cytoplasmic retention or degradation, resulting in inhibition of their interaction with TEAD and TEAD-mediated transcriptional activation, and thereby leading to suppression of cell proliferation. However, the mechanisms regulating YAP phosphorylation and inactivation are not fully understood. Furry (Fry) is an evolutionarily conserved protein in eukaryotes. Fry genetically and physically interacts with NDR. Both Fry and NDR are implicated in the control of cell morphogenesis, polarization, cell cycle progression, and neurite extension. Previous studies showed that Fry plays a crucial role in mitosis by regulating chromosome alignment and mitotic spindle formation. Although a recent study revealed that NDR kinases are also involved in YAP inactivation, the role of Fry in the regulation of YAP activity is still unknown. In this study, we demonstrated that Fry is involved in YAP inactivation. To examine the role of Fry in YAP activity, we generated Fry-knockout (KO) 293A cells using
a CRISPR/Cas9 system. We observed that Fry-KO cells exhibited the accumulation of YAP into the nucleus and the elevated activity of YAP, as compared to wild-type cells. Furthermore, we showed that Fry interacts with several Hippo components, YAP, SAV1, and LATS1/2. We also showed that the ectopic expression of full-length Fry, but not its fragments, rescued the cytoplasmic localization of YAP in Fry-KO cells. We next analyzed the effect of Fry KO on actin disassembly-induced YAP inactivation, because recent studies have shown that actin disassembly induces YAP translocation to the cytoplasm in Hippo-dependent and Hippo-independent manners. We observed that YAP preferentially localized in the cytoplasm in both control and Fry KO cells upon treatment with actin-disassembling drugs, suggesting that Fry is not involved in actin disassembly-mediated YAP inactivation. Since previous studies have shown that Fry bind to microtubules, we are investigating whether Fry could regulate YAP localization through the microtubule-dependent mechanism. Taken together, these results suggest that Fry plays a crucial role in YAP inactivation through binding to YAP and scaffolding the components of the Hippo pathway.

A novel splice variant of Sab (SH3BP5) alters mitochondrial physiology.
M. Rodriguez-Silva¹, J.W. Chambers¹²;
¹ Department of Neuroscience, Herbert Wertheim College of Medicine, Florida International University, Miami, FL, ²Department of Environment and Occupational Health, Robert Stempel College of Public Health, Florida International University, Miami, FL

Mitochondria-cell communication is required for optimal cell function and to monitor mitochondrial health. Ultimately, mitochondria-cell circuits transduce signals that influence biological outcomes. However, the precise mechanisms responsible for mitochondria-cell communication are not well understood. Scaffold proteins on the mitochondrial outer membrane (MOM) are crucial hubs for mitochondria-cell communication, where the relative abundance of discrete scaffold proteins will influence the magnitude of distinct signal transduction events and determine the local outcome. Furthermore, variation in scaffold proteins may diversify signaling modules or even polarize mitochondria-cell communication towards specific biological outcomes. The MOM scaffold protein Sab facilitates mitogen-activated protein kinase (MAPK) signaling on mitochondria which affects organelle function and cell viability. Our previous work demonstrates that Sab levels alter cellular sensitivity to chemotherapy agents in gynecological cancer cells. While screening glioma cells for Sab protein concentrations, we discovered a unique variant of Sab with an N-terminal truncation that deletes the original mitochondrial localization sequence and a coiled-coil motif. Thus, our current goal is to characterize the Sab variant, distinguish the function of the shortened Sab variant from that of full-length Sab, and determine the impact of variant-mediated events on mitochondrial function. We cloned Sab-variant expressing human SF268 cells and derived clones that expressed full-length Sab alone and those that expressed both full-length Sab and the truncated variant. We next characterized the cell morphology, growth rate, respiration and drug responsiveness. We found that the shortened Sab variant localizes to mitochondria, which may be attributed to an N-terminal stretch of cationic amino acids. Cells that express the variant have an increased growth rate compared to cells with only full-length Sab. Truncated Sab expressing cells display a large, round morphology, while cells without the variant are fibroblast-like. Expression of the variant promotes a metabolic shift from respiration to a more glycolytic phenotype. The truncated Sab variant also affects stress responsiveness, as cells without the variant are more sensitive to genotoxic stress, while cells with the variant are more sensitive to mitochondrial stress. This may suggest that alternative splicing of Sab transcripts may be a means to regulate cellular responsiveness to mitochondrial health. Our work illustrates that Sab variants may have
distinct effects on mitochondrial function and, altering the structures and concentrations of MOM scaffold proteins is a novel approach to manipulate organelle function and disease pathophysiology.

Alterations in outer mitochondrial signaling promote organelle and neuronal dysfunction.
K.T. Ashourian1, J.W. Chambers2;
1Department of Neuroscience, Florida International University, Miami, FL, 2Environmental and Occupational Health, Florida International University, Miami, FL

Mitochondrial outer membranes (MOMs) are critical interfaces for mitochondria-cell communication. MOM signaling cascades influence respiratory efficiency, mitochondrial dynamics, and cellular viability. Changing the concentrations of MOM signaling components alters organelle physiology. Specifically, protein kinase A (PKA) signaling on the MOM scaffold A-kinase anchoring protein 1 (AKAP-1) promotes complex I assembly and mitochondrial fusion. Conversely, mitochondrial c-Jun N-terminal kinase (JNK) signaling on the scaffold Sab inhibits complex I, promotes ROS generation, and triggers apoptosis. The magnitude and outcomes of MOM signaling correspond to the local abundance signaling components. We found that advanced age and prolonged mitochondrial stress increase Sab concentrations in neurons; the elevation in Sab occurred concurrently with a decrease in AKAP1. The shift in MOM scaffold proteins resulted in an escalation in mitochondrial JNK concentrations and a reduction in PKA activity. To reproduce the scaffold shift, we overexpressed Sab in neurons, which reduced AKAP1 levels and fragmented the mitochondrial network. Affinity purification of epitope-tagged Sab revealed direct interactions with mitochondrial fission machinery. Inhibition of JNK/Sab signaling prevented fission and mitigated changes in organelle morphology. Additionally, inhibition of Sab-facilitated signaling prevented JNK-mediated phosphorylation and degradation of Mfn2. These studies suggest that Sab-mediated signaling is crucial for segregating dysfunctional or depolarized organelles within neurons. Moreover, enhanced Sab expression resulted in impaired neuronal activity and the accumulation of dysfunctional mitochondria at synapses. Disrupting Sab-mediated events restored neurotransmission. To determine if targeting perturbations in MOM signaling improves neurological function in diseases affected by mitochondrial stress, we analyzed mouse models of Parkinson's and mitochondrial disease. We report that Sab levels were increased and AKAP-1 levels were decreased in specific areas of the brain and reducing the Sab/AKAP-1 ratio improved performance in behavioral studies. We propose that altering mitochondria-cell communication represents a unique approach to limit mitochondrial stress and restore neuronal activity in neurological disease.

Signalling via membrane receptors generate functional nanodomains at the plasma membrane of living cells.
J. Kalappurakkal1, A.A. Anilkumar1,2, T.S. van Zanten1, M.P. Sheetz3, S. Mayor1,4;
1National Centre for Biological Sciences, Tata Institute of Fundamental Research, Bangalore, India, 2St. Johns Research Institute, Bangalore, India, 3Mechanobiology Institute, National University of Singapore, Singapore, Singapore, 4Institute for Stem Cell Biology and Regenerative Medicine, Bangalore, India

The plasma membrane (PM) of the cell is a dynamic structure that exhibits lateral heterogeneities at various length and time scales [1]. The Outer-leaflet tethered GPI-anchored proteins (GPI-APs) are one of several such components that exhibit a non-random distribution on the PM [2,3,4]. In a resting cell
membrane, about ~40% of GPI-APs form transient (<1 sec) nanoclusters driven by the dynamics of the contractile actin machinery operating close to the inner leaflet of the plasma membrane via a transbilayer acyl-chain-mediated linkage mechanism [3,5,6,7]. While an understanding of the physical principles behind the active mechanics of actin filaments and myosin that drives this behavior is emerging [8], the molecular machinery behind the generation of this dynamic pool of actin and its mode of coupling to inner-leaflet lipids is lacking. Here we show that localized activation of the β1-integrin receptor generates localized nanoclusters of GPI-APs. Surface-tethered and soluble RGD-containing ligands engage the integrin receptor and activate FAK-src kinases and the RhoGTPase, RhoA. RhoA in-turn triggers actin-nucleation via specific formins and activates myosin-II to generate contractile actin filaments. In parallel, integrin signaling results in the talin-mediated opening of vinculin, which potentiates the coupling of actin to the negatively charged lipids at the inner leaflet. This provides a regulated machinery required to create as well as couple dynamic actin activity at the inner leaflet to the organization of outer leaflet GPI-APs. Upon integrin activation, ~80% of GPI-APs from nanoclusters in its vicinity [5]. Consistent with a functional relevance of this machinery, mutant cells that are unable to generate GPI-AP nanodomains at the cell surface, despite their normal integrin activation status, exhibit severe defects in integrin-mediated cell spreading behavior.

Live cell super-resolution microscopy measures membrane-driven sorting of B cell receptor signaling partners.
S.A. Shelby, S.L. Veatch; ^1
^1Biophysics, University of Michigan, Ann Arbor, MI

B cells are acutely sensitive to stimulation through antigen-induced clustering of the B cell receptor (BCR). Transduction of the activation signal, which is key for the adaptive immune response, involves rearrangement of membrane-resident signaling molecules relative to clustered BCR. The details and dynamics of this re-organization have been difficult to directly observe due to the small dimensions of signaling complexes and the potentially weak or transient interactions that drive their formation. To overcome these obstacles, we have utilized live-cell super-resolution localization microscopy to simultaneously image BCR and other membrane species during antigen-induced cell activation. The sensitivity of this quantitative technique has allowed us to measure the effects of subtle forces, such as those originating from lipid compositional heterogeneity, that influence the interactions of BCR with its signaling partners. We found that minimal membrane-anchored probes that partition into ordered domains of model membranes co-localize with BCR clusters, while anchors that partition into disordered domains are excluded from clusters, suggesting that BCR clusters can nucleate local enrichment of a specific lipid composition. We are exploring the effects of membrane-driven sorting on recruitment of BCR signaling proteins to receptor clusters and how it contributes to their specific role in signal
transduction. In particular, we have found that the palmitoylated transmembrane adapter proteins LAT2, LIME, and PAG, which serve distinct adapter functions in BCR signaling, are differentially recruited to BCR clusters. This differential recruitment is due to a combination of interactions between the transmembrane domains of these proteins with the membrane and to specific protein-protein interactions. Our results suggest that the membrane influences local sorting of downstream signaling proteins around BCR clusters and provide insight on the forces driving regulation of BCR signaling.

Protein sorting by phase-like domains supports emergent signaling function in B cell plasma membranes.
M.B. Stone¹, S.A. Shelby¹, S.L. Veatch¹;
¹Biophysics, University of Michigan, Ann Arbor, MI

Diverse cellular signaling events, including B cell receptor (BCR) activation, are hypothesized to be facilitated by domains enriched in specific plasma membrane lipids and proteins that resemble liquid-ordered phase separated domains in model membranes. However, this concept remains controversial due to the difficulty in directly observing these domains in intact cells. Here, we visualize ordered and disordered phase-like domains in intact B cell membranes using super-resolution fluorescence localization microscopy, demonstrate that clustered BCR resides within ordered phase-like domains capable of sorting key regulators of BCR activation, establish that ordered domains are local environments that favor tyrosine phosphorylation, and present a minimal and predictive model where clustering receptors leads to their collective activation by stabilizing an extended ordered domain. These results provide evidence for the role of membrane domains in BCR signaling as well as a plausible mechanism of BCR activation via receptor clustering. More generally, these studies demonstrate that lipid mediated forces can bias biochemical networks in ways that may broadly impact signal transduction.

The activation state of SRC family kinases in late endosomes determines cellular responses to Receptor Tyrosine Kinase signaling in neuroblastoma.
L.E. Foltz¹, J. Palacios-Moreno¹, M. Mayfield¹, S. Kinch¹, J. Syrenne¹, M.L. Grimes¹;
¹Division of Biological Sciences, University of Montana, Missoula, MT

Receptor Tyrosine Kinases (RTKs), a family of cell-surface receptors, activate intracellular signaling cascades that determine cellular responses such as proliferation, differentiation, migration, and apoptosis. Dysregulation of RTK signaling is known to drive the initiation and progression of several cancers and diseases. Therefore, strict spatial and temporal regulation of pathways activated by RTKs is necessary to determine appropriate cellular responses, but how this regulation is achieved remains unclear. SRC Family Kinase (SFK) signaling pathways are one of the main pathways activated by RTKs. SFKs are phosphorylated by RTKs at the plasma membrane and subsequently trafficked into endosomes and lipid rafts, where they continue to signal from endosomal surfaces. The scaffold protein PAG1 (phosphoprotein associated with glycosphingolipid enriched microdomains 1) normally regulates SFK activation in endosomes and lipid rafts by mediating an interaction with C-terminal SRC Kinase (CSK), which deactivates SFKs. Our previous research showed that the localization pattern of SFKs in different membrane fractions distinguishes signaling from different RTKs. Therefore, we hypothesized that

Sunday-364
disrupting SFK activation and localization within lipid rafts and endosome populations would influence cell fate decisions initiated by different RTKs. To disrupt SFK activation and trafficking, we generated a neuroblastoma cell line expressing a PAG1 fragment that lacks the membrane spanning domain (PAG1TM-). Cells expressing PAG1TM- exhibited higher global amounts of activated SFKs, higher amounts of activated SFKs in late endosome populations, and also sequestered more active SFKs in the lumen of multivesicular bodies. The sustained activation of SFKs in late endosomal populations mimics the signaling paradigms of the oncogenic receptors ALK and KIT. Accordingly, PAG1TM- cells exhibited increased proliferation, altered patterns of migration, and increased anchorage-independent growth in soft agar. PAG1TM- cells also failed to respond to signaling from the pro-differentiation receptors TRKA and RET. These results provide support for the role of PAG1 as a tumor suppressor in neuroblastoma, and suggest that localization of active SFKs in distinct endosome populations is a major method of regulating cell fate decisions triggered by RTK activation.

Exclusion of Notch from Mechanically Active Cellular Junctions.
K.M. Southard1,2, D. Seo3, Z.J. Gartner4, Y. Jun2;
1Pharmaceutical Chemistry, University of California, San Francisco, San Francisco, CA, 2Department of Otolaryngology, University of California, San Francisco, San Francisco, CA

Notch, an essential cell communication receptor, relies on contact of ligand and receptor across cells, mechanical force, and sequential steps of proteolytic cleavage by ADAM10 and -secretase carried out within the membrane for receptor activation. As such, the spatial organization and presentation of Notch, ligand, and proteases at the membrane is a key factor in regulating Notch activation. Despite its importance, the spatial distribution of Notch at the membrane remains understudied. Here we present work mapping Notch’s cell-surface distribution and organization, particularly relative to cellular adhesions; sites of cell contact, mechanical tension, and -secretase recruitment. Surprisingly, we find Notch to be excluded from cellular adhesion structures, including E-cadherin cell-cell junctions and focal adhesions and spatially segregated from presenilin 1 (PS1), the key catalytic subunit of -secretase. We explore the mechanism of Notch’s exclusion and find it to be dependent on the Negative Regulatory Region (NRR) and Notch activation. This study reveal’s Notch’s organization at the cell surface, uncovering restrictions on Notch’s distribution and segregation of inactive Notch from its protease, implicating cellular adhesions in the regulation of Notch signaling.

TNF-α priming regulates CD82 expression of Bone Marrow Homing of Hematopoietic Stem and Progenitor cells.
E.M. Pascetti1, C.M. Termini1, M. Floren1, C.A. Saito Reis1, J.M. Gillette1;
1Pathology , University of New Mexico Health Sciences Center, Albuquerque, NM

Hematopoietic stem/progenitor cell (HSPC) transplantation is a primary clinical therapy for the treatment of blood cancers, immunodeficiency disorders, and high-dose chemotherapy patients, who often develop bone marrow failure. Currently, the poor homing and engraftment of transplanted HSPCs results in reduced efficacy, which often leads to patients requiring multiple rounds of transplantation. For effective HSPC transplantation, stem cells must traffic through the blood and home to a specific microenvironment or “niche”, which is composed of soluble factors, matrix proteins, and supportive
cells. HSPC adhesion to, and signaling within the niche provide support and instructional cues to balance stem cell properties such as differentiation and self-renewal. Despite the clinical successes of HSPC transplantation, the molecular mechanisms that regulate HSPC trafficking to the bone marrow and the subsequent repopulation of the hematopoietic system remain unclear. Tetraspanins are molecular scaffolds that distribute proteins into highly organized microdomains consisting of adhesion, signaling, and adaptor proteins. As such, tetraspanins function as molecular facilitators or organizers for membrane proteins, thereby modulating cell adhesion and signal transduction. Previous work from our laboratory identified the tetraspanin, CD82, as a modulator of HSPC adhesion and bone marrow homing, where CD82 blocking antibodies and CD82 microdomain disruption inhibited niche cell adhesion and homing. Therefore, we hypothesize that the upregulation of CD82 expression may promote bone marrow homing, engraftment and improved transplantation. In the current study, we describe the use of tumor necrosis factor alpha (TNF-alpha), a cytokine produced by various tissues during inflammation, to modulate CD82 expression on the surface of HSPCs. A dose response analysis of HSPC TNF-alpha priming identified a significant increase in the surface expression of the regulatory tetraspanin, CD82. Real time-PCR analysis suggests that CD82 expression is upregulated transcriptionally along with nuclear factor kappa-light-chain-enhancer of activated B cells (NFkB), following acute treatment with TNF-alpha. In addition, our preliminary data suggest that TNF-alpha priming of HSPCs promotes the bone marrow homing of HSPCs in preclinical animal models. Future studies will evaluate the long-term engraftment potential of HSPCs primed with TNF-alpha and will further explore the mechanistic role of CD82 in the process. Taken together, we anticipate that these studies have the potential to offer new molecular targets and treatments to improve HSPC transplantation.

A mass spectrometry-based screen reveals FRMD8 as a novel regulator of iRhom/ADAM17-dependent inflammatory and growth factor signalling.
U. Kuenzel1, Y. Meng1, A.G. Grieve3, S.A. Cowley1, M. Freeman1;
1Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

The metalloprotease ADAM17 cleaves and releases membrane-tether forms of signalling molecules from the plasma membrane, such as the inflammatory cytokine tumour necrosis factor (TNF) and several ligands of epidermal growth factor receptor (EGFR). Thus, ADAM17 activity has to be tightly controlled. The multi-pass membrane proteins iRhom1 and iRhom2 are members of the rhomboid-like superfamily that control ADAM17 activity by trafficking ADAM17 from the endoplasmic reticulum (ER) to the Golgi apparatus, the site at which ADAM17’s inhibitory prodomain is removed. Furthermore, iRhoms also control the activity and substrate-specificity of ADAM17 on the cell surface. iRhoms ultimately regulate the release of ADAM17 substrates, and therefore TNF and most EGFR signalling. However, it remains unclear whether iRhoms require additional factors to exert their function as ADAM17 regulators. We performed a mass spectrometry-based screen for new binding partners of human iRhom2 and identified the largely uncharacterised FERM domain-containing protein 8 (FRMD8) as a novel iRhom1 and iRhom2 interactor. We mapped the binding site of FRMD8 within the cytosolic N-terminus of iRhom2. The loss of FRMD8 drastically affects the function of iRhom2 as regulators of ADAM17: knockdown and knockout of the FRMD8 led to almost undetectable levels of mature ADAM17 and significantly impaired the release of ADAM17 substrates. Using human induced pluripotent stem cell (hiPSC)-derived macrophages, we showed that FRMD8 also regulates the release of TNF in human macrophages. This shows that FRMD8 is a novel, specific regulator of the iRhom/ADAM17 pathway of
physiological relevance. To address the role of FRMD8 in vivo, we generated the first FRMD8 knockout mice and are currently analysing their phenotype.

Characterization of IQGAP1 binding to phosphoinositides and PIP kinases.
V.S. Yerramilli, S. Scarlata, A. Gericke
1Chemistry and Biochemistry, Worcester Polytechnic Institute, Worcester, MA

IQ motif-containing GTPase-activating protein 1 (IQGAP1) is a multidomain protein that scaffolds multiple signalling pathways by binding to its many partners. Recent studies have suggested that IQGAP1 plays a major role in the generation of the lipid messenger PtdIns(3,4,5)P3 by scaffolding the phosphoinositide kinases PIPKis and PI(4)KII class I phosphatidylinositol-3-OH kinase (PI(3)K). It is believed to do so by allowing the PtdIns(4,5)P2 generated from phosphatidylinositol-4-phosphate by PIPKis to be selectively used by PI(3)K for PtdIns(3,4,5)P3 generation by scaffolding the kinases involved very closely. Here, we investigate the binding of IQGAP1 to these proteins and phosphoinositides both in-vitro and in cells using fluorescence techniques like FLIM and FCS. We found that IQGAP1 associates with PIP kinases and PI3K in cells. We also find evidence of IQGAP1 binding weakly to PtdIns(4,5)P2. Our results indicate that IQGAP1 plays a role in modulating the synthesis of PtdIns(4,5)P2 and PtdIns(3,4,5)P3 by scaffolding the kinases involved, as well as the phosphoinositides themselves.

The Tetraspanin CD82 Regulates Hematopoietic Stem Cell Activation within the Bone Marrow Microenvironment.
C.A. Saito Reis, K.D. Marjon, E.M. Pascetti, K.L. Karlen, R.J. Dodd, C.M. Termini, J.M. Gillette
1Pathology, University of New Mexico Health Science Center, Albuquerque, NM

Hematopoietic stem and progenitor cells (HSPCs) are responsible for the continued production of new blood and immune cells. The interactions between HSPCs and the surrounding bone marrow microenvironment are critical for the long-term maintenance and protection of HSPCs from biological stresses that lead to activation. Previous analysis of the contact site between HSPCs and bone marrow components identified the enrichment of the tetraspanin CD82. CD82 is a membrane scaffold protein highly expressed on the surface of HSPCs, which we have shown regulates HSPC adhesion and homing to the bone marrow. In this study, we go on to analyze the contribution of CD82 to the maintenance of HSPC quiescence and activation, which are tightly regulated by interactions with the bone marrow. More specifically, we are testing the hypothesis that CD82-mediated bone marrow interactions promote HSPC quiescence and prevent cell cycle activation. Utilizing the CD82 knock out (CD82KO) mouse, we assessed the cell cycle status of HSPCs within the bone marrow. Flow cytometry analysis of Hoechst and Ki-67 stained HSPCs identified a significant decrease in the G0 population of cells and a subsequent increase in the G1 population of CD82KO HSPCs. Additionally, we measured HSPC cell cycle status in vivo with BrdU, which labels actively cycling cells. Using flow cytometry to quantify the BrdU incorporation into HSPCs isolated from the bone marrow, we find a significant increase of BrdU within the CD82KO HSPCs when compared to control animals. Taken together, these data implicate CD82 as a critical regulator of HSPC quiescence. Next, we evaluated the role of CD82 in HSPC activation. 5-fluorouracil (5-FU) treatment ablates cycling cells within the peripheral blood resulting in activation of dormant HSPCs within the bone marrow for immune cell repopulation. A two-week analysis of control and CD82KO mice
treated with 5-FU identified a survival advantage of the CD82KO animals. In addition, we found an increase in immune cells within the blood and bone marrow of CD82KO mice compared to control animals, suggesting that CD82 contributes to HSPC activation. More recently, we completed RNA-sequencing analysis of isolated HSPCs from CD82KO and control animals to identify differentially expressed genes. Future studies will be directed toward Gene Set Enrichment analysis of cell cycle regulated genes.

Poly( L -Lactic Acid)/Gelatin Fibrous Scaffold Loaded with Simvastatin/Beta-Cyclodextrin-Modified Hydroxyapatite Inclusion Complex for Bone Tissue Regeneration.

S.C. Hong1; D. Lee2;
1Dentistry / Oral and maxillofacial Surgery, Catholic Kwandong University International St. Mary’s Hospital, Incheon, Korea, South; 2Oral and Maxillofacial Surgery, Kyung Hee University School of Dentistry, Seoul, Korea, South

Recently, the application of nanostructured materials in the field of tissue engineering has garnered attention to mediate treatment and regeneration of bone defects. In this study, poly( L -lactic acid) (PLLA)/gelatin (PG) fibrous scaffolds are fabricated and β-cyclodextrin (BCD) grafted nanohydroxyapatite (HAp) is coated onto the fibrous scaffold surface via an interaction between BCD and adamantane. Simvastatin (SIM), which is known to promote osteoblast viability and differentiation, is loaded into the remaining BCD. The specimen morphologies are characterized by scanning electron microscopy. The release profile of SIM from the drug loaded scaffold is also evaluated. In vitro proliferation and osteogenic differentiation of human adipose derived stem cells on SIM/HAp coated PG composite scaffolds is characterized by alkaline phosphatase (ALP) activity, mineralization (Alizarin Red S staining), and real time Polymerase chain reaction (PCR). The scaffolds are then implanted into rabbit calvarial defects and analyzed by microcomputed tomography for bone formation after four and eight weeks. These results demonstrate that SIM loaded PLLA/gelatin/HAp-(BCD) scaffolds promote significantly higher ALP activity, mineralization, osteogenic gene expression, and bone regeneration than control scaffolds. This suggests the potential application of this material toward bone tissue engineering. This study was supported by a grant from the National Research Foundation of Korea (NRF-2014R1A1A1002630 and NRF-2016R1A2B4014600).

This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIP; Ministry of Science, ICT & Future Planning)(No. NRF-2017R1C1B5018358)

Tetraspanin 33 regulates migration, adhesion and invasion properties of human B cells.
1Cell Biology, Centro de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), MEXICO CITY, Mexico, 2Research Support Network, Universidad Nacional Autónoma de México, MEXICO CITY, Mexico, 3Biomedicine, Centro de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), MEXICO CITY, Mexico, 4Biophysic, Instituto de Ciencias Físicas, Cuernavaca, Mexico, 5Infectomic and Molecular Pathogenesis, Centro de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), MEXICO CITY, Mexico, 6Physic, Centro de Investigación y de Estudios Avanzados del IPN (CINVESTAV-IPN), MEXICO CITY, Mexico

Adhesion molecules allow interactions with the extracellular matrix and its substrates, favoring the presence or absence of diseases such as cancer. Some of these interactions can be mediated by transmembrane proteins such as tetraspanins. Proteins belonging to this family are characterized by four transmembrane domains and two extracellular loops that allow it to interact with adhesion molecules and other proteins, forming tetraspanin enriched microdomains. Currently 33 members of the family of tetraspanins in human and mouse have been described. The newly characterized tetraspanin 33 is mostly expressed in B lymphocytes, where its expression increases upon activation of these cells, suggesting its involvement in autoimmune diseases and B-cell lymphomas.

To characterize the role of tetraspanin 33 (TSPAN33) in adhesion, migration and invasion processes, TSPAN33-EGFP was overexpressed in B lymphocytes derived from Burkitt’s lymphoma (Raji cells). The endogenous expression of adhesion molecules such as β2 and β1 integrin subunits, with their respective α subunits, was evaluated by flow cytometry. Furthermore, adhesion assays were performed on different substrates, such as fibronectin or laminin. Also, various assays were conducted to monitor cell spreading, cell migration and Matrigel invasion both depending on the response to chemoattractant CCL21.

We found that the overexpression of TSPAN33-EGFP in Raji cells generates a decrease in β integrin subunits at the cell membrane, which leads to a lower cell adhesion in substrates such as fibronectin or laminin that are part of the extracellular matrix. Consequently, we also found that these cells have greater cellular extension, greater migration and greater invasion ability.

These data suggest that TSPAN33 may represent an important molecular determinant of lymphocyte B malignancy in pathologies related to cancer.

Coordination of acto-myosin contractility and mitochondrial positioning during neutrophil migration in live animals.
N. Melis1, B. Subramanian1, D. Chen1, C. Parent1, R. Weigert1;
1Laboratory of Cellular and Molecular Biology, National Cancer Institute - NCI, Bethesda, MD

Cell migration is a fundamental process which occurs during a variety of physio-pathological events such as embryonic development, wound healing, immune response, and cancer. This multi-step process
requires an extensive remodeling of the cellular membranes, which is mediated by the constant re-arrangement of the actin cytoskeleton. Neutrophil migration has been extensively used as a paradigm to investigate cell motility, due to its important role in the innate immune response. However, most of the studies have been carried out in in-vitro model systems (2-D or 3-D cell cultures) and only limited work has been performed on dissecting the molecular mechanisms that link membrane remodeling to cell motility in-vivo.

To this end, here we use intravital subcellular microscopy (iSMIC) and focus on understanding the mechanisms underlying the coordination among acto-myosin cytoskeleton, mitochondrial metabolism, and plasma membrane remodeling during neutrophil migration in the ear skin of live mice following laser-mediated injury. Specifically, neutrophils are isolated from the bone marrow of donor mice expressing selected fluorescently-tagged proteins, labeled with additional fluorescent dyes highlighting specific sub-cellular compartments, and injected subcutaneously in the ear of recipient mice. Our preliminary results show that the actin-based motor Myosin II (NMIIA) is not only present at the rear of the migrating cells, as previously described in vitro, but also at the leading edge. Moreover, we find that sharp changes in the direction of migration are preceded by the assembly of sub-populations of NMIIA filaments on the side of the cells, perpendicularly to the new direction. Finally, we observe that mitochondria: 1) constantly reposition in order to match the localization of NMIIA, most likely in order to supply the ATP required to sustain the contractile activity; and 2) change their polarization during the various phases of migration. In summary, we have begun to highlight a novel correlation between mitochondria repositioning and activity, and the dynamic rearrangement of the actomyosin complex in vivo.

Nanofiber Curvature Enables Quantitating Single Protrusions.
A. Mukherjee¹, B. Koons¹, P. Sharma², Z. Ye¹, B. Behkam¹, A.S. Nain¹;
¹Mechanical Engineering, Virginia Polytechnic Institute and State University, Blacksburg, VA,
²Department of Biomedical Engineering and Mechanics, Virginia Polytechnic Institute and State University, Blacksburg, VA

Our native extracellular matrix (ECM) is primarily comprised of fibrous proteins; the size and organization of which is now widely appreciated to be key in cellular biophysical sensing and motility. Despite decades of in vitro investigation using 2 and 3D substrates, a comprehensive description of initial protrusive events in metastatic invasion using nanofibers mimicking ECM dimensions is still critically missing. This is due to the inability of current approaches to (i) isolate single protrusions and (ii) provide controlled curvatures to quantitate protrusion sensitivity to geometry. Using contrasting diameter fibers deposited orthogonally on top of each other, we quantitate single protrusion dynamics at high spatiotemporal resolution in both breast adenocarcinoma MDA-MB-231 and brain glioblastoma DBTRG-05MG. Specifically, we constrain the cell body to the larger diameter base fiber (~2 μm), while allowing individual protrusions to form on protrusive high curvature small diameter fibers (~100, 200 and 600 nm) and low curvature flat ribbons of corresponding widths. Quantitating at ~minute temporal scales, our strategy allows us to quantitatively distinguish ('protrutype') between the protrusive dynamics of two cancer cell lines and report that the MDA-MB-231 is more sensitive to the fiber curvature compared to DBTRG-05MG. We find that in all cell types, protrusions are rich in actin and tubulin, but intermediate filament vimentin localizes only in mature protrusions. Furthermore, we show that vimentin depleted cells can still form long length protrusions, thus negating the currently understood role of vimentin in protrusion dynamics. Quantitating at ~second temporal scales, we report that protrusion initiation and maturation occurs by wrapping-around the nanofibers in a helical manner.
with the width and rotational speed of each turn regulated by curvature. Specifically, high curvature fibers (~100-300 nm) result in narrower widths (2.1 ± 0.1 µm), whereas low curvature fibers (~600-1000 nm) result in wider widths (4.4 ± 0.2 µm). Interestingly, we find that intracellular transport coincides with protrusion maturation and the kinetics of vesicle cytoplasmic trafficking occur inside protrusions at speeds of 0.7 ± 0.1, 1.0 ± 0.1, and 1.7 ± 0.1 µm/s on fiber diameters of 100, 600 and 1000 nm respectively. Mean square displacement measurements reveal a rapid shift from a sub-diffusion regime (exponents <1) for vesicles outside the protrusions to a super-diffusive regime (exponents >1) as vesicles travel within the protrusion at high persistence. In summary, we report a multiscale and integrative platform which allows the quantification of protrusion morphodynamics decoupled from cell migration and enables identifying the utility of sensory protrusions.

LINC complexes regulate cytoskeletal tension and focal adhesions through transcriptional and post-transcriptional mechanisms.
R.M. Stewart¹, M.C. King¹, V.J. Horsley²,³;
¹Cell Biology, Yale School of Medicine, New Haven, CT, ²Department of Molecular, Cell and Developmental Biology, Yale University, New Haven, CT, ³Department of Dermatology, Yale School of Medicine, New Haven, CT

The cytoskeleton forms a cohesive network between cellular adhesions at the plasma membrane and nuclear envelope-spanning LINC complexes. Our work demonstrates that functional crosstalk exists between these membrane domains. For example, SUN2-containing LINC complexes regulate desmosome localization and functional integrity in a microtubule-dependent manner in epidermal keratinocytes (Stewart et al., J Cell Biol (2015) 209: 403-418). Here, we have identified a role for LINC complexes in the regulation of cytoskeletal tension and focal adhesion organization. Primary keratinocytes isolated from LINC complex-deficient mice (Sun1-/-/Sun2-/- or SunDKO) display excessive actomyosin-containing stress fibers and altered active RhoA localization. These changes coincide with increased cellular traction forces, increased tension on vinculin molecules in focal adhesions as assessed using a genetically-encoded tension sensor, and increased β1-integrin engagement as assessed by immunofluorescence staining. We further observe that SunDKO cells exhibit enlarged focal adhesions that disassemble more slowly following nocodazole treatment than those in WT cells. Strikingly, SunDKO keratinocytes exhibit drastically reduced levels of vimentin at both the transcript and protein levels. As vimentin has previously been shown to modulate RhoA activity, cellular contractility, and focal adhesion dynamics, we suggest that the loss of vimentin may underlie many of the defects we observe upon LINC complex ablation. Vimentin expressed heterologously in SunDKO cells fails to organize into a typical filamentous network, suggesting that the LINC complex may additionally play a role in the polymerization of perinuclear vimentin filaments. In addition to vimentin, we similarly observe downregulation of other genes involved in the epithelial-to-mesenchymal transition (EMT) in SunDKO cells, including Zeb2 and Twist1, thereby implicating the LINC complex in EMT. Transcriptional analysis suggests that the LINC complex may exert its impact on the expression of vimentin and other EMT genes by promoting TGFβ signaling. Taking these observations together, we propose that the LINC complex acts as a critical regulator of focal adhesions and cytoskeletal tension through both transcriptional and post-transcriptional mechanisms. Moreover, we suggest that these two influences together drive the reduced migration speed and persistence consistently described for LINC complex-ablated cells in vivo and in vitro.

Mechanical Interaction between Macrophages and Soft Targets in Phagocytosis.  
D. Vorseelen¹, J.A. Theriot¹;  
¹Biochemistry, Stanford University, Stanford, CA

Macrophages are able to phagocytose targets of vastly different sizes and rigidities, ranging from bacteria during immune response to infection, to apoptotic cell fragments during tissue homeostasis, to cancer cells after blockage of CD47. At the same time, experiments have shown that phagocytosis of similar targets can be strongly affected by minor differences in target rigidity. It is currently poorly understood how phagocytes handle targets with such disparate physical properties, or how physical cues of the target feed back into the process of phagocytosis. Studying these processes is hampered by lack of tools to probe the mechanical interaction, and specifically the spatial distribution and orientation of forces, between phagocyte and target. We developed monodisperse (CV < 0.1) spherical polyacrylamide particles with tunable size (4-20 μm) and elastic properties. These model targets can be functionalized with a variety of ligands and conjugated with various fluorescent dyes. We show that IgG-functionalized hydrogel microparticles (~10 μm) are readily taken up by J774.1 macrophage-like cells. Using confocal microscopy, we show that the microparticles are deformed by the cells, implying strong (~nN) and highly localized phagocytic forces. Currently, our work focuses on the development of elasticity theory to allow calculation of the spatial distribution of cell-exerted forces from observed particle deformations. Finally, this method is expected to find broad applications in the study of in vitro and in vivo cellular forces.

Endothelial RhoGAP DLC1 is essential to allow leukocytes to change phenotype from rolling to spreading prior to diapedesis.  
L. Schimmel¹, M.M. van der Stoel², A. van Stalborsch¹, A.M. de Ligt¹, M. Hoogenboezem³, S. Tol³, V. de Waard², S. Huveneers³, J.D. Van Buul¹;  
¹Plasma Proteins, Sanquin Research and Landsteiner Laboratory, Amsterdam, Netherlands, ²Medical Biochemistry, Academic Medical Center, Amsterdam, Netherlands, ³Central Facility, Sanquin Research and Landsteiner Laboratory, Amsterdam, Netherlands

During immune surveillance and inflammation, leukocytes follow the well-defined stages of rolling, spreading and crawling prior to diapedesis through the endothelial cells (EC) to exit the vasculature. The essential endothelial adhesion molecules E- and P-selectin for rolling, and ICAM-1 and VCAM-1 for spreading are well known, but the intracellular mechanism that allows transition from rolling to spreading on ECs is not clear. Here we found a crucial role for the endothelial GTPase activating protein (GAP) DLC1 in regulating this transition. Using physiological flow assays, we show that silencing DLC1 in ECs prolongs the rolling phase of PMNs, evidenced by increased lateral migration distance and speed prior to the actual TEM and display of a round instead of spread adherent phenotype. Both expression and functional distribution into filopodia of EC adhesion molecules were not impaired by DLC1 depletion. Additional FRAP measurements in DLC1-deficient ECs showed no alterations in ICAM-1 surface mobility or recruitment dynamics. However, recruitment of actin adaptor proteins Filamin B, α-actinin-4 and cortactin to ICAM-1 upon clustering is perturbed in DLC1-silenced cells. The ‘rolling’-phenotype of PMNs caused by EC DLC1 depletion and the recruitment of actin adaptor proteins is rescued upon re-expression of full-length DLC1. Additional mechanistic studies showed that DLC1
functions independently from its GAP activity. In conclusion, endothelial DLC1 is crucial in providing a proper endothelial surface for leukocytes allowing them to transit from rolling to spreading by recruiting actin adapter proteins towards ICAM-1 to enhance local sub-endothelial stiffness, an essential step for leukocytes prior to diapedesis.

Model of Epithelial Tissues Based on Single Cell Mechanics.

S. Liu¹, S.X. Sun¹;

¹Mechanical Engineering, Johns Hopkins University, Baltimore, MD

The generation of shape, or morphogenesis, in biological structures is frequently driven by the deformation of epithelial tissues. A variety of modeling approaches has been developed to investigate dynamic features of epithelial layers, such as the self-propelled particle model, Potts model and the vertex model. Here we develop a multicellular model for computing the geometry of epithelial monolayer based on actomyosin cortical force balance for each cell. The geometric shape of cell-cell interfaces is calculated by considering force balance between hydrostatic pressure, cytoskeleton forces and membrane tension of the two cells as well as cell-cell junction forces between them. The configuration of the complete epithelial layer can be obtained utilizing the cell volume constraint and the shape of the epithelial boundary geometry. Comparing to traditional models, this method provides an explicit connection between single cell mechanical properties to the mechanics of the epithelial layer. This model will be used to analyze mechanical properties of epithelial tissues at the single cell level.

Distinct traction stress distributions in monolayers of MDCK cells are captured by an active vertex model.

E.N. Schaumann¹, M. Staddon³,⁵, G.R. Ramirez-SanJuan⁴,⁵, S. Banerjee⁷, M.L. Gardel⁴,⁶,⁷;

¹Department of Chemistry, University of Chicago, Chicago, IL, ²Department of Physics and Astronomy, University College London, London, United Kingdom, ³Institute for the Physics of Living Systems, University College London, London, United Kingdom, ⁴Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, ⁵Graduate Program in Biophysics, University of Chicago, Chicago, IL, ⁶Department of Physics, University of Chicago, Chicago, IL, ⁷James Franck Institute, University of Chicago, Chicago, IL

Monolayers of epithelial cells are characterized by both “classical” material properties as well as self-responsiveness and other properties defined by their non-equilibrium status, and as such pose compelling questions at the intersection of several disciplines. I have identified, in the case of wild type and zonula occludens (ZO) 1 and 2 dKD Madin-Darby Canine Kidney cells, at least two patterns of behavior in how monolayers distribute mechanical forces to their environment, i.e., traction stresses. In the first case, ZO dKD cells distribute stresses in analogy to a homogeneous and isotropic elastic contractile gel, results that are in accordance with previous results on single cells and colonies of keratinocytes. The wild type cells, on the other hand, distribute stresses in contradiction to these results, most notably in the movement of stress peaks over time. This underlines the need for a dynamic model of traction stresses; the discipline of active matter provides natural candidates for such a model. A newly-developed active vertex model recapitulates the wild type behavior with a small set of tunable parameters. This, taken together with the experimental results, implies a spectrum of traction stress dynamics that could unify tissue-scale mechanics for several systems under one model.

Going with the Flow: Water Flux and Cell Shape During Cytokinesis.
Y. Li1, L. He1, J. Graham1, C. Wolgemuth2, D. Wirtz1, S.X. Sun1;
1Johns Hopkins University, Baltimore, MD, 2University of Arizona, Tucson, AZ

Cell shape changes during cytokinesis in eukaryotic cells have been attributed to contractile forces from
the actomyosin ring and the actomyosin cortex. Here we propose an additional mechanism where active
pumping of ions and water at the cell poles and the division furrow can also achieve the same type of
shape change during cytokinesis without myosin contraction. We develop a general mathematical model
to examine shape changes in a permeable object subject to boundary fluxes. We find that hydrodynamic
flows in the cytoplasm and the relative drag between the cytoskeleton network phase and the water
phase also play a role in determining the cell shape during cytokinesis. Forces from the actomyosin
contractile ring and cortex do contribute to the cell shape, and can work together with water
permeation to facilitate cytokinesis. To influence water flow, we osmotically shock the cell during cell
division, and find that the cell can actively adapt to osmotic changes and complete division.
Depolymerizing the actin cytoskeleton during cytokinesis also does not affect the contraction speed. We
also explore the role of membrane ion channels and pumps in setting up the spatially varying water flux.

Variable rescue of microtubule defects in mdx skeletal muscle expressing miniaturized
dystrophins.
D.M. Nelson1, D. Duan2, L.M. Judge3, J.S. Chamberlain3, J.M. Ervasti1;
1Biochemistry, Molecular Biology, and Biophysics, University of Minnesota, Minneapolis, MN,
2Skeletal Muscle Research and Myology, Myology Institute, University of Arizona, Tucson, AZ,
3Molecular Microbiology and Immunology, University of Missouri, Columbia, MO, 4Neurology, University of
Washington, Seattle, WA

Duchenne muscular dystrophy (DMD) is a progressive and ultimately fatal loss of muscle function that
results from the absence of dystrophin protein. As a structural protein, dystrophin bridges between
the intracellular actin and microtubule cytoskeletons and the transmembrane dystrophin-glycoprotein
complex. It is believed that dystrophin provides a subsarcolemmal guide which directs the microtubule
cytoskeleton into a perpendicular lattice. When dystrophin is absent in mdx mice, the skeletal muscle
microtubule lattice becomes disorganized as characterized by the loss of 90° microtubule intersections.
Moreover, the mdx microtubule lattice exhibits increased density as compared to wildtype. We seek to
further understand the dystrophin-microtubule interface by determining which dystrophin domains
influence microtubule organization and density. A panel of truncated, therapeutic dystrophin constructs
expressed on the mdx background were utilized to quantify microtubule organization and density.
Through comparison of domain conservation across 6 transgenic mdx lines, we report here that the N-
terminus and cysteine rich domains are required for partial restoration of microtubule organization and
are competent to decrease microtubule density to wildtype levels. Full restoration of the microtubule
lattice however, appears to require additional dystrophin domains, potentially spectrin-like repeats 20-
24 which have been previously identified to influence the in vitro microtubule binding capability of
dystrophin. Additionally, the examined micro-dystrophins were capable of decreasing the elevated mdx
detyrosinated α-tubulin levels. Detyrosination is a tubulin modification that when elevated is proposed
to stiffen the microtubule cytoskeleton to drive mechanically stimulated reactive oxygen species and
disrupt Ca2+ homeostasis. We conclude that the tested therapeutic constructs, while differing in their

Sunday-374
truncations, are all capable of significantly improving toward wildtype the microtubule defects in \textit{mdx} skeletal muscle.

\textbf{Basal body associated striated fibers control their length to organize ciliary arrays.}
W. Soh\textsuperscript{1}, J. van Dam\textsuperscript{2}, A. Stemm-Wolf\textsuperscript{3}, C.G. Pearson\textsuperscript{1};
\textsuperscript{1}Cell biology, stem cells and development, University of Colorado Anschutz Medical Campus, Aurora, CO, 
\textsuperscript{2}Biodynamics and biocomplexity, Universiteit Utrecht, Utrecht, Netherlands

Multi-ciliary arrays are fields of motile cilia that beat in a coordinated and polarized manner. This organization of cilia is promoted by the basal bodies (BB) that nucleate, anchor and position cilia at the cell cortex. Extending from the base of BB, striated fibers (SFs) connect BBs to each other and to the cell’s cortex. SF are structurally conserved polymers composed of striations with organism-specific periodicities. The striations in Tetrahymena SFs are spaced 27 nm apart. These ciliated cells possess a network of polarized BBs and SFs that link the approximately 500 BBs per cell. The loss of SFs causes BB and ciliary disorganization that is exacerbated by increased ciliary beating forces. Consistent with a role for SFs in resisting ciliary forces, Tetrahymena SFs lengthen when ciliary beating is elevated. Conversely, SFs shorten when ciliary forces are reduced. This suggests that SFs modulate their length in response to their hydrodynamic environment. We next studied the structure and protein dynamics of SFs to understand how SF length is controlled. The periodicity between SF striations remains the same even when the total SF length changes. The SF architecture comprises a complex network of 10 SF-assemblin-like proteins. Tetrahymena cells possess the SF-assemblin homologue that forms the core SF structure in algae. In addition, other SF-assemblin-like proteins localize to unique domains within the SF structure. As SFs lengthen during maturation or force induced elongation, the level of SF protein components increases. Thus, local SF protein component levels likely promote SF elongation. In summary, we provide a mechanistic basis for how the complex molecular architecture of SFs controls their length in response to ciliary forces.

\textsuperscript{1}National Institute of Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, 
\textsuperscript{2}Institute for Biomedical Sciences, The George Washington University, Washington, DC, \textsuperscript{3}Psychiatry, National Institute of Mental Health and Neurosciences, Bangalore, India, \textsuperscript{4}Center for Information Technology, National Institutes of Health, Bethesda, MD, \textsuperscript{5}School of Medicine, The University of Connecticut, Farmington, CT, \textsuperscript{6}National Human Genome Research Institute, National Institutes of Health, Bethesda, MD

We have developed a live imaging system to study the growth of a single pioneer axon, TSM1, in the developing \textit{Drosophila} wing. We find that the TSM growth cone differs from the flat, lamellar growth cones typically documented in culture, and employs a novel mechanism of motility that is fundamentally different from the familiar adhesion-clutch model of axon growth. Our lower resolution movies (1 min/frame, 3 min/frame) show that actin accumulates in the distal portion of the extending TSM1 axon, and that the axon advances by cycles of de-condensation of the actin mass, followed by re-condensation.
at a slightly more distal position. When we use higher-resolution imaging (15 sec/frame), the distal accumulation of bulk actin is still observed, and we detect both retrograde and anterograde motion of individual actin speckles. To investigate the source of this motion, we are imaging the association of actin with vesicles and microtubules. We observe some co-localization of actin speckles with motile vesicles, while there are also actin speckles that appear to move independently of vesicle motion. Looking at microtubule distribution, our data suggest that the accumulation of actin may be distal to the mass of high microtubule density, potentially consistent with models of microtubule-driven advance of the actin mass. Using these high-resolution movies, we have observed fluctuations in the width of the actin peak as TSM grows. To inspect if there is oscillatory behavior in these fluctuations, we have conducted fast fourier transform, and no periodicity is detected in the change of the actin peak width. This indicates that the TSM axon advances by taking advantage of random fluctuations of the actin mass, perhaps in a fashion similar to the “Brownian ratchet” models. Our work provides a novel picture for axon growth in vivo, which we can use to study the underlying mechanisms regulating neuron motility.

Structure, dynamics, and mechanical forces: the actin cytoskeleton in neutrophil phagocytosis.
R.D. Labitigan\textsuperscript{1}, J.A. Theriot\textsuperscript{1};
\textsuperscript{1}Department of Biochemistry, Stanford University School of Medicine, Stanford, CA

Immune cell phagocytosis plays a key role in the immune response, development, and tissue homeostasis, and is implicated in a wide range of disease processes from infection to cancer. Even though immune cell phagocytosis was discovered over 100 years ago, we still lack a unified, mechanistic understanding of the process, largely because of technical challenges in studying the phagocytic cup—a transient, dynamic, and topologically complex, 3D structure. This is in stark contrast to our understanding of the lamellipodium, a stable, steady-state, flat actin structure at the leading edge of migrating cells, for which we have a well-developed understanding of the interplay between actin network structure, dynamics, and mechanics. I have designed an experimental system to map the actin cytoskeleton structure, dynamics, and force generation within the neutrophil phagocytic cup at high spatiotemporal resolution. I am using this experimental pipeline to answer unsolved mechanistic questions, including how target particle properties affect phagocytosis, how the phagocytic cup is resolved into a closed compartment, and how actin is dynamically disassembled during phagocytosis.

Actin regulators control cytoskeletal dynamics to enable critical functions such as migration and cell division. However, most detailed studies of actin regulators have been performed on cells adhered to glass coverslips. To study the role of actin regulators in a more physiological environment, we used light
sheet microscopy to enable high resolution imaging of cells deep in a 3D matrix. We systematically knocked-out a diverse set of actin regulators using CRISPR-Cas9, and evaluated the effect of each on cell spreading, cellular branching, and adhesion size and dynamics for cells embedded in stroma-like ECM environments. Early results suggest that cells require a delicate balance between actin polymerization and depolymerization to properly spread, and these effects are more evident when cells are placed in 3D ECM environments. In contrast, these phenotypes were absent when cells were seeded on 2D planar substrates. We suspect that the number and lifetime of cell-matrix adhesions, and the mechanical properties of the cortical actin network are affected in 3D (potentially inflicted by altered matrix geometry surrounding the cells), and is the subject of our ongoing investigation. Together these results emphasize the importance of the cellular environment, and suggest that subtle phenotypes may have been overlooked throughout the past several decades due to inappropriate contextual ECM cues.

3D cell migration is principally governed by environmental cues via subcellular mechanisms such as intracellular signaling and cytoskeletal dynamics. Directly observing the regulation of 3D cell migration therefore requires simultaneously imaging across multiple spatial and temporal scales, ranging from the small (<1 micrometers) and quick (<1 seconds) scales regulating cytoskeletal turnover to the large (>10 micrometers) and slow scales (>10 minutes) of the cell interacting with its environment. Recent advances in high-resolution light-sheet microscopy have begun to allow us to image cells in 3D over these scales with single molecule sensitivity. However, the large size and the difficulty of visualizing 3D objects with complex geometries on 2D computer screens prohibit interpretation of this microscopy data by eye. To facilitate automated analysis of these images, we developed a 3D morphological structure detector to locate and characterize protrusions. This detector combines techniques from computer graphics, machine learning, and computer vision to identify stereotyped protrusions, such as filopodia, blebs, and lamellipodia. The detector decomposes the cell surface into approximately convex patches, merges those patches via machine learning, and then, again via machine learning, classifies the merged patches by protrusion type. A surface patch is convex if any two points on the patch can be connected by a line that does not exit the cell. Since it relies on machine learning, to detect new protrusion types researchers do not need to mathematically describe protrusions, but rather click on examples of these structures in their own data. A support vector machine generalizes these examples to a model that can be used to detect this protrusion type in new data sets. Using this detector, we analyzed the membrane distribution of PIP2 and KRAS in blebbing melanoma cells embedded in 3D collagen. We found that PIP2 associates with individual blebs, whereas KRAS localizes to regions of high bleb surface density, but does not associate with individual blebs. This detector will facilitate the study of the subcellular regulation of 3D cell migration.

Transition between actin-driven and water-driven cell migrations depends on the external coefficient of hydraulic resistance.
Y. Li, K. Bera, A. Afthinos, R. Zhao, K. Konstantopoulos, S.X. Sun; 
1Johns Hopkins University, Baltimore, MD

Cells in vivo can reside in diverse physical and biochemical environments. For example, epithelial cells typically live in a two-dimensional (2D) environment while metastatic cancer cells can move through dense three-dimensional (3D) matrices. These distinct environments impose different kinds of mechanical forces on cells, and thus potentially can influence the mechanism of cell migration. For example, cell movement on 2D flat surfaces is mostly driven by forces from focal adhesion and actin polymerization, while in confined geometries, it can be driven by water permeation. In this work, we develop a two-phase model of the cellular cytoplasm, where the mechanics of the cytosol and the F-actin network are treated in single unified framework. Using conservation laws and simple force balance considerations, we are able to describe the contribution of water flux, actin polymerization and flow, and focal adhesions to cell migration in both 2D surfaces and in confined spaces. The theory shows how cell migration can seamlessly transition from a focal adhesion- and actin-based mechanism on 2D surfaces to a water-based mechanism in confined geometries. Moreover, the model explains the counterintuitive experimental observation that the cell velocity can increase with increasing external coefficient of hydraulic resistance.

YAP-independent mechanotransduction drives breast cancer invasion.
J.Y. Lee, J. Chang, S. Nam, H. Lee, A. Dominguez, S. Varma, L.S. Qi, R. West, O. Chaudhuri; 1Mechanical Engineering, Stanford University, Stanford, CA, 2Genetics, Stanford University, Stanford, CA, 3Bioengineering, Stanford University, Stanford, CA, 4ChEM-H, Stanford University, Stanford, CA, 5Chemical and Systems Biology, Stanford University, Stanford, CA, 6Pathology, Stanford University, Stanford, CA

Ductal carcinoma in situ (DCIS) progresses to invasive ductal carcinoma (IDC) when carcinoma cells break through the laminin-rich basement membrane (BM) into the type-1 collagen (col-1) rich stroma, a key first step towards metastasis. The drivers of progression remain unclear, with no established biomarkers. However, increased tissue stiffness correlates with invasion and the transcriptional regulator YAP has been implicated as a mechanotransducer, largely based on 2D culture studies. To identify drivers of DCIS progression, we encapsulated mammary epithelial cells (MECs) in 3D hydrogels with a range of stiffnesses and that presented either BM-ligands or col-1 containing microenvironments to the cells. Surprisingly, enhanced stiffness induced invasion in MECs independently of YAP activation in both BM-like and col-1 rich 3D hydrogels. To provide mechanistic insight into the unexpected lack of YAP activity during MEC mechanotransduction in 3D culture, we examined YAP activation in 2D culture as a point of comparison. Interestingly, confocal microscopy and mass spectrometry showed that YAP colocalized and immunoprecipitated with actin, respectively, and identified distinct YAP binding partners depending on cell context. As actin network architecture is dramatically altered in 3D culture, this may explain differences in YAP activation in 2D versus 3D culture. Further, RNA-seq identified the global gene expression changes induced by increased 3D stiffness, and bioinformatic analysis combined with inhibition studies identified transcriptional regulators p300 and STAT3 as mediators of stiffness-induced...
invasion. RNA-seq also showed that col-1 exposure in stiff gels promotes alterations in carcinoma phenotype, inducing tumor cell expression of genes whose protein products remodel the col-1 network including FN1 and LOX. 3SEQ analysis of breast cancer patient samples revealed that genes identified by 3D culturing in hydrogels were upregulated in breast cancer patients, suggesting expression of S100A7 as a potential biomarker of cancer progression. While genetic mutations initiate transformation, these results reveal the molecular events underlying breast cancer invasion initiated by physical properties of the microenvironment, as well as alteration of the carcinoma phenotype following invasion through the BM into the col-1 stroma.

Nuclear stress dependent DNA damage and DNA repair factor mis-localization after lamin-A depletion on rigid plastic and in constricted migration.

Y. Xia¹, J. Irianto², K. Zhu³, L. Smith³, C.R. Pfeifer³, D.E. Discher³;
¹Chemical and Biomolecular Engineering, University of Pennsylvania, Philadelphia, PA, ²University of Pennsylvania, Philadelphia, PA

Lamin A has long been associated with the role of protecting the nucleus. When lamin-A is partially depleted in the nucleus, nuclear envelope becomes more susceptible to stress-induced rupture. Here, we report that multiple repair factors will mis-localize to the cytoplasm immediately after rupture but the recovery process takes ~7 hours to complete. As the recovery process takes longer than time required for DNA repair (~3hr), elevated DNA damage will then occur in cells who experienced nuclear envelope rupture. Myosin-II mediated nuclear stress is one of the causality of the nuclear stress. Releasing stress by applying soft substrate or myosin II inhibitor is sufficient to minimize rupture and therefore rescue DNA damage. In contrast, overexpressing myosin II can increase the incidence of nuclear envelope rupture and DNA damage. During constricted migration where high fraction of nuclear envelope rupture is observed, myosin II inhibition can effectively minimize nuclear envelope rupture and DNA damage, which is consistent with the result in 2D experiments. Overexpressing multiple essential repair factors at the same time is sufficient to partially rescue DNA damage caused by nuclear envelope rupture as well, indicating again the importance of DNA repair factors during nuclear envelope rupture. In vivo, cancer cells in low lamin-A tumors experience more nuclear envelope rupture than cells in Ctl tumors, hinting low lamin-A tumors may have higher chance of developing genomic variation.

DNA damage in constricted migration impairs differentiation of myoblasts.

L.R. Smith¹, J. Irianto¹, Y. Xia¹, C.R. Pfeifer¹, D.E. Discher¹;
¹Chemical and Biochemical Engineering, University of Pennsylvania, Philadelphia, PA

**Introduction:** Tissue regeneration often relies upon a stem cell’s ability to proliferate, migrate, and differentiate to form new tissue. Chronic tissue injuries are often associated with fibrosis states that poses dense connective tissue networks with small pores and compromised the tissue regenerative capacity. Recent studies show that constricted migration of cancer cells causes DNA damage, genomic instability, and phenotypic alterations. Skeletal muscle has both a local stem cell population that is highly migratory and becomes fibrotic in diseased states. Thus, we hypothesized that muscle progenitors incur DNA damage and have impaired differentiation after constricted migration, which may account for defects in regenerative capacity of fibrotic muscle.
**Methods:** Both a murine myoblast cell line (C2C12) and a human rhabomyosarcoma, muscle progenitor cancer, (Rh30) were used. Cells were placed on top of a transwell membrane with either small 3 μm or large 8 μm pores and allowed to migrate through the membrane for 24-48 hours. Immunofluorescent imaging was used to count γH2AX foci within the nucleus as a marker DNA damage as well as the presence of nuclear blebbing indicated from lamin staining. DNA damage was chemically induced with etopside. Myoblasts were differentiated with low serum and stained for the presence of sarcomeric myosin to quantify differentiation. Serial transwell experiments used migrated cells from the bottom of a membrane that were expanded and then seeded on the top of another membrane.

**Results:** We find C2C12 myoblasts and Rh30 cells accumulate DNA damage as γH2AX foci (110% C2C12 and 60%, Rh30) after migration through rigid small pores that is mitigated in migration through large pores. After constricted migration, 32% of C2C12 cells show rupture of the nuclear lamina even though replication and proliferation rate are unaffected, with similar results for Rh30. Further rounds of constricted migration cause further accumulation of DNA damage that does not recover, even after 1 week in culture. Myoblast differentiation is temporarily reduced by 55% in cells migrating through small pores and nearly eliminated after 3 rounds of transwell migration through small pores. Chemical induction of DNA damage in C2C12 myoblasts reduced differentiation by 80% demonstrating DNA damage as a plausible mechanism for impaired differentiation.

**Conclusions:** The stresses induced by constricted migration through small pores causes DNA damage and nuclear disruption in myoblasts. Constricted migration impedes the differentiation capacity of myoblasts and is compounded by serial migration. This work establishes constricted migration as a plausible mechanism for impaired differentiation, particularly in a fibrotic environment with increasingly small pores.

**Forces and cytoskeletal dynamics during collective invasion of tumor spheroids.**

B. Fabry¹, C. Mark¹

¹Physics, University of Erlangen-Nuremberg, Erlangen, Germany

Cell movements and associated cell-generated forces are of central importance in cancer metastasis where tumor cells leave a primary tumor and invade the surrounding tissue. This invasion process is driven by cells at the tumor boundary that collectively exert physical forces on the extracellular matrix. To study the physical forces arising from these collective effects, we embed invasive HT-1080 fibrosarcoma spheroids and non-invasive MCF-7 spheroids containing 500-3000 cells in reconstituted collagen matrices. We measure the ongoing deformation of the collagen matrix over time by tracking embedded silica beads in the equatorial plane of the spheroids. We then compute the collective contractile forces from the matrix deformations with a finite element model that takes the highly non-linear mechanical properties of collagen into account. For the invasive cell line (HT-1080), we find that spheroids reach their maximal contractility after 30 min. At this time point, no cells have left the tumor. Subsequently, overall contractile forces remain constant while cells at the spheroid border invade the matrix. Surprisingly, spheroids from the non-invasive cell line (MCF-7) also generate substantial contractile forces, but these forces rise slowly over the course of 12 hours, and no cells leave the spheroid. We conclude that overall contractility is a poor indicator for cell invasiveness, and hypothesize that dynamical changes of forces and cytoskeletal reorganization may be more indicative. To measure cell dynamics, we record time-lapse images of four differently invasive cell types (A125, MDA-MB-231, HT1080, IFFUC, in increasing order of invasiveness in a 3-D collagen gel) on a fibronectin-coated, 2-dimensional plastic substrate. From the cell trajectories, we infer temporal changes in directional persistence and migration speed. We consistently find that temporal changes of directional persistence
and migration speed show a substantially higher cross-correlation in the more invasive cell lines. Together, these results suggest that cell invasiveness requires a tight coupling of cytoskeletal dynamics and force generation with cell polarization. An interesting corollary finding of this study is that collective 3-D cell invasiveness can be related to single cell behavior under standard 2-D culture conditions.

Basement membrane (BM) is a dense sheet of specialized extracellular matrix that separates epithelia from underlying tissue. The penetration of cells through BM barriers, called “invasion”, is an important process during normal organ development and in cancer metastasis. Invasive protrusions are rich in actin, but it is unclear whether actin polymerization produces forces that help pierce BM or if actin simply serves as a scaffold for trafficking of components to the invasive edge.

To address the role of actin-based force production in invasion, we studied an invasion event in a developmental process, anchor cell (AC) invasion in Caenorhabditis elegans. AC breaching of the BM is known to depend on an actin-rich protrusion and matrix metalloproteases are present, similar to cancer cell invasion. When the Arp2/3 complex activator WSP-1/WASP was deleted, AC invasion was delayed, despite the fact that essential invasive components were still correctly localized at the invasive membrane. Expression of a dominant negative form of WSP-1/WASP specifically in the AC showed that AC protrusion formation and invasion depended strongly on the activity of the Arp2/3 complex. Super-resolution microscopy indicated that the AC invasive protrusion was densely packed with filaments, in keeping with the idea that the actin network in the invasive protrusion was highly branched. Another Arp2/3 complex activator, WVE-1/WAVE, colocalized with WSP-1/WASP in the invasive protrusion, as observed using worm strains carrying endogenous fluorescently labeled proteins. WVE-1/WAVE appeared to enable invasion to a lesser extent than WSP-1/WASP, perhaps due to its lower capacity to activate the Arp2/3 complex, evaluated by an in vitro pyrene actin polymerization assay.

All together these results show that the invading cell forms a dense, branched actin network via the activity of the Arp2/3 complex in order to puncture the BM, providing evidence that actin-based forces play a role in BM invasion.

**Transient Mechanical Strain Promotes the Maturation of Invadopodia through PAK1 Signaling.**

A.N. Gasparski¹, J. Wilson¹, K.A. Beningo¹;

¹Department of Biological Sciences, Wayne State University, Detroit, MI

Cell invasion is a process used by normal and cancerous cells and can be affected by multiple forms of biomechanical forces encountered in the cells microenvironment. Our lab has previously shown that a transient tugging force within an in vitro mechano-invasion assay enhances the invasion of fibrosarcoma cells. This tugging force mimics the magnitude of contractile forces provided by fibroblast movements in the extracellular matrix. Tugging forces down-regulated integrin β3 expression and increased active
cofilin levels in fibrosarcoma cells. The active cofilin coincided with the maturation of invadopodia, as shown by an increase in both invadopodia length and enzymatic activity, and to greater cell invasion. This study targets an established signaling pathway that results from the reduction of integrin β3 expression and tests its relevance to the cellular response to transient tugging forces. p21-Activated kinase 1 (PAK1) is a serine/threonine-kinase that is involved in cytoskeletal remodeling, cell invasion and metastasis. It is downstream from integrin β3 in a signaling pathway that culminates in increased active cofilin levels. We have found that PAK1 expression and activity is reduced by the mechanical stimulation provided by our assay. Furthermore, overexpression of PAK1 kinase mutants corroborates that PAK1 activity must be down-regulated for enhanced invasion to occur in response to stimulation. These results implicate PAK1 in the signaling pathway utilized by the cell to increase its invasion abilities when transient tugging forces are encountered. This study provides additional insight into the cellular mechanism used during the process of invasion in response to extracellular mechanical cues.

S100A4 Regulates Macrophage Invasion by Distinct Myosin-Dependent and Independent Mechanisms.
N.G. Dulyaninova1, P.D. Ruiz2, M.J. Gamble2, A.R. Bresnick1, J.M. Backer1,2;
1Biochemistry, Albert Einstein College of Medicine, Bronx, NY, 2Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY

S100A4, a member of the S100 family of Ca2+-binding proteins, is a key regulator of cell migration and invasion. Our previous studies showed that bone marrow-derived macrophages (BMMs) from S100A4−/− mice exhibit defects in directional motility and chemotaxis in vitro, as well as reduced recruitment to sites of inflammation in vivo (Li et al., Mol Biol Cell 21:2598, 2010). We have now evaluated the role of S100A4 in the invasive capacity of macrophages. Zymography and MMP9 activity assays of conditioned medium from S100A4−/− BMMs revealed an increase in MMP9 secretion that was associated with stabilization of the microtubule network and an increase in alpha-tubulin acetylation. Paradoxically, despite the increase in MMP9 secretion, S100A4−/− BMMs exhibited marked defects in 2D gelatin degradation and invasion in a Matrigel transwell assay. Furthermore, podosome rosettes were reduced in number and size, and showed a decrease in their rate of turnover. Notably, the average area of podosome rosettes and their ability to degrade gelatin was rescued by treatment of S100A4−/− BMMs with blebbistatin, an inhibitor that maintains the myosin-II motor in a weak actin binding state and counteracts the actomyosin overassembly caused by S100A4 loss. These data suggest that the effect of S100A4 loss on podosome rosettes was due in part to myosin-IIA overassembly. However, neither the enhancement in alpha-tubulin acetylation nor the defect in invasion was affected by blebbistatin. Moreover, treatment of wild type BMMs with the HDAC6-selective inhibitor tubacin led to an increase in microtubule acetylation that was similar to that seen in S100A4−/− BMMs, and caused a comparable loss of invasion. Our data demonstrate that the loss of S100A4 produces two mechanistically distinct phenotypes with regard to macrophage invasion: a defect in matrix degradation, due to a disruption of podosome rosettes caused by myosin-IIA overassembly, and a myosin-independent increase in microtubule acetylation, which increases podosome rosette stability and is sufficient to inhibit macrophage invasion. These studies highlight the role of S100A4 as a critical regulator of matrix degradation, whose actions converge on the dynamics and degradative functions of podosome rosettes.

Chemotaxis and directionally persistent migration of cancer cells is promoted by exosome secretion.
B. Sung1, A.M. Weaver1,2;
1Cell and Developmental Biology, School of Medicine, Vanderbilt University, Nashville, TN, 2Pathology, Microbiology, and Immunology, Vanderbilt University Medical Center, Nashville, TN

Directional migration of cancer cells is promoted by exosome secretion but the underlying mechanisms are not well understood. Directional migration of cells could occur by responding to directional cues such as chemical, matrix, and topology of environment. Chemotaxis, directed cell motility toward chemical cues, is thought to occur in cancer cells but is poorly characterized. Here, we show that chemotaxis of cancer cells depends on exosome secretion. Migration of human fibrosarcoma cells toward a gradient of exosome-depleted serum was diminished by knocking down expression of Rab27a, an exosome secretion regulator. Rescue experiments, performed by coating extracellular vesicles and purified fibronectin onto the cell migration area of chemotaxis chambers, revealed that exosomes but not microvesicles affect both the speed and directionality of migrating cancer cells. In addition, fibronectin promoted only speed and not directionality of migrating cells. We also tested whether exosome secretion affects migration of cells in diverse topologies, using ECM-coated synthetic nanofibers to mimic in vivo environments. In these environments as well, we find that exosome secretion promotes persistent migration of cancer cells. Compared to control cells that migrate relatively persistently on aligned nanofibers, exosome secretion-inhibited cells continuously change their direction of migration in a bi-directional mode of migration. In random fiber meshworks, exosome-inhibited cells exhibit excessive pausing at the junctions of random nanofibers. Thus, exosomes promote multiple aspects of cell motility such as speed, directionality, and persistence, which are needed to navigate complex environments.

Fluctuations in directional persistence and cell speed define cell migration strategies.
C.W. Mark1, C. Metzner1, J. Steinwachs1, B. Fabry1;
1Physics, University of Erlangen-Nuremberg, Erlangen, Germany

Depending on cell type and the local environment, tumor cells show a variety of different migration modes, including mesenchymal and amoeboid motion. To invade a spatially heterogeneous extracellular matrix, the cell needs to coordinate cytoskeletal remodeling, polarization and force generation. Because of this interplay of processes, cell motility indicators such as cell speed and directional persistence are not constant over time but exhibit both gradual and abrupt changes. Since conventional statistical methods average over both time and ensembles of cells, the information contained in these temporal changes is lost. Therefore, common measures of cell motility like the step width distribution or the mean squared displacement fail to distinguish between cell migration strategies in different environments, or between the migration patterns of different cell types. They also cannot explain typical features of cell migration including the exponential step width distribution and power-law mean squared displacements that are a direct consequence of temporal fluctuations in cell speed and directional persistence. Using a novel approach to time series analysis based on Bayesian statistics, we infer the directional persistence and cell speed for each time step of a cell trajectory, taking into account both gradual and abrupt changes in those parameters [1]. We demonstrate that the temporal changes in
persistence and migratory speed provide a distinct fingerprint of the strategies that cells employ to migrate through different environments. For example, persistence is positively correlated with speed in a 3D collagen matrix over much longer time periods compared to migration on 2D substrates, supporting the hypothesis that cells are able to pull themselves along collagen fibers and hence use the surrounding matrix to their advantage. In agreement with this, we find that the directional persistence of invading tumor cells is highly correlated with contractility and cell elongation [2]. The invasion behavior of these cells can thus be described by a gliding motion with alternating phases of simultaneously high or low contractility, elongation, migratory speed and persistence.

**Mechanisms of Persistent Cell Migration in Aligned Collagen Matrices.**

J. Szulczewski\(^1\), S.M. Ponik\(^1,2\), A.S. Nain\(^3\), K.M. Hahn\(^4\), P.J. Keely\(^1,2\);

\(^1\)Cellular and Regenerative Biology, University of Wisconsin-Madison, Madison, WI, \(^2\) Molecular and Cellular Pharmacology Graduate Program, University of Wisconsin-Madison, Madison, WI, \(^3\) Mechanical Engineering, Virginia Tech, Blacksburg, VA, \(^4\) Pharmacology, University of North Carolina-Chapel Hill, Chapel Hill, NC

Increasing evidence demonstrates that the organization of collagen in the tumor microenvironment is a key factor in breast cancer progression. Stromal collagen surrounding mouse mammary tumors is often aligned and reorganized perpendicular to the tumor boundary. Our lab has demonstrated that aligned collagen enhances tumor progression and metastasis in a mouse model, and predicts poor outcome for breast cancer patients. At the cellular level, aligned collagen increased migration persistence of breast cancer cells by limiting protrusion number. However, the cellular mechanisms involved in regulating protrusions within an aligned collagen matrix is not understood. Using multiple methods to generate various fiber arrangements, we found that the ROCK signaling pathway plays a role in limiting cellular protrusions. MDA-MB-231 breast cancer cells cultured in an aligned 3D collagen matrix had fewer protrusions, which were oriented along the fibers, compared to cells cultured in random collagen matrices. Treatment with low dose ROCK inhibitor (5μM H1152), to decrease rather than abolish ROCK activity, resulted in an increase number of protrusions in cells cultured in aligned and random collagen compared to control cells. Additionally, mammary carcinoma cells cultured in random collagen had more dynamic protrusions, which was enhanced further with ROCK treatment. Together, these results suggest a role for ROCK signaling in the regulation of protrusion number and dynamics in mammary carcinoma cells.

Myosin II governs intracellular pressure and traction force by distinct mechanisms.
K. Sao¹, T.M. Jones¹, A.D. Doyle², G. Schevzov³, P.W. Gunning³, R.J. Petrie³;
¹Biology, Drexel University, Philadelphia, PA, ²NIDCR, National Institutes of Health, Bethesda, MD,
³Medical Sciences, University of New South Wales, Sydney, Australia

During wound healing by dermal fibroblasts and tissue invasion by metastatic cells, the actin-binding proteins tropomyosin (Tpm) and non-muscle myosin II control the cellular contractile forces that drive cell motility. Classically, two-dimensional (2D) substrate rigidity is known to promote myosin II activity to increase traction force and enlarge focal adhesions in a process coordinated by Tpm 2.1. Traction force can facilitate 3D migration by aligning and stiffening the collagen bundles surrounding moving cells. We recently discovered myosin II activity can also compresses the cytoplasm to increase intracellular hydraulic pressure and switch cells from low-pressure lamellipodia to high-pressure lobopodial protrusions during 3D migration. Both intracellular pressure and traction force require actomyosin contractility. However, it remains unclear whether these myosin II-generated cellular forces are produced simultaneously, by the same molecular machinery. To test the hypothesis that intracellular pressure and traction force are generated by two distinct mechanisms, we first compared intracellular pressure and adhesion size in cells on soft (5 kPa) versus stiff (70 kPa) 2D substrates. We found adhesion size decreased and intracellular increased on soft material, suggesting traction force and pressure can be controlled independently. To identify a potential pressure-specific regulator of actomyosin contractility, we overexpressed individual tropomyosin isoforms and discovered Tpm 1.6 expression increased intracellular pressure on 2D, while reducing traction force. In contrast, Tpm 2.1 expression increased adhesion size and decreased traction force, but had no effect on intracellular pressure. Knocking down endogenous Tpm 1.6 expression reduced intracellular pressure and switched cells migrating in 3D ECM from lobopodia to lamellipodia protrusions, consistent with inhibiting myosin II directly. Together, our results indicate that Tpm 1.6 expression is a positive-regulator of intracellular pressure, while Tpm 2.1 is a negative regulator of traction force. This suggests that actomyosin contractility generates intracellular pressure and traction force by distinct molecular mechanisms. Future work will establish how these two molecular machineries are integrated to generate complex cell behaviors on 2D and in 3D environments.

Cellular mechanics of 3D migration: Uniaxial contraction induces matrix prestress to enhance efficiency of 3D mesenchymal cell migration.
A.D. Doyle¹, D.J. Sykora¹, G. Pacheco¹, K.M. Yamada¹;
¹Cell Biology Section, National Institute of Dental Craniofacial Research, NIH, Bethesda, MD

Cell migration is a complex, integrated function that is highly dependent on attributes of the surrounding microenvironment. During cell migration, cytoskeletal contractile forces are transmitted to the microenvironment through integrin-based focal adhesions in a process known as mechanotransduction. This process provides a bidirectional pathway for local application of cellular forces to the ECM, while cells concurrently receive information about physical characteristics of the ECM. A specific characteristic of extracellular matrix (ECM) known to alter cell migration is stiffness, which many cells can discern through the process of mechanosensing. This process has classically been characterized on two-dimensional, flat surfaces where it has been shown that many cells, including
mesenchymal fibroblasts, can “sense” and migrate towards stiffer ECM. However, it remains unclear how mechanotransduction occurs within a three-dimensional (3D) microenvironment and whether this is a common process required for efficient 3D cell migration by various cell types. Here we describe a unique contractile mechanism utilized by mesenchymal fibroblasts and their malignant counterpart, HT-1080 fibrosarcoma cells, to migrate efficiently through 3D collagen gels. Analysis of ECM deformations reveal that both cell types periodically pinch the matrix locally immediately behind the leading edge. This uniaxial contractile process is obscured by a large, anterior matrix prestress generated solely in the direction of cell motility. Through quantitative temporal analysis, we find this contraction occurs prior to leading edge protrusion. Analysis of 3D cell spreading suggests initial cell polarization is highly force dependent, with cells protruding and migrating in the direction of highest ECM deformation. Myosin IIA is required for both force polarization during spreading and maintenance of matrix prestress during cell migration, while myosin IIB is only required for the latter. Local matrix severing by two-photon ablation to disrupt matrix prestress in front of a cell results in cell repolarization and an eventual change in cell trajectory, indicating mesenchymal cells can sense ECM stiffness in 3D and generate their own prestress in soft matrices to migrate efficiently.

Hierarchical influence of cell-mediated fiber movement on protrusion alignment, cell polarization, and directed migration.
M.Z. Pamonag1, N. Jafari1, D. Sales1, V. Shuklis4, K. Kubow1;
1Biology, James Madison University, Harrisonburg, VA

Directed cell migration plays a critical role in numerous physiological processes, such as cancer cell metastasis and tissue regeneration, and is guided by numerous factors including the physical structure of the extracellular matrix (ECM). Indeed cells have long been observed to follow anisotropic substrate features such as blood vessels and aligned fibers. However, migrating cells can also align ECM fibers, suggesting a positive feedback system in which cells simultaneously follow and align fibers, making migration persistence self-reinforcing. This phenomenon has typically been studied in the context of large cell masses and large-scale ECM deformations. Here we asked whether the same positive feedback system is able to influence individual cell directionality.

To study how the ability of cells to generate fiber alignment affects cell polarity and migration behavior, we examined scenarios in which this ability was impaired. Inhibiting non-muscle myosin II (MII) in HT-1080 fibrosarcoma cells cultured in collagen type I matrices with randomly oriented fibers reduced the cells’ overall polarization in accordance with MII’s role in establishing cell polarity. However, individual cell protrusions nevertheless exhibited contact guidance along matrix fibers. Further experimentation utilizing cells on rigid, aligned polycaprolactone (PCL) fiber scaffolds revealed that cell polarity in fibrous environments can be determined at the level of individual protrusions, which are individually guided by local fiber orientation, independent of MII. The co-alignment of multiple protrusions, such as occurs in the presence of co-aligned fibers, polarizes the entire cell. However, if the fibers are not aligned and cannot be aligned by cell-generated forces, contact guidance of individual protrusions still occurs along fibers, but does not produce overall cell polarization. This behavior is observed regardless of whether fiber reorganization is prevented mechanically (i.e. stiff fibers) or via MII inhibition.

The inability of cells to develop a persistent polarization in environments with randomly aligned fibers that cannot be aligned by the cell, led us to ask how this would affect migration persistence. We monitored the migration of HT-1080 cells in collagen matrices that were or were not photocrosslinked to reduce cell-mediated fiber movement. Our preliminary results indicate that HT-1080 cells in
crosslinked matrices are less persistent, suggesting that cells’ ability to align fibers affects migration persistence. These findings could have implications for the control of cell invasion, e.g. in cancer metastasis and in tissue engineering scaffolds, by modulating cells’ ability to generate their own contact guidance cues.

J.J. François¹, J.C. Del Alamo², R.A. Firtel³, J. Lasheras²;¹Bioengineering, University of California, San Diego, La Jolla, CA, ²Mechanical Aerospace Engineering, University of California, San Diego, La Jolla, CA, ³Division of Cell and Developmental Biology, University of California, San Diego, La Jolla, CA

While much research has been dedicated to identifying the cascade of specific biochemical processes involved in the recruitment of neutrophils, much less is known about the mechanical events driving their migration; in particular, how they generate the necessary traction forces to migrate across three-dimensional (3-D) extravascular spaces and the effect of matrix porosity during this process is unclear. In this study, we investigate the importance of extracellular matrix properties on the mechanics of 3-D neutrophil motility in collagen gels using Elastographic 3D Force Microscopy (E3DFM). We embedded neutrophil-like differentiated human promyelocytic leukemia (dHL-60) cells in collagen matrices of different concentrations containing fluorescent micro-beads. Neutrophil motility was induced via the introduction of the neutrophil chemokine formyl-Methionyl-Leucyl-Phenylalanine (fMLP) in a custom build device. Both Confocal and Fluorescent microscopy techniques were used to image the movement of the embedded micro-beads as well as fluorescently labeled cells. Particle Image Velocimetry (PIV) and Finite Deformation Theory were used to compute displacement fields in the collagen matrices. Stress fields in the matrices were computed using our E3DFM method. We will present data showing that morphological changes and migratory patterns differed depending on the porosity of the collagen matrices. We will also provide data showing a clear relationship between the aforementioned migratory characteristics and computed displacement and stress fields around migrating neutrophils in collagen matrices. The results from our study show that neutrophils migrating in 3-D environments employ distinct mechanical mechanisms that depend on the structure of their mechanical environments.

Achieving a unified understanding of amoeboid cell migration by analyzing the coordination of cell shapes and cytoskeletal components on a global scale.

C.K. Chan¹, J.A. Theriot¹;
¹Biochemistry, Stanford University School of Medicine, Stanford, CA

There is a fundamental gap in understanding how the different cytoskeletal components of amoeboid-type motile cells are coordinated and rearranged during migration, resulting in the versatility of shape change in these cells and allowing them to adapt to complex and changing environments, such as when neutrophils navigate to sites of infection, or migrating tumor cells begin their journeys through metastasis. We use the human neutrophil-like HL-60 cell line as a model system to capture the morphological changes as cells migrate through 2D confinement in vitro, decompose and map the neutrophil morphological space that contributes to motility behavior by cell shape mode and global...
protein distribution analysis. We have also developed a novel computational methodology that can decompose motile cell shapes into different cytoskeletal protein arrangements. This method allows us to objectively and quantitatively compare overall protein distributions among images of different cells and also over time as a single cell dynamically changes its shape and cytoskeletal protein distribution as it moves. We find that individual cells can explore a wide variety of shapes and cytoskeletal organizations as they undergo cycles of persistent movement, pauses, and directional changes. Many individual cells appear to follow a similar set of stereotypic state transitions as they move. We also find that amoeboid motility can be decomposed into several major shape modes, and that the shape space explored by a large population of cells is similar to the shape space explored by a single cell over time. Given this understanding, we aim to extend our analysis to make predictions on amoeboid motility behavior through the tracking of cell shapes and correlation with changes in intracellular protein distributions. Overall we aim to develop a unified quantitative understanding of how the different cytoskeleton components are coordinated on a global scale at the cellular level to give rise to directed migration.

Dynamics of Focal Adhesions and Invadosomes

RhoG regulates migration through focal adhesion dynamics and contractility.

A.E. Zinn¹, D. Maity², Y. Chen², R. Garcia-Mata¹;
¹Department of Biological Sciences, The University of Toledo, Toledo, OH, ²Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD

The integrity and development of tissues depends on the ability of cells to form physical contact with the surrounding extracellular matrix (ECM). These contacts, known as focal adhesions (FA), serve as traction points for migration by anchoring the actin stress fibers (SF) of the cytoskeleton to the ECM, thus contributing to organogenesis, wound healing, and tissue maintenance. Both assembly and disassembly of FA and SF is dependent upon forces (tension and contractility) exerted by the ECM and other cytoskeletal elements.

The Rho family of GTPases has been implicated in many processes that regulate cell migration, including the assembly and disassembly of adhesions and cytoskeletal dynamics. Here, we have characterized the lesser-studied RhoGTPase, RhoG, in adhesion dynamics and contractility, providing evidence against a correlation between focal adhesion formation and increased contractility.

Our results show that RhoG influences the number, location, and size of FA on both collagen and fibronectin and in multiple cell types. Using live imaging, we found that when RhoG is silenced (KD), FA lifetime is increased, contributing to an increase in the number and size of adhesions, and their more central location in the cell. Additionally, we found that RhoG affects protrusion dynamics, which may be a direct result of adhesion lifetime. We also noted that KD cells are more rounded with increased alignment of FA and SF, and increased number of SF, all characteristics traditionally thought to be associated with increased contractility. However, our results show reduced contractility in RhoG KD cells, both in 2D and 3D. Taken together, our results suggest that RhoG may play an important role in the signaling pathways that couple contractility with focal adhesion turnover.

Complement mediated phagocytosis involves mechanical coupling of β2 integrins to the actin cytoskeleton by a myosin-independent molecular clutch.
V. Jaumouillé¹, T. Liu², E. Betzig², C.M. Waterman¹;
¹National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD, ²Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA

αMβ2 and αXβ2 integrins (also called complement receptor 3 and 4) are highly expressed in macrophages, neutrophils and dendritic cells, and are thought to be the main phagocytic receptors for many pathogens, and participate in the clearance of dead cells and tumor cells. In other contexts, integrin functions are intimately linked to the actin cytoskeleton dynamics. For instance, at focal adhesions, coupling of the force provided by the actin retrograde flow to engaged integrins through a molecular clutch generates mechanical tension that is thought to switch integrins to a high affinity conformation and to generate traction on the substrate. Although it is established that phagocytosis requires actin, its dynamics and specific contribution to β2 integrin functions remain largely unknown. Thus, we sought to test the hypothesis that transmission of mechanical tension to β2 integrins by molecular coupling to the actin cytoskeleton is essential for particle binding, outside-in signaling, and engulfment. Using live cell imaging, we observed that engagement of complement-opsonized particles led to a dramatic reorganization of the actin cytoskeleton, characterized by the formation of large protrusions that wrapped around the particle, contrasting with the particle sinking mechanism previously proposed. Quantitative live cell imaging showed that the Arp2/3 complex, which was required for particle internalization, was recruited to the leading edge of the protrusion and drove phagosome formation. However, slow actin retrograde flow within the phagocytic cup suggested a strong coupling between engaged β2 integrins and the actin network. β2 integrins appeared to form small focal complex-like adhesions at the phagocytic cup, characterized by the recruitment of mature adhesion markers, such as Vinculin, α-Actinin, Zyxin, as well as tyrosine phosphorylation of Paxillin, FAK and Syk. We found that Src family kinases, Syk and FAK/Pyk2 activities were important for particle engulfment. Tyrosine kinases were required for the recruitment of Vinculin, independently of Myosin II, which provided higher transmission of mechanical tension to integrins. Our observations indicate that professional phagocytes co-opt the focal adhesion-lamellipodium machinery, and use signaling to rapidly achieve strong coupling of integrins with the cytoskeleton in order to protrude faster and engulf large particulate material.

IDENTIFICATION OF A RHO-GEF THAT DIRECTS SITE-SPECIFIC ASSEMBLY OF INTEGRIN ADHESION COMPLEXES IN STRIATED MUSCLE.
J.C. Moody¹, H. Qadota¹, N. Shanmugam¹, A.R. Reedy¹, G.M. Benian¹;
¹Pathology, Emory University, Atlanta, GA

The adhesion of cells to extracellular matrix is mediated by “integrin adhesion complexes” (IACs) consisting of integrin and a large number of associated proteins. Although much is known about their composition and molecular mechanisms that initiate assembly, little is known about what determines where such assemblies will form. We use the model genetic organism C. elegans to discover new and conserved aspects of muscle assembly, maintenance and regulation. Nematode striated muscle has 3 types of IACs; M-lines, dense bodies and attachment plaques at muscle cell boundaries. At the worm
muscle cell membrane, IACs begin with integrin and a number of core proteins (e.g. kindlin, ILK, PINCH, α-parvin), and then become specific for each site more distally. From a screen for mutants that disrupt the localization of PAT-6 (α-parvin), we discovered a gene that as a loss of function mutant results in the absence of PAT-6 at muscle cell boundaries, but not at the other IACs (M-lines and dense bodies). This gene encodes PIX-1, the nematode ortholog of vertebrate βPIX. PIX-1 is predicted to have 2 isoforms, PIX-1a (646 residues) and PIX-1b (450 residues); both begin with an SH3 domain followed by a RhoGEF domain; PIX-1a has a predicted coiled-coil region at its C-terminus. The PAT-6 localization defect is found in 5 pix-1 mutant alleles including 2 premature stop mutants, 2 intragenic deletions, and one missense mutation in the RhoGEF domain. In addition, for one premature stop mutant, pix-1(gk299374), at least two other IAC components, UNC-112 (kindlin) and UNC-95, are also missing at muscle cell boundaries. Based on studies of βPIX in mammals and its role in other tissues in C. elegans, we hypothesize that PIX-1 functions in the following pathway: that it activates a Rac or Cdc42 family member, perhaps via the scaffold and ArfGAP protein GIT-1, and Rac or Cdc42 acts through a PAK protein kinase. Mutants in these proteins are being examined for the PAT-6 mis-localization phenotype of pix-1 mutants; so far, we have found this phenotype in git-1 and pak-1 mutants. In both swimming and crawling assays, pix-1(gk299374), moves more slowly than wild type, suggesting that the muscle cell boundaries consisting of cell-ECM-cell contacts is important for proper transmission of lateral forces between muscle cells that occur during whole-animal locomotion. We are generating and analyzing antibodies to PIX-1, with the goal of determining the localization of endogenous PIX-1 in nematode body wall muscle. We hypothesize that PIX-1 either is located exclusively at muscle cell boundaries, or that it is localized at all three IACs in muscle, but is only activated (by an unknown mechanism) as a RhoGEF at muscle cell boundaries.

Distinct focal adhesion morphologies emerge from interplay between retrograde actin flux and stress fiber.
Z. Wu1, J. Liu1;
1National Institutes of Health, Bethesda, MD

Focal adhesion (FA) is an anchorage of the cell that transduces traction force on substrate for migration. FA is a dynamic structure that develops from its nascent stage into diverse morphologies. While many essential players are individually well characterized, it is unclear how these components work together in FA growth. We establish a theoretical model that bridges this gap, suggesting that the FA morphology reflects the spatiotemporal coordination between retrograde actin flux and stress fiber formation. The model thus sheds light on the underlying mechanism of FA growth.

PI 3-Kinase-β regulates invadopodial maturation and β1-integrin signaling.
Z. Erami1, A.R. Bresnick2, J.M. Backer1,2;
1Department of Molecular Pharmacology, Albert Einstein College of Medicine, New York, NY,
2Department of Biochemistry, Albert Einstein College of Medicine, New York, NY

Invasive tumor cells move through the extracellular matrix by forming invadopodia, which are actin protrusions that mediate matrix degradation. Invadopodia formation is crucial for several steps of the metastatic process, including traversal of basement membranes, intravasation and extravasation. The
PI3Kβ isoform of PI3K, which is uniquely regulated by both receptor tyrosine kinases and GPCRs, and also binds to the small GTPases Rab5 and Rac1, is an important regulator of invadopodial formation. We have previously reported that in MDA-MB-231 breast cancer cells, replacement of endogenous PI3Kβ with kinase dead (110β<sup>K799R</sup>; KD) or GPCR-uncoupled (p110β<sup>526KK-DD</sup>; KKDD) mutants of PI3Kβ leads to defects in gelatin degradation. By co-immunostaining with Tks5 and cortactin antibodies, we now find that the number of invadopodial precursors is unaffected by mutant PI3Kβ. However, the number of mature invadopodia (co-localization of cortactin and Tks5 with gelatin degradation) is significantly lower in cells expressing KD-DD and KD PI3Kβ mutants. Surprisingly, we find a similar phenotype in cells expressing a mutant PI3Kβ that cannot bind to Rab5 (p110β<sup>596D-C</sup>).

Previous studies have demonstrated a role for β1 integrins in invadopodia stability and maturation, and PI3Kβ has been implicated in integrin signaling in platelets. We therefore tested if PI3Kβ is required for integrin function in breast cancer cells. In a haptotaxis assay towards collagen I, MDA-MB-231 cells expressing KD, KK-DD, and Rab5-uncoupled PI3Kβ show a significant decrease in migration as compared to cells expressing wild type PI3Kβ. Similarly, cell spreading on collagen I was significantly reduced in cells expressing KD, KK-DD, or Rab5-uncoupled PI3Kβ. Spreading was also impaired in cells treated with pertussis toxin, to block GPCR activation of PI3Kβ. Specific inhibitors of other Class I PI3Ks (PI3Kα, γ or δ) had no effect on cell spreading, which was significantly impaired by TGX221 (PI3Kβ inhibitor) or LY294002 (pan-PI3K inhibitor). Surprisingly, treatment of cells with TGX221 had no effect on Akt activation, which was completely blocked by inhibition of PI3Kα. In addition, the Akt inhibitor MK2206 had no effect on cell spreading. These data suggest that PI3Kβ has a critical Akt-independent role in integrin-mediated signaling in breast cancer cells, which may contribute to its role in invadopodial maturation and tumor cell invasion.

**Talin autoinhibition regulates cell behavior and migration in vivo.**

A.M. Haage<sup>1</sup>, K. Goodwin<sup>1</sup>, A.B. Bogutz<sup>2</sup>, L. Lefebvre<sup>2</sup>, S.V. Plotnikov<sup>3</sup>, B.T. Goul<sup>4</sup>;

<sup>1</sup>Cell Physiological Sciences, University of British Columbia, Vancouver, BC; <sup>2</sup>Medical Genetics, University of British Columbia, Vancouver, BC; <sup>3</sup>Department of Cell and Systems Biology, University of Toronto, Toronto, ON; <sup>4</sup>School of Biosciences, University of Kent, Canterbury, United Kingdom

Cells in multicellular organisms are arranged in highly complex three-dimensional patterns. To achieve this organization requires cells to form both transient and stable adhesive contacts with their surroundings or extracellular matrix (cell-ECM adhesion). The main family of proteins that mediate cell-ECM adhesion are the integrins, which bind ECM ligands outside the cell and build an adhesion complex inside the cell. Integrin-mediated adhesion to the ECM is precisely regulated during development and homeostasis to ensure proper tissue formation and maintenance. The mechanisms that regulate integrin-mediated cell-ECM adhesion have been the subject of intense study in both in vitro and cell culture systems, but much of their biological role in whole animal contexts remains elusive. Some of the key mechanisms that regulate integrin-mediated cell-ECM adhesion work through the adapter protein Talin. Talin is essential for the formation of the integrin adhesion complex and for linking this complex to the cytoskeleton. In particular, Talin can act as a positive regulator of integrin-based adhesion by activating integrins directly. To explore the importance of this positive mode of regulation in an in vivo context, we introduced a point mutation in mouse Talin1 that alleviates an autoinhibitory interaction within the protein. Characterization of this mutation in primary mouse embryonic fibroblasts revealed an increase in integrin activation, an increase in relative adhesive strength, and a shift to more mature focal adhesions. The upregulation of cell-ECM adhesion due to the loss of Talin autoinhibition also results in diverse cellular phenotypes such as changes in cell morphology, impaired cell spreading, and...
impaired generation of traction force. This results in delayed cell migration *in vitro* and in delayed wound healing *in vivo*. Based on our results we propose Talin autoinhibition is an important mechanism for regulating integrin-based cell-ECM adhesion *in vitro* and that autoinhibition defective mutants can be used as a general tool to investigate phenotypes resulting from wholesale activation of integrins *in vivo*.

*Ca²⁺*-dependent activation of Arf5 at ER/plasma membrane contact sites by an IQSec1/ORP3 complex controls focal adhesion turnover and cell migration.*

R.S. D’Souza¹, J. Lim¹, A. Turgut¹, J.F. Durel², J. Zhang², K. Orth³, J.E. Casanova⁴;

¹Cell Biology, University of Virginia, Charlottesville, VA; ²Molecular Biology, University of Texas, Southwestern, Dallas, TX

Migrating cells establish focal adhesions at the leading edge that provide the traction required for motility, and disassemble them at the cell rear to allow translocation in the direction of movement. Many studies have shown that focal adhesion disassembly, which is essential for migration, requires Ca²⁺ influx. While Ca²⁺ is known to trigger multiple events related to adhesion disassembly, our understanding of this process is still incomplete. BRAG2/IQSec1 belongs to the Sec7 family of Arf-specific guanine nucleotide exchange proteins. We have previously shown that the related protein, BRAG1/IQSec2, is activated by Ca²⁺ at synapses where it drives internalization of neurotransmitter receptors. In non-neuronal cells, we have shown that BRAG2/IQSec1 modulates cell adhesion by controlling the level of surface beta1-integrins, but whether (and how) this might be regulated by Ca²⁺ is unknown. Here we demonstrate that BRAG2/IQSec1 is activated by Store-operated Calcium Entry (SOCE) via the bipartite STIM1/Orai Ca²⁺ channel, and that this is essential for focal adhesion disassembly. Depletion of BRAG2/IQSec1 from the breast cancer cell line MDA-MB-231 leads to enlarged, stable focal adhesions and decreased cell motility. Surprisingly, adhesion disassembly requires activation of Arf5, an Arf isoform typically associated with ER/Golgi transport. We found that knockdown of Arf5, but not Arf6, phenocopies knockdown of BRAG2/IQSec1, and that expression of active Arf5, but not Arf6, is sufficient to restore motility to BRAG2-depleted cells. To better understand how BRAG2/IQSec1 promotes adhesion turnover, we identified BRAG2-interacting proteins by mass spectroscopy. This analysis identified ORP3, a member of the family of oxysterol binding protein (OSBP) related proteins that mediate the direct exchange of lipids between the ER and other organelles. ORP3 has been previously reported to localize to ER-plasma membrane contact sites, although its lipid cargoes remain unknown. Importantly, like BRAG2 and Arf5 depletion, ORP3 knockdown slows adhesion turnover and impairs motility, suggesting that the three proteins act together to promote adhesion dynamics. In support of this hypothesis, we show that activation of SOCE results in rapid recruitment of ORP3 to the PM where it colocalizes with STIM1/Orai. Conversely, inhibition of STIM1/Orai-mediated Ca²⁺ influx blocks recruitment of ORP3 to the PM, and inhibits activation of Arf5. Finally, we show that knockdown of ORP3 inhibits Arf5 activation, suggesting that ORP3 acts upstream of BRAG2/IQSec1 in a Ca²⁺-dependent signaling cascade. We are currently working to identify the lipid cargoes whose exchange is mediated by ORP3, and how they may promote BRAG2-mediated Arf5 activity and subsequent focal adhesion turnover.
Structure and Function of the Extracellular Matrix

Extracellular matrix and postnatal development of GLAST+ cells.
I.N. Dominova1, O. Tuchina1, L. Klimaviciusa1, N.A. Filiakova1, A.A. Vasilev1, M.V. Patrushev1, V.A. Kasymov1;
1Neurobiology and medical physics, Immanuel Kant Baltic Federal University, Kaliningrad, Russia

It is now well-known that astrocytes, GLAST+ cells, are active participants in the tripartite synapse. However, today there is an opinion that synapse represents tetrapartite structure, which includes pre- and postsynaptic neurons, astrocytes and the extracellular matrix (ECM) which is formed by glycoproteins and proteoglycans released by neighbouring neurons and glial cells. ECM does not only affect the synapse stability and function, but the development of the glial cell as well. Our aim was to study age-dependent diversity in the levels of expression of ECM-associated molecules in glial GLAST+ cells. Analysis of transcriptomic data of glial GLAST+ cells from Bst and Hip of P3 and P11/12 rats demonstrated decrease in expression values of ECM-associated molecules genes during development, but at the same time in Ctx expression values (EVs) of some genes increased to P11/12. Further studies of the most numerous gene families of ECM-receptor interaction pathway showed, that EVs of most Col family genes were increased or remained unchanged in three regions by comparison P3 and P11/12 rats. Indeed in all regions we observed increase in the EV of Col11a2 in P11/12 rat, but Col3a1 in Bst and Ctx, Col2a1 in Hip and Col1a1, Col4a1 and Col5a1 in Bst were significantly downregulated in P11/12. The similar tendency we found in P3 rats for TnC was significantly upregulated in Bst and Ctx and TnR was significantly downregulated in Bst and Hip. For Lam family genes EVs we found that in P3 rats in Bst Lam genes were upregulated, while in Ctx they were downregulated, but in Hip genes were up- and downregulated simultaneously. Itga family genes EVs showed up- and downregulation in the same region at the different ages, in addition the highestnumber of downregulated genes in P3 rats was found in Ctx, as well as Itga7 gene EV was significantly decreased. Analysis of Sdc genes EVs in P3 rats demonstrated that in Bst and Hip these genes were downregulated, but in Ctx two out of four genes were upregulated, indeed Sdc1 and Sdc4 were significantly up- and downregulated, respectively. Gene EVs of synaptic vesicle glycoprotein family were decreased in all regions of P3 rats, as well as two out of three genes of thrombospondin family had decreased EVs. Furthermore we determined that EVs of Acan, Bcan and Ncan were increased, but expressions of Agrn, Reln and Vcan were downregulated in P11/12 rats in comparison with P3. Altogether obtained data indicate on significant contribution of glial cells in releasing of ECM-associated molecules and formation ECM in the brain, as well as on an on going postnatal maturation of GLAST+ cells. This work was supported by Contract №14.575.21.0074, unique identifier of applied scientific research and experimental development RFMEFI57514X0074.

Epithelioid Osteoblasts Deposit Dense Hydroxyapatite in Type I Collagen in a pH Dependent Manner That Is Supported by Aquaporin 1.
H.C. Blair1,2, Q.C. Larrouette3, D.B. Stolz4, D.J. Nelson5, P.H. Schlesinger6;
1Pathology, Veteran’s Affairs Medical Center, Pittsburgh, PA, 2Pathology, University of Pittsburgh, Pittsburgh, PA, 3Nuffield Department of Orthopaedics, Rheumatology and Musculoskeletal Sciences, University of Oxford, Oxford, United Kingdom, 4Cell Biology, University of Pittsburgh, Pittsburgh, PA, 5Dept of Neurobiology, Pharmacology Physiology, University of Chicago, Chicago, IL, 6Cell Biology, Washington University, Saint Louis, MO

To form bone, osteoblasts initially secrete collagen I as a type 2 helix of 3 collagen monomers. A polarized osteoblast epithelium isolates bone matrix from extracellular space by tight junctions, communicating in the epithelial plane by gap junctions. In the matrix space, phosphate is generated by alkaline phosphatase; calcium is passively transported. Amorphous calcium phosphate crystals form on the collagen template, but must be matured into a stable hydroxyapatite—collagen composite by the established equation: 6 HPO$_4^{2-}$ + 2 H$_2$O + 10 Ca$^{2+}$ $\leftrightarrow$ Ca$_{10}$(PO$_4$)$_6$(OH)$_2$ + 8H$^+$
Since bone forms in a closed space, osteoblasts must remove protons to the extracellular space. Our genetic and transport evidence supports a model of proton movement by highly expressed CIC3 and CIC5 proteins in apical surfaces, and Type 1 Na$^+$,H$^+$ exchangers in basolateral surfaces, of osteoblasts. We generated a type I collagen layer on surface plasmon resonance chips using carboxymethyl dextran-modified gold activated by reaction with N-hydroxysuccinimide and N-ethyl-N’-(dimethylaminopropyl)-carbodiimide HCl, followed by capture of collagen I monomers in PBS at pH 7. We studied deposition of hydroxyapatite onto this surface in 0-5 mM phosphate with 1 mM calcium buffered to pH from 6.94-7.6 in increments. At pH 6.94 very little hydroxyapatite accumulated. Mineral accumulation increased >10 fold at pH 7.4. As controls, mineral was removed by EDTA with reduction to baseline RUs. In accord with earlier studies, electron microscopy of bone with mineral formation showed periodic deposition of crystals in new matrix. This has been predicted to occur in a pH dependent fashion. Measurements of pH during bone formation have been consistent with a strong pH dependence, and with H$^+$ removal by Cl/H$^+$ and Na$^+$,H$^+$ transporters. The condensation of mM calcium and phosphate ions with the sub-mM collagen into the solid composite of bone displaces huge amounts of water. For water to escape requires a novel diffusion path across the osteoblast. By cRNA screening, we detected aquaporins in human osteoblasts, aquaporin 1 being prominent. Quantitative PCR confirmed high levels of aquaporin 1. Antibody-gold labeling of newly synthesized bone showed aquaporin 1 complexes adjacent to new bone in a characteristic pattern in osteoblast membranes. We conclude that mineral deposition in bone collagen is pH dependent, in keeping with a model of H$^+$ removal by Cl/H$^+$ and Na$^+$,H$^+$ exchangers on the apical and basolateral faces of osteoblasts. Further, periodic orientation hydroxyapatite is organized on type I collagen coiled-coils, consistent with earlier work on organization of mineral during initial amorphous crystallization. Conversion to dense mature tissue is supported by aquaporin 1 in apical osteoblastic cell membrane.

Effects of aragonite particles derived from skeleton of Montipora digitata applied as a scaffold on cell proliferation and collagen fiber productivity of cultured human normal dermal fibroblasts.
T. Okamura1, K. Tominaga1, T. Nishikawa1,2, A. Tanaka3;
1Department of Oral Pathology, Osaka Dental University, Hirakatashi, Japan, 2Innovations in Dental Education, Osaka Dental University, Hirakatashi, Japan, 3Department of Pathology, Osaka Dental University, Hirakatashi, Japan

[Introduction] Collagen fiber which is extracellular matrix, functions as a scaffold of capillaries. This is an important factor in formation of neonatal bone. Coral is a bioabsorbable porous material widely known as a bone prosthetic material. On the coral transplanted into the living body, mesenchymal tissue and capillaries are formed in the lumen. Cellular response, namely the formation of collagen fiber when adding aragonite particles derived from the Montipora digitata skeleton (Aragonite particles) to cultured fibroblasts is unknown. In this experiment, we cultured human normal dermal fibroblasts (NHDF) with aragonite particles derived from Montipora digitata skeleton as a scaffold. The morphological assay of NHDF was performed with a scanning electron microscope (SEM). The biochemical assay of cell proliferation was performed with measurement of formazan. The amount of collagen fibers produced by the cultured cells was colorimetrically determined. [Materials & Methods] Aragonite particles were deproteinized with 1 N sodium hydroxide. NHDF (PromoCell, Heidelberg, Germany) was cultured aragonite particles were not added to the control group and coral were added to the experimental group. Cell proliferation of NHDF was measured by formazan (WST-1; Roche Applied Science, Indianapolis, USA). Cell proliferation was also observed with a fluorescently labeled stained EdU (EdU Alexa Fluor® 647; Thermo Fisher Schientific K. K, Kanagawa, Japan). The morphology of NHDF and collagen fibers grown inside and outside Aragonite particles was observed with SEM. The production of collagen fibers was quantified by colorimetric determination of collagen fibers by hydroxyproline (Hydroxyproline assay; Cosmo Bio Co., Ltd., Tokyo, Japan). [Results] The formazan value was significantly higher in the experimental group compared to the control group 1, 3, and 7 days after cell seeding. The proliferation of NHDF and hyperplasia of collagen fibers were observed inside and outside aragonite particles. At 28 days after aragonite particles addition, significantly higher hydroxyproline increase was observed in the experimental group than in the control group. [Discussions] The surface of aragonite particles has an uneven rough structure on the nano-level. This rough surface structure and the calcium contained in aragonite may have promoted cell adhesion and cell proliferation. [Conclusion] It was inferred that the cell proliferation ability and collagen formation ability of the cultured NHDF were enhanced by addition of aragonite particles.

Quantifying the dynamics of tissue-induced alignment of collagen fibers.
B.A. Nerger1, A.S. Piotrowski-Daspit1, A.E. Wolf1, S. Sundaresan1, C.M. Nelson1,2;
1Chemical and Biological Engineering, Princeton University, Princeton, NJ, 2Molecular Biology, Princeton University, Princeton, NJ

The extracellular matrix (ECM) consists of a fibrous polymer network that provides both physical and chemical cues to cells and tissues. During tissue morphogenesis and cancer progression, cell-ECM interactions drive matrix remodeling, which can result in collagen fiber alignment. While the interplay
between collagen fibers and single cells has been reported, little is known about alignment at the tissue scale. Here, we quantified tissue-induced collagen fiber alignment and investigated the mechanisms that dictate the dynamics of the alignment process. A previously reported soft-lithography technique was used to generate three-dimensional (3D) microfabricated tissues embedded in a matrix of Matrigel and type-I collagen [1]. 3D tissues were fabricated using functionally normal mouse mammary epithelial, mammary carcinoma, fibroblast, or human breast cancer cells. A broad-spectrum matrix metalloproteinase (MMP) inhibitor was used to inhibit proteolysis, and a myosin II ATPase inhibitor, Rho kinase inhibitor, and Rho activator were used to modify cytoskeletal contractility. Collagen fibers were imaged using confocal reflection microscopy, and fiber alignment was quantified over a period of 24 hours by assessing changes in pixel intensity gradients. Collagen fiber alignment typically reached a plateau within 6 hours when ~50% of collagen fibers were aligned perpendicular to the tissue surface. Fiber alignment was observed concurrently with a decrease in tissue size, which indicated that tissues exerted strain on the surrounding ECM. Collagen fiber alignment was not observed in tissues treated with a Rho kinase or myosin II ATPase inhibitor, while an increase in the rate and extent of alignment was observed in tissues treated with a Rho activator. These results suggested that Rho-mediated contractility is important for alignment. Inhibiting MMPs had no effect on alignment, which indicated that alignment is primarily a physical process. We further found that breast cancer cells, which have weaker cell-cell adhesions, took longer to align the fibers despite having higher individual cell contractility. These results indicated that collective tissue contractility is important for dictating collagen fiber alignment. Lastly, we found that tissue geometry affected the pattern and extent of collagen fiber alignment by dictating the pattern of strain surrounding the tissue. Our results indicate that tissue-induced collagen fiber alignment is driven by Rho-mediated contractility, whereby tissues collectively contract and exert strain on the ECM. We found that alignment was dictated by cellular contractility, the level of expression of intercellular adhesions, and tissue geometry.

Low adhesive scaffold collagen prepared from type I collagen induces the osteogenic differentiation of rat bone marrow stromal cells.

S. Kunii1, E. Yamamoto2, K. Morimoto1;

1Genetic Engineering, Kindai University, Kinokawa, Japan, 2Biomedical Engineering, Kindai University, Kinokawa, Japan

[Objective] Collagen is a major component of extracellular matrices and utilizes as a scaffold for cell culture. Cells adhere to collagen scaffold and then accelerate the proliferation. These days, we succeeded in developing low adhesive scaffold type I collagen from pig skin (LASCol, patent pending). The cells on the LASCol coated dish collide each other one after another and get to form spheroid larger. In this study, we report that LASCol markedly facilitates osteogenic differentiation of rat bone marrow stromal cells (rMSCs). [Methods] Two types of culture dish, LASCol (own coated) and Atelocollagen (commercially pre-coated), were used. Rat MSCs (4x10^4 cells/dish) were cultured on each coated-dish with osteogenic basal medium. The cell motility was monitored by time-lapse observation with a microscope. To evaluate osteogenic differentiation, we investigated a mineralization by alizarin red S staining, and measured Gla-Osteocalcin concentration of culture medium supernatant by an ELISA kit. Moreover, the quantity of mRNA of osteogenesis-related genes (Alpl, BGP, Osx, and Runx2) was analysed by RT-qPCR. [Results] Rat MSCs on LASCol coated-dish formed spheroid bodies, and each cell...
clearly showed alkaline phosphatase activity earlier than usual. In the conditions of LASCol coated-dish, Calcium deposits showed increasing (Day 3-6). Similarly, Gla-Osteocalcin of LASCol scaffold group significantly increased to 41 ng/mL (Day 6). Most of the mRNA of cells cultured on LASCol coated-dish much expressed than others. [Summary and Conclusions] We demonstrated, by analysing mRNA expression, that LASCol has the acceleration effects of osteogenic differentiation. [Funding] This work was supported by the Adaptable and Seamless Technology Transfer Program through target-driven R&D, AMED (AS2414037P to K.M.) and JST (AS2715177U to K.M.).

Regulation of collagen processing and fibrillogenesis by the fibronectin matrix.
J.T. Saunders1, J.E. Schwarzbauer1;
1Molecular Biology, Princeton University, Princeton, NJ

The extracellular matrix (ECM) is a complex network of glycoproteins, proteoglycans, and fibrous proteins that is responsible for regulating cell behaviors and developmental processes. Of the numerous members that comprise the ECM, type I collagen (coll) is the most abundant and provides the ECM with structure, stability, and tensile strength. Up-regulation of coll deposition into the ECM occurs in scar formation after tissue trauma and in chronic injury resulting in fibrosis. Fibrillar collagen is deposited once a provisional fibronectin (FN) matrix is established by cells, and only after it is proteolytically processed from its immature form, procollagen. This cleavage of the procollagen N- and C-propeptides is carried out by distinct proteases, ADAMTS-2 and BMP-1 respectively, and cleavage of the C-propeptide but not the N-propeptide is necessary for fibril assembly. Despite extensive understanding of supramolecular collagen fiber structure, the molecular interactions that initiate collagen fibrillogenesis have not been elucidated, in particular the role of FN matrix in that process. Our microscopic analyses of the ECM fibril organization by fibroblasts show co-localization of coll containing the N-propeptide with FN fibrils suggesting that coll-FN interactions occur as procollagen is being processed. When FN matrix assembly by fibroblasts was inhibited in culture, the proteolytic processing of procollagen was reduced and collagens containing one or both propeptides were enriched. Since BMP-1 has been shown to bind to FN, these results suggest that in vivo BMP-1 processing of procollagen requires binding to FN matrix. In solution, procollagen cleavage was recovered by treatment with recombinant BMP-1 and enhanced in the presence of FN. Additionally, both procollagen cleavage by BMP-1 and BMP-1 binding to FN were enhanced by the addition of heparin. Since BMP-1, its enhancer protein PCPE-1, and procollagen bind to FN and heparin, our results suggest a model in which heparin conveys these proteins to their respective binding sites on FN matrix so that FN can act as a template to initiate procollagen processing and to facilitate fibrillogenesis.

Phenotype transformation of proliferative smooth muscle cells using crosslinking collagen gel.
T. Yamashita1;
1Graduate School of Environmental Engineering, The University of Kitakyushu, Kitakyushu, Japan

Smooth muscle cells (SMCs) reveal two different phenotypes according to their external condition including contractile and proliferative phenotypes. The contractile SMCs usually exist within the normal tissue in vivo, and proliferative SMCs are found in a number of diseases, the fetal period and angiogenesis. When SMCs are explanted from normal tissue, they rapidly transform from contractile to
proliferative phenotypes in culture condition. On the other hand, it is difficult to retransform the proliferative SMCs into contractile one. It was reported that proliferative cells retransformed into contractile phenotype only when cultured on intact type IV collagen gel. Thus, we considered that physicochemical properties of the type IV collagen gel are important for the phenotype regulation of SMCs. In this study, we investigated what kind of physicochemical properties of the gel are involved in the retransformation of proliferative SMCs. We purchased pepsin treated type IV collagen gel and prepared type IV collagen gel by crosslinking with glutaraldehyde. SMCs were obtained from chick embryo gizzard and well transformed into proliferative cells by several passages. SMCs were cultured on crosslinking type IV collagen gel, cells showed a slow growth and elongated shapes. Immunostaining for SMC specific calponin was detected in cells on crosslinking type IV collagen gel. Then we measured physical properties of the crosslinking type IV collagen gel. Young's modulus of type IV collagen gel was about 0.23 kPa and this value was clearly lower than that of crosslinking or non-crosslinking type I collagen gel. We tried to evaluate a mesh size of the crosslinking type IV collagen gel using measuring the molecular diffusion coefficient in the gel by Fluorescence correlation spectroscopy. The fluorescence probes with \( r = 1.01 \) nm or 3.56 nm, the diffusion of the probes in the gel was not different from that in solution. Therefore, crosslinking type IV collagen gel mesh size was probably larger than 10 nm. This is credible much larger than the mesh of basement membrane and intact type IV collagen. We have assumed that mechanical property and other chemical properties of type IV collagen gel will be important for retransformation of proliferative SMCs.

Muscle meets immunity: Biological intersections in Drosophila melanogaster.
N.M. Green\(^1\), J. Walker\(^2\), C. Clark\(^3\), N. Odell\(^2\), M. Zych\(^2\), M. Dushay\(^3\), E.R. Geisbrecht\(^{1,2}\);

Maintenance of muscle tissue during development is dependent upon the extracellular matrix (ECM) to stabilize and sense changes in the local environment. Muscle has a particularly high demand for a dynamic ECM to allow for contraction and force transmission. Inefficient contraction and/or detachment can lead to muscle tissue damage and is often seen in muscle pathologies such as muscular dystrophies and myopathies. Recent evidence shows that damaged and stressed tissues can release tissue-intrinsic and/or extracellular molecules known as damage-associated molecular patterns (DAMPs), which overactivate immune responses. Our lab is using the Drosophila muscle attachment site (MAS) as a model to understand the connection between DAMP-mediated immune activation and muscle tissue maintenance. Initially, we were focused on characterizing a novel ECM protein, Fondue (Fon), which is a critical mediator of ECM stability in the hemolymph clot. Loss of fon causes body wall muscles to detach and also creates large gaps between muscle hemisegments. Transmission electron microscopy (TEM) analysis of fon mutant MASs revealed a loss of ECM integrity through disruption of cuticle and tendon architectures, a lack of muscle-tendon interdigitation, and a depletion of electron-dense matrix accumulation. More interestingly, a sensitized background screen revealed a subset of coagulation proteins, Fon, Tiggrin, and Lsp1\(^\text{y}\), that were necessary for stabilizing muscle attachment sites. Further investigation into gene expression profiles of mutants with hypercontraction-induced muscle tissue stress indicated a clear trend of innate immune activation, suggesting a broader connection between muscle development and innate immunity. In fon mutants with muscle detachment, we also observe abnormal melanin accumulation as tumors or along the larval MASs, activation of Toll signaling in the fat body, and constitutive expression of the antimicrobial peptide (AMP), drosomycin. In a fon-sensitized
background assay, we identified genetic interactions between *fon* and Toll pathway members, including the NFκB inhibitor/κB, *cactus*. At the local level, *fon*-mediated muscle detachment and muscle hypercontraction mutants, *Mhc* and *Brkd*, cause JAK/STAT activation within muscle tissue. We propose a model where muscle tissue stress caused by altered mechanical forces of damaged MASs progresses muscle disease through overactivation of the innate immune system. Understanding the mechanisms by which these two biological processes are intertwined will advance our knowledge of how tissue stresses can be sensed and elicit multi-tissue responses.

*Triops cancriciformis;* a potential non-mammalian animal model for studies on mechanisms of kidney ultrafiltration.

K.H. Oliver¹,²,³, A. Mittal², J. Cartailler²,³, E. Pokidysheva¹,²,³, J.R. Fitzgerald², J. Hudson², B.G. Hudson¹,²,³,¹Nephrology, Vanderbilt University Medical Center, Nashville, TN, ²Aspirnaut Research Program, Nashville, TN, ³Center for Matrix Biology, Nashville, TN

The mechanism of ultrafiltration of the blood by the kidney remains obscure. In a search for a primitive animal model that is tractable for investigation of ultrafiltration mechanisms, we carried out studies on *Triops cancriciformis*, a primitive crustacean. We hypothesized that the maxillary gland of the *Triops* is a primitive kidney. We performed structural analysis using serial sectioning and 3D reconstruction. Toluidine blue stained histology cross sections were layered to reconstruct the entire organism virtually using ImageJ. The 500 nm to 1µm thick images were aligned using the TrakEM2 plugin to correct initial deviation in alignment. Next, the maxillary gland structure was isolated using machine learning strategies set to recognize colored marks outlining each cavity. The 3D image revealed the overall architecture of the maxillary gland. When correlated with electron microscopy images, podocyte foot processes were found to surround the interior tubule, suggesting that this tubule is an ultrafiltration barrier. Interestingly, the basement membrane is exposed to the hemolymph with no cell lining in contrast to that of vertebrate animals. These findings suggest that the *Triops* maxillary gland is a “primitive kidney” that lacks endothelial cells. Potentially, *Triops* represent a tractable non-vertebrate animal model to probe the mechanisms of kidney ultrafiltration utilizing advanced molecular biology techniques.

Alpha 2 Laminin Chain Induces Cardiomyocyte Maturation In Vitro.

C. Hochman-Mendez¹,², D. Campos¹,², K.L. Costa¹, L.C. Sampaio², A.B. Carvalho¹, D.A. Taylor², A.C. Carvalho¹;

¹Institute of Biophysics, Federal University of Rio de Janeiro, Rio de Janeiro, Brazil, ²Regenerative Medicine Research, Texas Heart Institute, Houston, TX

Human pluripotent stem cell-derived cardiomyocytes (hPSC-CMs) often remain immature expressing fetal isoforms of structural and functional proteins. Several methods to enhance maturation of hPSC-CMs have been developed with limited success. Extracellular microenvironment is critically important for several physiologic processes, such as cell growth, survival and differentiation. Laminin is a key extracellular matrix (ECM) molecule involved in cardiomyocyte-matrix interactions. The main goal of this work is to characterize the ECM isoforms synthesized by hPSC-CM and evaluate the impact of those on cell maturation in vitro. To this end, hPSC-CM culture were analyzed by western blot and
immunofluorescence to characterize their ECM content. We also performed PCR and qPCR assays to compare laminin expression between hPSC-CM and adult tissue. hPSC-CMs were fixed and processed for immunofluorescence or transmission electron microscopy. Using both immunoblotting and immunostaining, we demonstrated that hPSC-CMs expressed three of the most important ECM molecules in the heart (i.e., laminin, collagen IV, and fibronectin) in a similar amount. Since specific laminin isoforms modulate function in several tissues, we probed various laminin chains expressed by these cells. We found that hPSC-CMs, primarily expressed the laminin α1 chain whereas adult heart expressed greater amounts of laminin α2 chain. Both adult heart and hPSC-CMs expressed similar α5 laminin chain amounts. To evaluate the ability of laminin chains to induce maturation in vitro, we created three different culture substrates (laminin 111, 211 and 511). After 5 days, hPSC-CMs cultured on laminin 211 substrate showed a more organized z-line striation pattern compared to both 111 and 511 laminin substrates. To increase substrate flexibility by adding stiffness to the system, we then created a cardiac “microtissue” using layer-by-layer technique (collagen I, collagen IV, and laminin). We observed that cells attached and grew on this layered microtissue. Data regarding maturation are in process. Together, these findings suggest that specific ECM molecules, both by chemical and physical cues, can induce maturation of human PSC-CMs in vitro.

Extracellular matrix performs multi-faceted roles in ciliated sensory neurons of Caenorhabditis elegans.
D.M. De Vore¹, M. Barr¹, D. Hall², K. Nguyen²;
¹Cell and Developmental Biology, Rutgers University, New Brunswick, NJ, ²Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Extracellular matrix (ECM) is made up of a network of interacting proteins that surround and support cells in functions such as mechanosensation, attachment, and signaling. ECM is necessary for tissue morphogenesis and homeostasis throughout the lifespan of an organism. Alterations in ECM quality and quantity may contribute to many human diseases and disorders such as polycystic kidney disease (PKD). PKD1 and PKD2 encode polycystin proteins found in primary cilia of mammalian cells and C. elegans neurons. In humans, PKD mutations result in Autosomal Dominant PKD (ADPKD). Given the ancient and evolutionarily conserved role for polycystins in cilia, we use C. elegans as a model to identify new genes required for polycystin ciliary localization and function.

We recently found that ECM components are important for C. elegans polycystin LOV-1 and PKD2 localization and function. mec-1, mec-5, and mec-9 encode ECM components that play a role in mechanosensation and degenerin/epithelial sodium channel (DEG/ENaC) localization in non-ciliated touch neurons (Du 1996, Emtage 2004). mec-1 and mec-9 encode proteins that contain multiple EGF and Kunitz domains; mec-5 encodes a collagen (Du1996, Emtage 2004). Here, we show mec-1, mec-5, and mec-9 play multifaceted roles in ciliated sensory neurons.

These ECM components regulate polycystin localization and polycystin-mediated male mating behaviors, control ciliary and dendritic integrity, and modulate the release of ciliary extracellular vesicles. Intriguingly, mec-9 has cell-specific functions that are controlled by a short isoform that is specifically expressed in ciliated sensory neurons. Our findings reveal the promiscuity of these ECM components and activity in ciliated and non-ciliated neurons of the worm. Transmembrane and ECM proteins such as cadherins and galectins act in cilium retraction/elongation and play a role in cell-to-cell junction signaling in mammalian cells (Seeger 2012, Rondanino 2011). While the polycystins have been implicated in sensing and regulating collagen in zebrafish models, roles for ECM proteins in regulating
ciliary integrity, ciliary polycystin localization, and ciliary function have not been previously appreciated. Our study lends insight on how ECM contributes to ciliary localization and function of sensory receptors like PKD-2 and LOV-1 and expands options for treatment of ADPKD.

Determining Matrix Metalloproteinase Homology across Phylum Ctenophora.
S.B. Rashid\(^1\), M.G. Tassia\(^1\), K.M. Halanych\(^1\), A.G. Moss\(^1\);
\(^1\)Biological Sciences, College of Science and Mathematics, Auburn University, Auburn, AL

Matrix Metalloproteinases (MMPs) are conserved zinc-dependent endopeptidases that are found across all kingdoms of life. They are members of a diverse protein family characterized by their catalytic domain, Metzincin, and are divided into subfamilies based on sequence architecture and functional properties. Other major functional domains classically found in MMPs are the N-terminus propeptide domain which plays a regulatory role and the hemopexin domain which is thought to play a role in protein-protein interaction. MMPs play roles in tissue remodeling events, such as wound repair and regeneration, and activate other proteins through proteolytic activity, namely signaling pathways regulating immunity. This class of metalloproteinases has been widely studied in vertebrate model systems but less so in early diverging metazoans that lack “complex” extracellular matrix structures; thus, MMP’s ancestral role in metazoans has yet to be determined. Ctenophores are planktonic, marine invertebrates classically positioned as a sister taxon to Cnidaria based on morphological data; however, more recent molecular studies have placed ctenophores as the earliest diverging extant group of animals. Furthermore, ctenophores have been shown to exhibit rapid wound repair and regenerative properties alluding to the involvement of MMPs as an integral component of their wound repair machinery. In this study, we analyze transcriptomic and genomic data through bioinformatics to reveal the presence of putative archetypal MMPs amongst different ctenophore species. Primary putative homologs were filtered through a series of inclusion criteria including size and domain presence. Each of the ctenophore MMP amino acid sequences includes a highly conserved cysteine switch motif, XRCGXXD, in the N-terminus and the family-defining zinc-binding site motif, HEXXHXGX/XXD, in the catalytic domain. The hallmark “Met-turn” found downstream from the catalytic domain and signature hemopexin domain was found in the C-terminus in ctenophore MMPs. These structural consistencies with MMPs from model systems alludes to conserved function of these proteins in disparate taxa. Phylogenetic relationships amongst the ctenophore MMPs will inform the relatedness of this protein family within species of this phylum. Support: NSF EPS-0447675

14-3-3 sequesters the tight junction protein ZO-2 in the cytoplasm of cells cultured in low calcium.
E. Amaya^1, L. Alarcón^1, D. Martín-Tapia^1, F. Cuellar^1, B. Cisneros Vega^2, A.J. Rodríguez^3, L. Gonzalez-Mariscal^1;
^1Department of Physiology Biophysics and Neuroscience, Cinvestav, Mexico City, Mexico, ^2Department of Genetics and Molecular Biology, Cinvestav, Mexico City, Mexico, ^3Department of Biological Sciences, Rutgers University College, Newark, NJ

ZO-2 is a cytoplasmic tight junction (TJ) protein whose subcellular localization varies according to the confluence of the culture and the presence of calcium in the incubation media. In confluent monolayers incubated in low calcium media (LC, 1-5 μM), ZO-2 is absent from the cell borders and displays a diffuse cytoplasmic staining. Here, we aimed to discover how cytoplasmic ZO-2 avoids degradation in the LC condition and the mechanism involved in its arrival to TJs when the monolayers are transferred to normal calcium media (NC, 1.8 mM). We analyzed whether ZO-2 in the LC condition associates to 14-3-3 proteins that bind to phosphoserine/phosphotreonine residues in target proteins. We observed that when confluent monolayers of MDCK cells cultured in LC were treated with BV02, a inhibitor of 14-3-3, ZO-2 moved from the cytoplasm to the cell borders, thus suggesting that in the LC condition, 14-3-3 sequesters ZO-2 in the cytoplasm. The interaction between ZO-2 and 14-3-3 was then demonstrated by co-immunoprecipitation and by a proximity ligation assay. Then, we analyzed the co-localization of isoforms 14-3-3σ and 14-3-3ζ with ZO-2 before and after a Ca-switch in confocal images employing the Fluorescence Covariance Index. We found that in the LC condition ZO-2 is associated with 14-3-3ζ and 14-3-3σ in the cytoplasm, and that transfer to NC media induces recruitment of these complexes to the plasma membrane and their dissociation as ZO-2 incorporates into the nascent TJs. By in silico analysis we found that cZO-2 has 25 putative 14-3-3 binding sites and that 11 of them are located within the U2 segment of the molecule. Interestingly, we found that mutation of one of this residues (T248A), inhibited the capacity of ZO-2 to interact with 14-3-3ζ in a proximity ligation assay and reduced the stability of the protein. Overall, our results indicate that 14-3-3 sequesters ZO-2 in the cytoplasm in the LC condition.

Effect of ZO-actin complexes on tight junction barrier function.
T. Hamkins-Indik^1, B. Belardi^1, D.A. Fletcher^1;
^1Bioengineering, UC Berkeley, Berkeley, CA

Tight junctions are responsible for regulating paracellular transport of ions, proteins and immune cells through cell layers. How these junctions are assembled and maintained remains a topic of significant interest, and many questions remain about the complex interactions between transmembrane proteins and the actin cytoskeleton at the junction. A critical link between tight junction transmembrane proteins and actin are the ZO proteins (ZO-1 and ZO-2). ZO proteins are scaffolding proteins that in addition to tethering proteins to actin are known to regulate barrier function, proliferation and motility. Using in vitro methods, we have identified a small actin-binding motif in ZO-1 and ZO-2 within the larger actin binding region of ZO proteins. To test the role of actin interactions through this motif and the larger
actin binding region, we created knockout cell lines for ZO-1 and ZO-2 and quantified organization, barrier function, and the dynamics of tight junction protein organization. We find that ZO lacking the actin-binding motif or actin binding region alters the barrier function suggesting that ZO-actin complexes directly influence the assembly and maintenance of tight junctions.

Tight junctions remodeling modifies polarized epithelial apical surface tension, fluidity, and intercellular adhesive forces.
A.X. Cartagena-Rivera¹, C.M. Van Itallie², J.M. Anderson², R.S. Chadwick¹;
¹NIDCD, National Institutes of Health, Bethesda, MD, ²NHLBI, National Institutes of Health, Bethesda, MD

The maintenance of epithelial tissue integrity requires coordination between cell-cell adherens junctions (AJ), tight junctions (TJ), and the perijunctional actomyosin cytoskeleton. The perijunctional actomyosin cytoskeleton lies just inside the lateral plasma membrane near the apical junctions, and mainly consists of filamentous actin, non-muscle myosin II motor proteins, and proteins that regulate actin filament dynamics. Here we addressed the hypothesis that alterations in TJ structure and remodeling of the actomyosin cytoskeleton can modify the epithelial tension, fluidity, and intercellular adhesive forces. These supracellular mechanical properties are difficult to measure in intact monolayers and the current methods are disruptive. We developed a novel method to determine the epithelial tension using noncontact acoustic frequency modulation atomic force microscopy (FM-AFM) and tested it on Madin-Darby canine kidney polarized monolayers. Our results show that double knockdown (dKD) of zonula occludens ZO-1 and ZO-2 elevate the apical epithelial tension and effective viscosity in monolayers. Interestingly, epithelial tension is more sensitive to inhibition of myosin II ATPase activity than to inhibition of ROCK activity, but viscosity is highly sensitive to both. Additionally, we showed the epithelial intercellular pulling forces at tricellular junctions and adhesion forces in dKD cell lines are elevated with an increase in contractility. In conclusion, FM-AFM enables the physiological and quantitative study of relevant mechanical forces in intact biological tissues, and can be used to decipher the molecular regulation of epithelial organization and morphogenesis.

Flares of active Rho and F-actin locally reinforce the tight junction barrier in response to mechanical stress.
R.E. Stephenson¹, T. Higashi¹,², I. Erofeev³, B. Coy¹, T.R. Arnold¹, A. Goryachev³, A.L. Miller¹;
¹Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Fukushima Medical University, Fukushima, Japan, ³Centre for Systems Biology, School of Biological Sciences, University of Edinburgh, Edinburgh, United Kingdom

The epithelial barrier is important for generating specialized compartments in multicellular organisms. The barrier property of vertebrate epithelia is dependent on tight junctions, which restrict the flow of ions, water, and small molecules between epithelial cells. Epithelia are subject to a number of cell- and tissue-scale forces, such as cell divisions, extrusions, wound healing, and morphogenetic events. During these events, cell-cell junctions must remodel to accommodate changes in cell shape and mechanical force. However, very little is known about how tight junctions are able to maintain barrier function during these events. In order to examine this question, we developed a highly sensitive barrier assay
compatible with live imaging. When we applied this barrier assay to gastrula-stage *Xenopus laevis* embryos, we found that the epithelial barrier is not uniform across space and time. Instead, small barrier breaches occur – often around dividing cells – and persist for minutes before barrier function is restored.

We have previously reported that “flares” of active Rho accumulate at cell-cell junctions, particularly in situations where the cell-cell junctions are compromised (1, 2). Because Rho flares occur on similar time scales and at similar locations as barrier breaches, we investigated whether the two may be correlated in space and time. Indeed, we found that local barrier breaches are followed by local increases in Rho activity. As Rho returns to baseline levels, the barrier function is restored. Thus, we hypothesized that Rho may be involved in restoring barrier function on subcellular scales. To further investigate this possibility, we examined fluorescently-tagged tight junction proteins ZO-1 and Occludin with respect to Rho. Intriguingly, we observed local discontinuities in ZO-1 and Occludin prior to the flare, and both proteins remained locally increased over baseline, or reinforced, following the flare. In order to investigate how active Rho contributes to reinstatement of the barrier and reinforcement of ZO-1, we perturbed actin polymerization and junction contraction using pharmacological tools. Both junction contraction and actin polymerization appear to contribute to ZO-1 reinforcement, as disruption of either results in only partial ZO-1 reinforcement. When both junction contraction and actin polymerization are lost, ZO-1 fails to be reinforced, and the barrier function is not reinstated. Taken together, these data indicate that transient breaches of the tight junction barrier arise in response to mechanical force, and Rho flares serve to rapidly repair these breaches, preserving the overall barrier function of the epithelium.

**Na⁺-K⁺-ATPase beta1 Subunit fortiﬁes alveolar epithelial tight junctions via ion transport-independent pathway.**

H. Bai¹,², D.A. Dean³, A. Friedman³, M. Barravecchia²;
¹Department of Pathology Laboratory Medicine, University of Rochester Medical Center, Rochester, NY, ²Department of Pediatrics, University of Rochester Medical Center, Rochester, NY, ³Department of Chemistry, SUNY buffalo, Buffalo, NY

Normal epithelial barrier function is dependent on intact tight junctions. The Na-K-ATPase, an ion transporter that regulates intracellular sodium homeostasis, has been shown to regulate cell polarity and cell junctions in multiple tissues, however, the mechanism is largely unknown. In this study, we used lipopolysaccharide-induced mouse lung injury model and isolated rat primary alveolar epithelial cells to study the Na-K-ATPase mediated tight junction regulation. Overexpression of the beta1 subunit of Na-K-ATPase in mouse lungs by electroporation results in decreased wet to dry ratio and lung permeability, suggesting an improvement of the lung barrier function. Western blot analysis indicates that overexpression of the beta1 subunit in alveolar type I cells induces the expression of occludin, zo1 and zo2 by at least 2-fold. In addition, these proteins and claudin4 show higher degree of localization to cell borders, leading to tighter epithelial monolayer measured by transepithelial electrical resistance and paracellular flux of 4 kDa FITC-dextran. Unlike beta1, the beta2 and beta3 isoform of the Na-K-ATPase are unable to enhance tight junctions, suggesting a pump independent pathway that may arise from the unique amino acid sequence of the beta1 subunit. Treatment of 1uM ouabain, which inhibits the transport activity, does not block the upregulation of tight junctions, further confirming a transport-independent pathway, which may act via protein interaction. Mass spectrometry analysis of the immunocomplex pulldown by a beta1 subunit specific antibody detects many unreported interacting
partners of the beta1 subunit, including several protein kinases that is involved in cytoskeletal dynamics and cell junctions. Knockdown experiment of these kinases reveals that MRCKalpha, a CDC42 downstream serine/threonine-protein kinase, appears to mediate the beta1 subunit induced tight junction regulation. These results suggest that the Na-K-ATPase beta1 subunit fortifies lung epithelial tight junctions through transport independent mechanism. Manipulating the Na-K-ATPase beta1 subunit levels thus provide new therapeutic target for many human disease that are characterized by a dysfunction of tight junctions.

The Mechanotransduction role of cell-cell junction in cell extrusion context.
A. Le1,2, R. Mege3, B. Ladoux1,3, C. Lim1,2,4;
1Mechanobiology Institute, National University of Singapore, Singapore, Singapore, 2NUS Graduate School for Integrative Sciences and Engineering, National University of Singapore, Singapore, Singapore, 3Institut Jacques Monod, Université Paris Diderot, Paris, France, 4Biomedical Engineering, National University of Singapore, Singapore, Singapore

Extrusion is the process of cell removal from monolayer to maintain tissue homeostasis, which implies in various physiological and pathological processes such as embryonic development, intestinal tract diseases and bacterial invasion. The active role of cell-cell junction (CCJ) during extrusion process has not been extensively discusses in the literature despite a plethora of research on its role in maintaining epithelial integrity. At CCJ, alpha-Catenin (a-Cat) plays a key role as a mechanotransducer at adherent junctions of epithelial cells. In the cadherin adherent complex, a-Cat can interact with F-Actin or via vinculin in a mechano-responsive manner. Such tension-dependent vinculin recruitment process involves biphasic transition of a-Cat structure from the weak-binding state to the stabilized-binding state to Factin, and hence, stabilizes the adherent junction. Here we show that by changing CCJ strength via manipulating different forms of a-Cat mutants, the extrusion rate, global dynamics and local traction changes were observed in MDCK monolayer. We transfected two forms of a-Cat mutants into MDCK cells with a-Cat knock-down background and observed the cell extrusion from the confluent monolayer for 24-48 hours. The extrusion rate was decreased and the duration was prolonged in the mutant that binds to vinculin constitutively and vice versa, there was increased rate and duration for the mutant with deficiency of vinculin-binding domain compared to both WT and MDCK with a-Cat knock-down with rescued WT a-cat. Moreover, re-localization of traction force tissue exerted on the substrate was observed with a-Cat mutants, implying different mechanism surrounding extrusion site with different CCJ strength. Instant drop of traction followed by recovery from neighboring cells with weakened CCJ suggests a lamellipodia-forming mechanism to help extrude the cells and close the gaps. Overall, our experimental results demonstrate that cell-cell adhesion via the stabilization of cadherin-catenin-vinculin complex regulates epithelial homeostasis.

Effect of influenza infection on epithelial monolayer integrity.
N. Reilly1, L. Martinez2, L. Rodriguez Garcia3, P.W. Oakes1,3;
1Department of Physics and Astronomy, University of Rochester, Rochester, NY, 2Department of Microbiology and Immunology, University of Rochester Medical Center, Rochester, NY, 3Department of Biology, University of Rochester, Rochester, NY

In vitro methods for studying disease dynamics have proven to be a productive and cost effective alternative to in vivo approaches. While significant effort has been committed to exploring the dynamics of virus production and distribution in epithelial sheets, less is known about how infection impacts the contractile and adhesive behavior of cells in a monolayer. Here, we use replication-competent fluorescence-expressing influenza viruses to infect monolayers of Madin-Darby Canine Kidney (MDCK) epithelial cells. Using fibronectin coated micropatterns on polyacrylamide gels to control the morphology of the epithelial cell cultures, we quantify how individual cell morphology and cytoskeletal architecture change over time in response to influenza virus infection. We found that cells steadily weaken in their adhesive contact to neighboring cells, resulting in gaps and holes in the cell monolayers. The spread area of the cells at later time points post-infection also decreased, suggesting weakened contractile behavior. Using Traction Force Microscopy (TFM) to measure the contractile work done between the cells and the substrate we found that the entire contractile output of the cell monolayer weakens during the course of viral infection. Studying fundamental dynamics of epithelial sheet mechanics during influenza virus infection will further the understanding of this important respiratory human disease, and may assist in identifying alternative therapeutic treatments in the future.

Aquaporin-5 in carcinogenesis: expression decreases levels of cell:cell adhesion proteins in MDCK cells.
F.H. Login1, H.H. Jensen1,2, J.J. Morgen1,2, G.A. Pedersen1,3, J.S. Koffman4, J. Palmfeldt1, P. Bross1, M. Parsons5, L.N. Nejsum1,4;
1Department of Clinical Medicine, Aarhus University, Aarhus, Denmark, 2Department of Molecular Biology and Genetics, Aarhus University, Aarhus, Denmark, 3King’s College, London, United Kingdom, 4Interdisciplinary Nanoscience Center, Aarhus University, Aarhus, Denmark

Aquaporins (AQPs) are water channels that facilitate transport of water across the plasma membrane. Moreover, increasing evidence indicates oncogenic properties of some AQPs, especially AQPS: AQP5 is overexpressed in several cancers and overexpression correlates with poor prognosis. In cell cultures, ectopic expression induces cell migration and loss of epithelial cell markers. When AQP5 is phosphorylated on S156 by protein kinase A (PKA), major signaling pathways such as NF-κB and Ras are activated. To further elucidate the role of AQP5 in carcinogenesis, we investigated the effects of AQP5 on proteins involved in cell adhesion. We found that AQP5 expression in MDCK cells affected both mRNA and protein levels of several junctional proteins. Immunofluorescence showed that AQP5 expression decreased protein levels of β-catenin, ZO1, p120 catenin and plakoglobin (γ-catenin) and fluorescent in situ hybridization analysis showed a drastic decrease in β-catenin and ZO1 transcripts. Surprisingly, the AQP5S156A mutant that is impaired in phosphorylation by PKA also promoted low levels of adhesion proteins, indicating a Ras independent pathway. The Wnt pathway feedback inhibitor
Axin2, a β-catenin/TCF-regulated gene, was also down-regulated in AQP5 expressing cells. Inhibition of glycogen synthase kinase-3β (GSK-3β) with LiCl partially restored β-catenin levels in AQP5 expressing cells. This indicates that AQP5 expression may interfere with the Wnt signaling pathway by activating or preventing inhibition of GSK-3β. Moreover, pull-down and mass spectrometry analysis revealed that AQP5 interacted with β-catenin, plakoglobin and ZO1. Thus, AQP5 may downregulate adhesion proteins via interference with the Wnt signaling pathway as well as interactions with adhesion proteins, which triggers degradation. Our findings suggest that AQP5 may contribute to carcinogenesis by several mechanisms including interference with the Wnt pathway and degradation of adhesion proteins.

The role of VASP in modulating actin architecture at adherens junctions.
B. Hissa¹, Y.M. Beckham¹, M.L. Gardel¹;
¹Institute for Biophysical Dynamics and Physics Department, University of Chicago, Chicago, IL

Cell-cell adhesions and cell-extracellular matrix adhesion sites (focal adhesions) are regions of intense actin remodeling. Some actin-binding proteins appear to be recruited to both of those regions to regulate the actin remodeling. Enabled/Vasodilator-stimulated phosphoproteins (Ena/Vasp) are a family of tetrameric proteins that are recruited to both adherens junctions and focal adhesions. In mammals, Ena/VASP family protein encompasses Mena, VASP and Ena/VASP-like protein (EVL). Ena/VASP is thought to promote actin assembly by two main mechanisms: protecting barbed ends from premature capping and promoting polymerization via profilin-bound g-actin. Ena/VASP proteins are also finely tuned by PKA and PKG phosphorylation. PKA specifically phosphorylates Ena/VASP at Ser 157 to regulate localization of the protein to either focal adhesions or to the cell surface. In order to isolate the contribution of VASP to adherens junctions we plated Caco2 cells on e-cadherin-Fc coated surfaces. These adherens junction plaques contain VASP that is preferentially localized at beta-catenin macroclusters. We also showed that transient knockdowns for VASP (siVASP) decrease adherens junction plaque size and the percentage of cells that have perpendicular stress fibers terminating at those plaques. siVASP monolayers are less stable and present holes. Inhibition of PKA-mediated VASP phosphorylation by H89 show a similar phenotype in comparison to siVASP Caco2 cells, with reduction in plaque size and generation of holes in the monolayers. Stabilization of PKA mediated VASP phosphorylation by NECA treatment maintained plaque size and monolayer integrity. These results indicate that VASP is important for modulating actin architecture at adherens junction plaques and play an important role in stabilizing Caco2 monolayers.

The RhoGEF Trio induces junctional F-actin bundles by locally activating Rap1 to stabilize VE-cadherin-based cell-cell junctions.
J.D. Van Buil¹, I. Timmerman¹, M. Hoogenboezem¹, Y. Wu², J.v. Rijsdel¹;
¹Molecular Cell Biology, Sanquin Research and Landsteiner Laboratory, Amsterdam, Netherlands,
²Center for Cell Analysis and Modeling, UConn Health, Farmington, CT

Endothelial cell-cell junctions maintain a restrictive barrier that is tightly regulated to allow dynamic responses to permeability-inducing angiogenic factors as well as inflammatory agents and adherent leukocytes. The ability of these stimuli to transiently remodel endothelial adherens junctions (AJs)
depends on Rho- and Rap-GTPase-controlled cytoskeletal rearrangements. How activity of Rho and Rap-GTPases is spatiotemporally regulated at endothelial AJs by guanine-nucleotide exchange factors (GEFs) is incompletely understood. Here, we identify a crucial role for the RhoGEF Trio in stabilizing VE-cadherin-based junctions. Trio interacts with VE-cadherin and locally activates Rac1 at AJs during nascent contact formation. The N-terminal domain of Trio, including the spectrin-repeats and the GEF1 domain, is responsible for remodeling of junctional actin from radial to cortical actin bundles, a critical step for junction stabilization. Additional evidence using a DORA-Rap1 biosensor shows that this domain of Trio indirectly activates Rap1 through Rac1 and RhoG and the RapGEFs C3G and PDZGEF2 at cell-cell junction regions. Phenotypically using super resolution structural illumination microscopy, we show that Trio activation results in the formation of Rap1-dependent linear AJs and thick F-actin fibers that co-localize with phosphorylated Myosin Light Chain but not with VE-cadherin or beta-catenin. Functionally, we found a dramatic 4-fold increase in the endothelial monolayer resistance when expressing the N-terminus of Trio. Unexpectedly, laser ablation studies revealed low tension at junctional F-actin and high tension at cortical F-actin fibers, indicating a balanced distribution of tension between endothelial F-actin cables and peripheral F-actin cables. Reducing tension using blebbistatin in the presence of active Trio reduced the endothelial barrier resistance independently from VE-cadherin. Collectively, our data reveal that Trio can regulate the endothelial junction integrity in two ways: 1. upon formation of cell-cell junctions: Trio directly binds to the C-terminus of VE-Cadherin and locally promotes the activity of Rac1 and 2. for the increased stability of already matured endothelial cell-cell junctions by locally regulating tension of cortical actin bundles through the signaling axis Trio-Rac1-C3G/PDZGEF2-Rap1-F-Actin in a VE-cadherin-independent fashion.

Rapamycin reduces TNFα-induced VCAM-1 expression in endothelial cells by promoting VCAM-1 degradation via autophagy.
L. Chu¹, H. Cheng¹, K.K. Wu¹²;
¹Metabolomic Medicine Research Center, China Medical University Hospital, Taichung, Taiwan, ²Institute of Cellular and System Medicine, National Health Research Institutes, Miaoli, Taiwan

VCAM-1 is a cell adhesion molecule and plays important roles in inflammatory responses. Rapamycin is known to reduce cytokine-induced VCAM-1 expression in endothelial cells. However, the mechanism by which rapamycin reduces VCAM-1 expression is not clear. Although it is reported that rapamycin inhibits VCAM-1 transcription by increasing ERK1/2 activation, our data does not support this mechanism. We hypothesize that rapamycin reduces VCAM-1 expression in endothelial cells by promoting VCAM-1 degradation. To test this hypothesis we treated human umbilical vein endothelial cells (HUVECs) with tumor necrosis factor α (TNFα) along with rapamycin. The results show that rapamycin had no effect on TNFα-induced MAPKs or NF-κB activation and did not reduce TNFα-induced VCAM-1 mRNA level. By time-course analysis, we found that rapamycin did not affect short-term (<16 h after TNFα stimulation) but reduced long-term (20~24 h after TNFα stimulation) TNFα-induced VCAM-1 expression. Moreover, short-term VCAM-1 expression was reduced in HUVECs pretreated with rapamycin for 16 h, which indicates that the effect of rapamycin takes time. These results are not consistent with inhibition of VCAM-1 transcription by Bay11 or SB202190 and suggest that rapamycin reduces VCAM-1 expression by promoting VCAM-1 degradation. Rapamycin is known to induce autophagy. With western blotting and fluorescence lysotracker staining, we confirmed that rapamycin induces LC3-II accumulation, p62 degradation and increases lysosomal activity in HUVECs. To test whether autophagy is involved in rapamycin-reduced VCAM-1 expression, we blocked autophagy and lysosomal degradation with Atg5

Sunday-408
siRNA and Bafilomycin A, respectively. Atg5 siRNA and Bafilomycin A blocked the effect of rapamycin on VCAM-1 expression, suggesting that reduction of VCAM-1 expression is mediated by autophagy. To further clarify the mechanism of VCAM-1 degradation, we blocked endocytosis of VCAM-1 by dynasore. Dynasore blocked VCAM-1 degradation, which suggests that the degradation is happened after VCAM-1 endocytosis. In this study, we shed light a novel mechanism by which VCAM-1 expression is regulated via autophagy-mediated degradation.

In Vitro Evaluation of Damage by Heavy Metals in Tight and Gap Junctions of Sertoli Cells.
J. Ramos Treviño1, S. Bassol Mayagoitia1, J. Hernández Ibarra1, P. Ruiz Flores2, P. Espino Silva2, O. Saucedo Cardenas3,4, M. Nava Hernandez1;
1Biología de la Reproducción, Universidad Autónoma de Coahuila, Torreón, Mexico, 2Genética y Medicina Molecular, Universidad Autónoma de Coahuila, Torreón, Mexico, 3Histología, Universidad Autónoma de Nuevo León, Monterrey, Mexico, 4Genética Molecular, Centro de Investigación Biomedica del Noreste, Monterrey, Mexico

The Sertoli cell plays a vital role during the spermatogenesis process and has been identified as one of the main targets of the toxic action of heavy metals on the seminiferous epithelium. In the present work, the effect of lead (Pb), Arsenic (As), and Cadmium (Cd) in primary cultures of Sertoli cells was analyzed by measuring the expression of the genes Cldn11, Ocln, and Gja1 that participate in the tight and gap junctions, which are responsible for maintaining the blood-testis barrier. Sertoli cells were isolated from the testes of Wistar rats. Sertoli cell cultures were exposed separately and at the same concentrations of three heavy metals for 48 h. Subsequently, gene expression was measured by real-time polymerase chain reaction. In the morphological analysis of the cultures, after 24 h, the cultures exposed to Cd showed greatest detachment of the monolayer, followed by those exposed to As and Pb. As for gene expression patterns, As induced a decrease in the expression of the Cldn11 gene at 24 and 48 h (p < 0.01) and in that of Ocln at 24 (p < 0.001) and 48 h (p < 0.01), whereas Cd induced overexpression of the Gja1 gene from day 1 of exposure (p < 0.001) and subexpression of the Ocln gene (p < 0.05) at 24 h. Because each of these three metals generated different expression patterns in the three genes, we can postulate that the mechanisms of damage that they induce are different; therefore, the effect that they exert on the Sertoli cell occurs through different pathways, generating changes in structural proteins, altering Sertoli cell morphology, and compromising its function in the regulation of the spermatogenesis process.

Use of a Time-Resolved Fluorescence Resonance Energy Transfer-based screening assay to identify a claudin-4 binder that attenuates tight junction barrier function.
A. Watari1, M. Kondoh1, K. Yagi1;
1Graduate School of Pharmaceutical Sciences, Osaka University, Suita, Japan

Objectives: Claudins, a 27-member family of proteins with four transmembrane domains each, play a pivotal role in maintaining tight junction (TJ) seals in epithelial and endothelial tissue. The C-terminal fragment of Clostridium perfringens enterotoxin (C-CPE) binds to claudin-4, which is a key functional and structural component of the TJ in mucosal epithelial cells. Upon binding, C-CPE reversibly modulates TJ seals, yielding an enhancement of the paracellular transport of solutes. However, the use of C-CPE as an
In the present study, we developed a high-throughput screening system using Time-Resolved Fluorescence Resonance Energy Transfer (TR-FET) to identify small-molecule compounds that bind to claudin-4.

Methods: A europium-tagged (Eu (K)) -anti-His Antibody (Ab) and an allophycocyanin (XL665) -tagged-anti-glutathione S-transferase (GST) Ab were used for detection of the interaction between GST-C-CPE and His-claudin-4 using Eu (K) as a donor and XL655 as an acceptor in FRET. To screen for a small-molecule claudin-4 binder, a 32,560-compound library was used. The effects of thiostrepton, a candidate molecule identified in this screen, on epithelial barrier function were confirmed by measurement of transepithelial electrical resistance (TER) and by a paracellular tracer flux assay. The effect of thiostrepton on jejunal absorption was analyzed using a rat loop assay. Results: To construct the claudin-4 binder screening system, we developed a TR-FRET-based assay system for detection of the claudin-4 - C-CPE interaction. The formation of a quaternary complex containing Eu (K) -conjugated-anti-His antibody (Ab), XL-665-conjugated-anti-GST Ab, His-claudin-4, and GST-C-CPE resulted in fluorescence energy transfer between the donor and acceptor. Using this screening system, we performed a claudin-4 binder screen of a library (32,560 compounds), and identified 33 compounds, including thiostrepton, as novel claudin-4 binders. Among these binders, thiostrepton decreased the TER value and increased the flux of 4-kDa fluorescein isothiocyanate (FITC) -dextran in Caco-2 cell monolayers. Furthermore, thiostrepton enhanced rat jejunal absorption of 4-kDa FITC-dextran in a dose-dependent manner. We therefore successfully identified a novel claudin-4 binder, which has the potential to function as an absorption enhancer. Conclusion: The TR-FRET-based screening system is expected to be of use in identifying compounds that modulate the permeability of the intestinal epithelial cell barrier.

**Concatemerization of connexins - a tool to analyze the oligomerization behavior of heteromeric connexins.**

P. Schadzek¹, D. Hermes¹, Y. Stahl¹, A. Ngezahayo¹²;
¹Institut für Biophysik, Leibniz Universität Hannover, Hannover, Germany, ²Centre for System Neurosciences (ZSN), Hannover, Germany

Gap junction channels (GJCs) are built between neighboring cells by docking of two connexons (hemichannels), which are made up of six connexins (Cx). It is assumed that hemichannels can be homomeric or heteromeric, depending on whether they are composed of one or more connexin isoforms. Accordingly, the formation of gap junctions with variable connexin combinations has been postulated as a mode of fine tuning of the gap junction channels and their regulation in tissue. eGFP labelled monomeric hCx26 and hCx46, two homodimers (hCx46-hCx46, hCx26-hCx26) and two heterodimers (hCx26-hCx46, hCx46-hCx26) were expressed in communication deficient HeLa cells. Confocal laser scanning microscopy showed that the tandems formed gap junction plaques, which, however, had a reduced plaque area compared to the monomeric hCx26 or hCx46. Using the whole-cell patch-clamp configuration with pipette solution containing Lucifer Yellow or AMCA (7-Amino-4-methyl-3-coumarinylacetic acid), we found that the homodimeric and heterodimeric constructs formed metabolically coupled gap junction channels like the monomeric constructs. Expressed in Xenopus laevis oocytes, patch-clamp experiments in inside-out modus revealed that single hemichannels composed of the tandems, or the monomeric constructs were opened by depolarizing voltage steps and closed by classical hemichannel blockers, such as Ca²⁺ or CBX. Additionally, hemichannels composed of the heterodimers hCx46-hCx26 and hCx26-hCx46 showed a higher single channel fluctuation rate, as well as more open states than those composed of the monomers or the homodimers. Furthermore, we
observed similar junctional currents of whole gap junction channels in double whole-cell patch-clamp measurements using N2A cells transfected with the monomeric or homodimeric constructs. The study shows, that the concatemerization of connexins can be used to analyze biophysical properties of heteromeric connexons, as well as the heteromeric-heterotypic gap junction channels.

The interactions between β1 subunits of the Na⁺,K⁺-ATPase promote cell-cell adhesion in CHO fibroblasts and ouabain intensified it.

C.A. Vilchis Nestor¹, M.L. Roldan Gutierrez², T. Padilla-Benavides², L. Shoshani¹;
¹physiology, CINVESTAV-IPN Mexico, Mexico city, Mexico, ²Department of Biochemistry and Molecular Pharmacology, UMASS, Worcester, MA

Adhesion is the most important characteristic of epithelial cells to provide a crucial barrier to pathogens and substances. In polarized epithelial cells, adhesion depends on tight junctions, adherent junctions and the Na⁺, K⁺-ATPase, all these located in the basolateral membrane of the cells. The hormone ouabain, member of cardiotonic steroids binds to the α subunit of Na⁺, K⁺-ATPase and inhibits the pump activity when used at above uM concentrations. At physiologic concentrations (nM) it affects the adhesive properties of epithelial cells (Larre et al. 2010). Our group demonstrated the homotypic interactions between β1 subunits of the Na⁺, K⁺-ATPase of neighboring cells (Padilla-Benavides et al. 2010). In the present study we investigate whether the adhesion between β1 subunits is also affected by ouabain. We used CHO fibroblasts stably expressing the β1 subunit of the Na⁺, K⁺-ATPase (CHO-β1) and characterized the effect of ouabain on cell adhesion. Our previous work has shown that non-adherent CHO cells transfected with dog β1 subunit turn out to be adhesive (Shoshani et al. 2005). Here we observe, by IF and Biotinylation assays that ouabain (50 nM) increases the expression of the β1 subunits of Na⁺, K⁺-ATPase at the cell membrane. Aggregation assays show that ouabain increments the adhesion between CHO-β1 cells. It was previously demonstrated that ouabain affects cell adhesion molecules through activation of signaling pathways associated to the α subunit (Larre et al. 2010). We therefore analyzed the effect of ouabain on activation of different kinases in CHO-β1 cells and their effect on cell adhesion. Our results strongly suggest that c-Src, ERK1/2 and AKT are activated by ouabain and have a direct effect regulating the adhesive properties of the sodium pump.

Role of Connexin 32 on gap junctions in breast cancer cells with varying metastatic potential.

D. UGUR¹, E. Ozcivici², G. Mese¹;
¹Molecular Biology and Genetics, Izmir Institute of Technology, Izmir, Turkey, ²Bioengineering, Izmir Institute of Technology, Izmir, Turkey

Connexins (Cx) are primary components of gap junctions. Their role in gap junctional intercellular communication (GJIC) is to selectively allow molecules to pass between adjoining cells to regulate many cellular processes. Connexins play a variety of roles in different stages of tumorigenesis, both dependent and independent of gap junction channel functions. While, Cx26 and Cx43 are expressed in healthy breast tissue, they were found to be downregulated in early stages of breast cancer. On the other hand, cytoplasmic accumulation of Cx32 was shown in some breast cancers, and compared to the primary tumors Cx32 is further upregulated in metastasis. However, the complete picture for the role of Cx32 in breast cancer remains to be elusive. By overexpressing Cx32, we investigated localization of Cx32
protein as well as its effect on gap junction function, hemichannel activity and proliferation in Hs578T metastatic breast cancer cells that do not express Cx32 and MCF-7 non-metastatic breast cancer cells that endogenously express Cx32. Transient transfections of Cx32 showed cytoplasmic accumulation of Cx32 proteins in both cell lines and no gap junction plaques were observed between adjacent cells. Proliferation analysis using MTT and trypan blue analysis showed increased viability for Hs578T cells upon Cx32 infection with no significant change on MCF7 cells. In parallel with this, cell cycle analysis demonstrated significant increase in S phase in Cx32 infected Hs578T cells while not showing any effect on MCF7 cells. Further, overexpression of Cx32 in MCF-7 cells did not result in the formation of functional gap junctions but it significantly reduced dye transfer between Hs578T cells in scrape loading assay. However, Cx32 overexpression did not affect hemichannel functions in neither cell type. Our data showed that Cx32 infection does not have any effect on MCF7 cells while it reduces gap junction functions in Hs578T cells without affecting their hemichannel activity. Decrease in dye transfer upon Cx32 infection in Hs578T cells might indicate a suppressive effect of Cx32 on other connexins. Significant increase in the number of Cx32 expressing Hs578T cells in S phase may indicate a tumor promoting effect of Cx32. This effect of Cx32 needs to be confirmed by checking its effect on invasion and metastasis of both cells.

Relocalization of the adhesion molecule nectin-1 from cell junctions is induced by herpes simplex virus glycoprotein D.

G.J. Haila¹, P.W. Rothlauf², A.A. Hakim², A.K. Bhargava³, C. Krummenacher²,⁴;

¹Chemistry and Biochemistry, Rowan University, Glassboro, NJ; ²Biological Sciences, Rowan University, Glassboro, NJ; ³Biochemistry, University of Pennsylvania, School of Dental Medicine, Philadelphia, PA; ⁴Molecular and Cellular Biosciences, Rowan University, Glassboro, NJ

Nectins are conserved adhesion molecules found at specialized intercellular junctions including adherens junctions (AJ) in epithelia and neuronal synapses. Nectins participate to the initial organization and maintenance of these junctions through homophilic or heterophilic trans-interactions within the nectin family. Responses to nectin trans-interactions include recruitment of other adhesion molecules, connection to and remodeling of the actin cytoskeleton. Interestingly nectins act as receptors for various human viruses like measles virus, poliovirus and several herpesviruses. In particular nectin-1 is the main receptor for herpes simplex virus (HSV) infection of epithelial cells and neurons. These viruses evolved to trigger and use cellular responses that favor infection of target cells. The objective of this study is to understand whether the HSV ligand, glycoprotein D (gD), mimics a natural cellular ligand or triggers a unique response upon interaction with nectin-1. Structural data show that HSV gD binds to the canonical adhesive interface between nectin-1 homodimers. Despite structural similarities with the binding of natural nectin-1 ligands, we found that HSV gD triggers a unique response which causes endocytosis of nectin-1 together with viruses. Here we used purified soluble gD to study how nectin-1 can be displaced from cell junctions. We found that disruption of nectin-1 trans-interaction at cell contacts led to rapid relocalization of nectin-1-GFP at the cell surface of model B78H1 murine melanoma cells. Real time recording of cells exposed to gD also showed that the rapidity of this relocation correlated with the affinity of gD for nectin-1. In human ECC1 epithelial cells, gD-induced delocalization of nectin-1 from established AJ appeared less efficient than in B78H1 cells. We also found that forms of nectin-1 lacking the ability to interact with cytoplasmic adaptors to the actin cytoskeleton responded to soluble gD in similar ways. This suggests that connection of nectin-1 with known adaptors (e.g. afadin) and the cytoskeleton is not needed for gD-induced movement of nectin-1 away from junctions. Interestingly,
nectin-1-GFP failed to accumulate at contacts between B78H1 cells seeded on gD-coated glass, when gD is not intercalating between nectin-1 trans-dimers at junctions. This suggests that gD may induce a global cell response which prevents nectin-1 to accumulate at cell contacts. Altogether these data indicate that HSV gD is unique in inducing nectin-1 delocalization in target cells through binding and signaling.

Contribution of ppGalNAc transferase-1 to mucin-type O-glycosylation on the Ebola virus glycoprotein and subsequent loss of cell adhesion.
E.J. Simon1, A.D. Linstedt1;
1Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

As evidenced by the 2014-2015 outbreak in West Africa, Ebola virus (EBOV) poses a significant public health risk with mortality rates as high as 90%. As of now, no vaccine against EBOV has been approved for widespread use and few therapeutic options exist to specifically combat Ebola virus disease. Infection is characterized by uncontrolled inflammation and endothelial damage, often resulting in hypovolemic shock, multi-organ failure, and death. The EBOV surface glycoprotein (GP) is known to be instrumental in causing many of the virus’ pathogenic effects, including a dramatic loss of both cell-cell and cell-matrix adhesion in the endothelium. Significantly, this de-adhesion depends upon the extracellular mucin-like domain of GP, which contains a dense cluster of mucin-type O-glycosylation sites. O-glycosylation enzymes may therefore provide excellent therapeutic targets against Ebola virus disease. Mucin-type O-glycosylation is initiated by transfer of a single GalNAc sugar to a serine or threonine residue by the the polypeptide GalNAc transferase enzyme (GalNAcT), of which there are up to 20 distinct isoforms in humans (GalNAcT1-T20). To test which, if any, of the GalNAcTs are individually required for attachment defects, we assayed for changes in cell adhesion following expression of GP in mammalian wild-type or knockout cell lines each deficient in a single GalNAcT isoform. We found that GalNAcT1 knockout cells displayed reduced cell rounding and cell detachment, and more robust adhesiveness with GP expression as compared with wild-type cells. Moreover, we attribute the detachment resistance of GalNAcT1-deficient cells to changes in the glycosylation pattern on GP itself, as both cell lines showed similar overall adhesive properties before transfection, and expressed identical levels of mature surface GP with indistinguishable turnover rates. We are currently conducting mutational analyses to determine the specific residues that GalNAcT1 glycosylates, and how these residues contribute to de-adhesion. In conclusion, we have found that a single GalNAcT isoform is largely required for decreased cell adhesion upon Ebola GP expression, identifying GalNAcT1 as a promising therapeutic target to reduce vascular damage during EBOV infection.

MMP28 is overexpressed in bronchial and alveolar epithelial cells in Idiopathic Pulmonary Fibrosis.
M. Maldonado¹, A. Salgado-Aguayo², I. Herrera², B. Ortiz², C. Staab-Weijnitz³, M. Selman², A. Pardo¹;
¹Facultad de Ciencias, Universidad Nacional Autonoma de Mexico, Mexico City, Mexico, ²Instituto Nacional de Enfermedades Respiratorias, Mexico City, Mexico, ³Comprehensive Pneumology Center, Helmholtz Zentrum München, Munich, Germany

Idiopathic Pulmonary Fibrosis (IPF) is a devastating and destructive aging-associated disease of unknown etiology and limited therapeutic options. The disease is characterized by epithelial injury and activation followed by the upregulation of multiple mediators that induce the migration, proliferation and activation of fibroblasts with the consequent destruction of the lung architecture. Some matrix metalloproteinases (MMPs) are upregulated in IPF, indicating that they may be important in the pathogenesis and/or progression of the disease. MMP28 (epilysin) is expressed during development and recent evidence has demonstrated that it is upregulated in diverse pathological conditions. In this study, we examined the expression of MMP28 in IPF and evaluated its functional effects in alveolar and bronchial epithelial cells. We found that the enzyme is expressed in bronchial (apical and cytoplasmic localization) and alveolar epithelial cells (cytoplasmic and nuclear localization) in IPF lungs. In vitro, MMP28 epithelial silencing decreased the proliferation rate and delayed wound closing, while overexpression showed the opposite effects, protecting from apoptosis and enhancing epithelial-mesenchymal transition (EMT). These effects were lost when the catalytic domain was affected by site-directed mutagenesis changing the glutamate in the MMP-28 catalytic site for an alanine. These findings demonstrate that MMP28 is upregulated in the respiratory epithelium of IPF lungs where it may be implicated in its proliferative and migratory phenotype.

Matricellular Tinagl1 affects cilia function in early zebrafish embryos.
H. Neiswender¹, S. Navarre², J.S. Mumm³, D.J. Kozlowski³, E.K. LeMosy³;
¹Department of Cellular Biology and Anatomy, Augusta University, Augusta, GA, ²Department of Neuroscience and Regenerative Medicine, Augusta University, Augusta, GA, ³Wilmer Eye Institute, Johns Hopkins University School of Medicine, Baltimore, MD

Tinagl1 (tubulo-interstitial nephritis antigen-like protein 1) is a matricellular glycoprotein broadly associated with basement membranes in animal species having three germ layers; mammals have an additional family member, Tinag, that is largely restricted to the developing and adult kidney. Drosophila Tinagl1 binds tightly to the Wnt, Wg, and is required for Wg stability in vitro, while the mammalian proteins have been associated with a FAK-dependent cell survival pathway and with reduced metastatic potential of mammary tumor cells. However, no clear in vivo requirement or pathway mechanisms have been defined for Tinagl1 in these animal models. Using MO knockdown in zebrafish, we observed defects consistent with a ‘ciliopathy’ spectrum, including small eye, body curvature, L/R randomization of heart looping, hydrocephalus, renal cysts, and craniofacial defects (CPCI 54:381-90, 2017, and manuscript in preparation). Transient Crispr/Cas9 mosaic knockdown and an ENU truncation mutant support heart looping, renal, and craniofacial defects. With the MOs, we documented shorter and fewer cilia in Kupffer’s vesicle (KV) and pronephric duct. Interestingly, tinagl1 morphant pronephros defects were enhanced by co-injection with wnt3a MO but not control MO, and partially rescued by tinagl1 and

**Equilibrium structure and mechanics of the cellular glycocalyx.**
J.G. Gandhi¹, D.L. Koch², M.J. Paszek³;
¹Chemical and Biomolecular Engineering, Cornell University, Ithaca, NY

Cells can employ distinct modes of cell migration, ranging from mesenchymal-like or amoeboid-like single cell motility to collective migration, where cells move as coherent strands. Each mode of migration is characterized by a unique balance of cell-matrix and cell-cell adhesion. Carbohydrates called glycans are concentrated on the cell surface in a complex structure called the glycocalyx. While the glycocalyx is known to impede cell adhesion by acting as a steric barrier, the mechanical response of the glycocalyx and its molecular constituents to force is largely unknown. Therefore, we have developed a physical model of the glycocalyx in order to understand and predict its deformation and reorganization under compressive loads, such as those that would be expected on cells in confined three-dimensional environments. Simulations of our model predict that the glycocalyx can sustain substantial pressures without undergoing significant deformations, but beyond a critical pressure it experiences a pressure-sensitive response, followed by increased resistance at high strains. These results suggest that cells could switch between a weakly adherent state and highly adherent state depending on the degree of confinement and the compression of the glycocalyx. Additionally, the simulations predict the formation of load-bearing clusters of glycoproteins in favorable regions away from the cytoskeletal membrane attachments. We elucidate the effect of the biophysical properties of the glycocalyx and the cell membrane on the mechanical response. We find that increasing the stiffness and the density of glycoproteins and the membrane bending modulus or decreasing the length of glycoproteins and the spacing between cytoskeletal filaments increases the collective stiffness of the glycocalyx and the critical pressure required to generate significant deformations. Together, our results demonstrate how the bulk material properties of the glycocalyx emerge from the physical properties of its molecular constituents and how these constituents rearrange under load. The understanding that we develop with this study has broad relevance in cell migration, cell adhesion, cell communication, and other receptor-mediated processes occurring within the glycocalyx.

---

**cttnb2** mRNA but not control **egfp** mRNA. Overall, our results support a hypothesis that, in zebrafish, Tinagl1 is broadly required for motile cilia function and may interact with Wnt/beta-catenin signaling that functions upstream of the motile cilia regulator **foxj1a** in pronephros and KV. Signaling via integrins and associated focal adhesion proteins is also a consideration in how Tinagl1 may affect cilia function. We are currently focusing on knockout mutant generation in zebrafish, needed for definitive analysis of these possibilities, and on testing whether Tinagl1 can also regulate primary cilia function in mammalian cell lines. This ongoing work is relevant to deciphering the complex interplay of extracellular matrix, Wnt signaling pathways, and cilia in human developmental defects and in diseases such as cancer.

Cellular reprogramming of primary human adipocytes into brown adipose tissue (BAT)-like cells.
K.M. Cartwright1, C.E. Long1; P.A. Harding1,2; S.R. Taylor1;
1Biology, Miami University, Oxford, OH, 2Biological Sciences, Miami University Regionals, Hamilton Middletown, OH

Objective: To examine the molecular mechanism of transdifferentiation of primary human adipocyte cells into Brown Adipose Tissue (BAT)-like cells.

Methods: Previous results from our lab have demonstrated lipid-accumulation, lack of cellular proliferation, stimulation of genes involved in the BAT pathway and increased number of mitochondria when heparin binding EGF-like growth factor (HB-EGF) and a soluble form of a disintegrin and metalloproteinase 12 (ADAM 12S) were co-expressed in cells. HB-EGF and ADAM 12S adenoviral expression vectors were engineered in order to recapitulate these results with the goal of using these vectors in vivo and in vitro. Human primary adipocytes were infected with either mock or ADAM 12S high titer adenovirus, monitored for fluorescence and lipid accumulation, and RNA was extracted after 3 weeks of infection. Gene expression patterns will be examined using qRT-PCR for the BAT-like genes, PRDM16, PGC-1α, and UCP-1.

Results: Infection of the primary human adipocyte cells was confirmed by the presence of enhanced green fluorescent protein. Both the mock infected and the ADAM 12S adenovirus infected cells exhibited fluorescence. The ADAM 12S infected cells demonstrated noticeable lipid droplet accumulation in comparison to the mock infected cells. RT-PCR results demonstrated the presence of endogenous hHB-EGF. We would expect the BAT-like genes PRDM16, PGC-1α, and UCP-1 to be upregulated in the cells that were infected with ADAM 12S, while the mock infected cells will not be expected to exhibit this pattern of gene expression.

Conclusions: These results further support previous findings of co-expression of HB-EGF and ADAM 12S stimulating cellular reprogramming into brown adipose tissue (BAT)-like cells. We believe that ADAM 12S stimulates cellular reprogramming into BAT-like cells utilizing endogenous hHB-EGF. These novel insights may provide the first evidence demonstrating BAT-like cellular reprogramming occurs in vivo in humans. This research has possible therapeutic applications to combat obesity and type 2 diabetes.

HB-EGF and ADAM 12S co-expression of mouse fibroblasts results in increased metabolic activity.
D.C. Pfeil1, S.R. Taylor1; P.A. Harding1,2;
1Biology, Miami University, Oxford, OH, 2Biological Sciences, Miami University Regionals, Hamilton Middletown, OH

Objective: To examine the metabolic profile of HB-EGF/ADAM 12S BAT-like cells via oxygen consumption and extracellular acidification rate.

Methods: Previously our lab demonstrated lipid-accumulation, lack of cellular proliferation, up-regulation of genes involved in the BAT pathway and stem-cells, down-regulation of WAT pathway genes, and increased number of mitochondria when heparin binding EGF-like growth factor (HB-EGF) and a soluble form of a disintegrin and metalloproteinase 12 (ADAM 12S) were co-expressed. MLC, MLC HB-EGF, MLC ADAM 12S, MLC HB-EGF/ADAM 12S, 3T3-L1 cells were cultured and grown to confluence. 3T3-L1’s were split and differentiated into WAT-like cells and BAT-like cells according to Asano et al.,

Sunday-416
(2014) protocol. After 8 days Seahorse extracellular flux assays were conducted on the Seahorse XF24 according to manufacturer’s (Agilent) recommendations. Besides basal conditions, exposure to catecholamines (200 nM) and FCCP (1 µM) + Oligomycin (1 µM) and results were analyzed. The same experiments will be carried out on a mutant form of HB-EGF with truncated extracellular and intracellular domains while maintaining the processing site for ADAM 12 referred to as ΔNAC and ΔNAC co-transfected with ADAM 12S (ΔNAC/ADAM 12S).

Results: MLC HB-EGF/ADAM 12S co-transfected cells show an increased metabolic rate at basal conditions for oxygen consumption, when exposed to catecholamines, and FCCP+oligomycin when compared to controls (MLC, HB-EGF, ADAM 12S, HB-EGF/ADAM 12S, 3T3-L1, and 3T3-L1 WAT-like cells) and a very similar metabolic profile with 3T3-L1 beige/BAT-like cells. Co-transfected cells saw an increase in OCR when exposed to catecholamines 19.8% while BAT-like cells showed at 62.8% increase. However co-transfected cells demonstrated higher basal levels of metabolism and when comparing their OCR to ECAR ratio when exposed to catecholamines their ratios are nearly identical as they both only saw a 7% and 8% change respectively. It is expected that ΔNAC/ADAM 12S will mimic these results as we have previously demonstrated that ΔNAC/ADAM 12S accumulates multilocular lipid droplets recapitulating the results of HB-EGF/ADAM 12S when stained with Oil Red O.

Conclusions: These results further demonstrate that HB-EGF and ADAM 12S co-expression results in cellular reprogramming into BAT-like cells. Of particular note, HB-EGF/ADAM 12S co-expressing cells can be activated with catecholamines resulting in increased metabolic output and thus may provide a novel therapeutic approach to combating obesity and type II diabetes.

Spinal Muscular Atrophy (SMA) is a neuromuscular disorder caused by homozygous loss-of-function mutations in the human survival motor neuron 1 (SMN1) gene, which leads to reduced levels of functional survival motor neuron (SMN) protein. Expression of a duplicate gene (SMN2) primarily results in skipping of exon 7 and production of an unstable protein isoform, SMNΔ7. Although SMN2 exon skipping is the principal contributor to SMA severity, mechanisms governing stability of SMN isoforms are poorly understood.

We generated transgenic Drosophila melanogaster that express only flag-tagged wild-type SMN using the endogenous promoter. We collected embryos from these animals and analyzed Flag-purified lysates by ‘label-free’ mass spectrometry. We identified Flag-SMN, along with other core SMN complex components such as the Sm proteins and the Gemins.
In addition, we identified the SCF真的很 ubiquitin E3 ligase complex as a novel SMN binding partner. Each component: supernumerary limbs (Slmb), SkpA, and Cullin 1 was highly enriched (at least 10 fold) in Flag-SMN samples as compared to the control sample. SCF真的很 interacts with a phospho-degron embedded within the human and fruitfly SMN YG-box oligomerization domain. Substitution of a conserved serine (S270A) interferes with SCF真的很 binding and stabilizes SMNAΔ7. Proteins containing SMA-causing missense mutations that block multimerization of full-length SMN are also stabilized in the degron mutant background. Overexpression of SMNAΔ7S270A, but not wild-type SMNAΔ7, provides a protective effect in SMA model mice and human motor neuron cell culture systems. Our findings support a model wherein the degron is exposed when SMN is monomeric and sequestered when SMN forms higher-order multimers.

Histidine Ammonia-Lyase is a Proteasome Interacting Protein.
F. Bardag-Gorce1, A.M. Laporte1, D. Cortez2, R. Niihara1, S. Sunada1, J. Stark1, A. Gorce1, R.H. Hoft1, J. Whitelegge1, J. Oliva1, S.W. French1, Y. Niihara1;

1Medicine, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, Torrance, CA, 2NPI-Semel Institute, Pasarow Mass Spectrometry Laboratory, University of California at Los Angeles, Los Angeles, CA

The purpose of this study was to investigate histidine ammonia-lyase (HAL) (EC 4.3.1.3) interaction with the proteasome. HAL is the histidine-degrading enzyme that catalyzes the non-oxidative deamination of histidine to urocanic acid. HAL was found in the 20S proteasome fraction highly purified from the liver using FPLC-chromatography and MALDI-TOF mass spectrometry analysis. HAL gene expression was significantly decreased when proteasomes were specifically inhibited by PS-341. The role of HAL associating with the proteasome is not known. It is possible that HAL is associated with the proteasome to regulate Zinc tolerance via high availability of histidine that chelates zinc. Zinc is present in high concentrations in the eye and plays a key role in maintaining vision. However, the excess of Zinc leads to proteasome dysfunction and aggresome formation. Methods: Cornea tissue sections from rabbit model of limbal stem cell deficiency (LSCD) were analyzed for HAL expression. Oral mucosa epithelial cells (OMEC) were isolated from a small biopsy of rabbit buccal cheek, cultured and treated with 100 uM of Zn, 100 uM of carnosine (a precursor for histidine biosynthesis) and Zn+CR. Results: Healthy corneal epithelium stained for HAL in a granular pattern. However, HAL expression was weakly detected in LSCD diseased corneal epithelium but markedly detected in the invasive blood vessels in central cornea. Results showed that a high concentration of Zinc significantly inhibited proteasome chymotryptsin-like activity when OMEC were incubated with Zinc. However, when carnosine was combined in the cell culture media with Zinc, proteasome chymotryptsin-like activity was significantly recovered. These results indicated the negative role of Zinc excess on the proteasome activity and the positive effect of carnosine supplementation in the recovery. The high level of histidine was expected to chelate Zinc—allowing the proteasome chymotryptsin-like activity to recover and to inhibit HAL as a feedback mechanism. To support this observation, OMEC were cultured and treated with L-cystein (a competitive inhibitor of HAL). Results showed no proteasome inhibition, even when Zinc was added to culture media along with L-cystein, indicating the protective effects of HAL inhibition or high availability of histidine in the presence of Zinc excess. Conclusion: The present study reports HAL interaction with the proteasome and documents the role of HAL in modulating proteasome activity, providing new insights that will help our future understanding of protein degradation in healthy and diseased corneal epithelial cells. Arkadia (RING finger protein 111) mediates sumoylation-dependent stabilization of Nrf2 through K48-linked ubiquitylation.

D. McInstosh¹, T. Walters¹, I. Arinze², J.S. Davis³;
¹Pharmacology Neuroscience, Meharry Medical College, Nashville, TN, ²Physiology, Meharry Medical College, Nashville, TN, ³Biochemistry Cancer Biology, Meharry Medical College, Nashville, TN

The transcription factor Nrf2 is a master regulator of the antioxidant defense system that serves to protect cells from oxidative damage. We previously reported that the SUMO-targeted E3 ubiquitin ligase (STUbL), RING finger protein 4 (RNF4) accelerated the degradation rate of Nrf2 in promyelocytic leukemia-nuclear body (PML-NB)-enriched fractions and decreased Nrf2-mediated gene transcription. STUbLs contain SUMO-interaction motifs that enable it to target substrate proteins that have been modified by SUMO resulting in ubiquitylation. These ubiquitylation events help in regulating eukaryotic cellular activity. In this study, we establish the second mammalian STUbL, Arkadia/RNF111 ubiquitylates polysumoylated Nrf2 to stabilize it, but has no effect on Nrf2-mediated gene transcription. Interestingly, we discovered that the Arkadia-mediated stabilization of Nrf2 occurs through Ub-K48 linkages rather than the predicted Ub-K63 linkages. These results suggest Arkadia-mediated ubiquitylation of Nrf2 protects it from degradation, thereby allowing Nrf2-dependent gene transcription. Collectively, these findings highlight a novel mechanism to positively regulate nuclear Nrf2 levels in response to oxidative stress.

A Model Substrate whose Degradation Pathway is Determined by Aggregation Propensity.

Z. Sun¹, J.L. Brodsky¹;
¹Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA

Cellular protein homeostasis is maintained by a hierarchy of protein quality control checkpoints, including endoplasmic reticulum-associated degradation (ERAD), which leads to the efficient degradation of misfolded proteins in the ER. Although most aberrant proteins in the ER are degraded by ERAD, some misfolded membrane proteins can escape ERAD and are degraded instead by lysosomal/vacuolar proteases. To date, it remains elusive how ERAD cooperates with post-ER quality control pathways to destroy misfolded membrane proteins. Here, we designed a novel model substrate, SZ, to investigate how ERAD substrate selection is regulated in yeast. We discovered that SZ is degraded by both the proteasome and vacuolar proteases, which occurs after ER exit and requires the multivesicular body (MVB) pathway. After interrogating cells with a variety of stresses, we found that both heat-shock and SZ* overexpression increase ERAD targeting. These events correlate with substrate aggregation. In addition, the aggregation of the large, cytosolic misfolded domain in SZ* is concentration-dependent, and both the cytosolic Hsp70 Ssa1 and Hsp40 Ydj1 molecular chaperones are required to maintain substrate solubility. Finally, fusion of this misfolded domain targets a post-ERQC substrate, which is normally routed to the vacuole, for ERAD. Together, we have identified a novel substrate that can be used to investigate ERAD and post-ERQC degradation pathway selection, and show that a misfolded membrane protein with a higher aggregation propensity is preferentially targeted for ERAD.

Sterol oxidation mediates stress-responsive Vms1 translocation to mitochondria.
E. Fredrickson¹, J. Rutter², C.P. Hill³, J.R. Nielson¹;
¹Biochemistry, University of Utah, SALT LAKE CITY, UT

Mitochondrial function is constantly threatened by damaging agents, including mitochondria-derived reactive oxygen species. This stochastic burden damages mitochondria, which left unchecked leads to mitochondrial dysfunction. The detrimental consequences of mitochondrial dysfunction are highlighted by its presence in many human diseases including cancer, Parkinson’s Disease, and diabetes. To prevent mitochondrial dysfunction, cells have evolved mitochondrial quality control mechanisms, which include protein degradation. A critical component in mitochondrial protein quality control degradation is the protein Vms1 (VCP/Cdc48-associated mitochondrial stress-responsive 1). Vms1 serves as an adaptor to promote the mitochondrial localization of Cdc48, the S. cerevisiae p97 homolog, and its cofactor Npl4 when cells are exposed to mitochondrial stressors such as H2O2. In the absence of the Vms1-Cdc48 complex, cells accumulate ubiquitylated mitochondrial proteins, suffer progressive mitochondrial failure, have elevated levels of mitophagy, and fail to survive under mitochondrial stress conditions. Mitochondrial targeting of Vms1 is mediated by its conserved Mitochondrial Targeting Domain (MTD), which in unstressed conditions is inhibited by intramolecular binding to the Vms1 N-terminal Leucine Rich Sequence (LRS). In the absence of the Vms1-LRS, Vms1-MTD constitutively localizes to mitochondria in the presence or absence of stress, suggesting that translocation of the full-length protein is regulated by this intramolecular interaction. Localization is also regulated by mitochondrial damage because full-length wild type Vms1 localizes specifically to damaged but not to undamaged mitochondria, indicating that damaged mitochondria are uniquely marked for Vms1 recruitment. These data prompt several questions regarding the mechanism of Cdc48-Vms1 complex recruitment to damaged mitochondria in response to stress. First, how does the Vms1-LRS inhibit localization of the Vms1-MTD to mitochondria? Second, what is the mitochondrial molecule(s) that recruits Vms1-MTD to mitochondria? Third, what is the stress signal that modifies mitochondria and/or Vms1 to promote Vms1 translocation to damaged mitochondria? We here report a 2.7Å crystal structure of Vms1 that reveals that the LRS lies in a hydrophobic groove on the autoinhibited MTD. We also demonstrate that the oxidized sterol, ergosterol peroxide, is necessary and sufficient for Vms1 localization to mitochondria, apparently by binding the MTD in an interaction that is competitive with binding to the LRS. These data support a model in which stressed mitochondria generate an oxidized sterol receptor that recruits Vms1 to support mitochondrial protein homeostasis.

Bromodomains control amyloid-like aggregation of aberrantly acetylated proteins.
H. Olzscha¹, O. Fedorov², B.M. Kessler³, S. Knapp⁴, N.B. La Thangue¹;
¹Department of Oncology, University of Oxford, Oxford, United Kingdom, ²Structural Genomic Consortium, University of Oxford, Oxford, United Kingdom, ³Nuffield Department of Medicine, University of Oxford, Oxford, United Kingdom, ⁴Institut für Pharmazeutische Chemie, Universität Frankfurt, Frankfurt, Germany

Lysine acetylation is becoming increasingly recognized as a general biological principle which underpins many different aspects of cellular homeostasis, and is subject to aberrant control in different human
pathologies. Lysine acetylation is regulated through the concerted action of acetyltransferases (HAT) and deacetylases (HDAC), where bromodomain proteins read the mark and effect the functional consequence of the acetylation event.

However, it has been unclear, how protein acetylation influences the stability of the proteome, the folding and protein homeostasis at a global level. Here, we describe amyloid-like protein aggregation in human cells that result from aberrant lysine acetylation. The protein aggregation disturbs proteostasis by causing abnormalities in the ubiquitin proteasome system (UPS), autophagy and protein translation, resulting in decreased cell viability. Bromodomain reader proteins are involved in forming the aggregates and, using a chemical biology-led approach to probe their composition, we establish p300/CBP proteins as necessary to form the aggregates. Other proteins, many involved in proteostasis, are also present in the aggregates as confirmed by quantitative mass spectrometry. Further, small molecule inhibitors of bromodomain recognition impede aggregate formation, which coincides with enhanced UPS function and increased cell viability. Significantly, amyloid-like protein aggregates formed by a pathologically relevant form of huntingtin protein, causally involved with Huntington’s disease, are similarly susceptible to intervention by bromodomain inhibition.

Our results show that the amyloid-like protein aggregates which occur upon aberrant protein hyperacetylation disturb proteostasis, cause reduced cell viability and involve bromodomain recognition. Since the aggregates are susceptible to small molecule intervention, our results have important implications for treating amyloid-like pathologies and related protein folding diseases with bromodomain inhibitors. Our results also imply that aggregate formation and disturbed proteostasis contributes to the cytotoxic effect of pan-HDAC inhibitors and may explain some of their side effects.

USP3 regulates the fate of cargo proteins that enter cells by Clathrin-independent endocytosis (CIE).

S. Niyogi1, J.L. Wayt1, J. Donaldson1, C.D. Williamson1, L. Eshun-Wilson1; 1NHLBI, National Institutes of Health, Bethesda, MD

We are interested in studying the turnover of plasma membrane proteins that enter cells by clathrin-independent endocytosis (CIE). CIE cargo proteins include the major histocompatibility complex Class I protein (MHC-I), which normally traffics either for recycling back to the PM or to lysosomes for degradation and a number of cargo proteins (CD44, CD98 and CD147) that are directly recycled to the PM and not directed to lysosomes. As a consequence, CD44, CD98 and CD147 are long-lived PM proteins. Ubiquitylation of CIE cargo proteins can target them to the lysosomes for degradation. Conversely, Ubiquitin-specific proteases/deubiquitylating enzymes (DUBs) that catalyze the removal of ubiquitin allows CIE cargo proteins to recycle back to the PM. We sought to identify DUBs that might be responsible for the longer half-life of CD44, CD98 and CD147. We performed an siRNA screen using the library of human DUBs to identify DUBs in HeLa cells responsible for this longevity such that loss of these DUBs would result in downregulation of surface CD44, CD98 and CD147. We found that depletion of either USP3 or TRE17/USP6 resulted in reduced surface levels of CD44, CD98 and CD147. USP3 or TRE17 knockdown shifted the trafficking of the above proteins away from recycling tubules to lysosomal compartments, resulting in reduced surface levels. But the extent of traffic of MHC-I to the lysosomes remained unchanged in cells depleted of USP3. The specificity of the siRNA experiment was validated by the rescue of the siRNA effect by expression of an siRNA-resistant form of USP3. Expression of wild type USP3 alone in Hela cells did not change the route followed by the cargo s. Interestingly, a cysteine-to-serine substitution at 168 of the USP3 gene that inactivates the
deubiquitination activity of USP3 shifted the fate of CD98 to degradative compartments, similarly to that observed in cells depleted of USP3. Thus USP3(C168S) acts as a dominant negative and might provide a way to identify USP3 cargo and/or regulators. Our lab has shown previously (Eyster et al, 2011) that expression of an E3 ubiquitin ligase MARCH8 promotes trafficking of CIE cargo proteins to lysosomes by ubiquitylating the proteins. Here, we show that over-expression of USP3 counteracts the MARCH8 dependent targeting of CD98 to the lysosomal compartment. This study demonstrates that cycles of ubiquitylation and deubiquitylation can determine whether CIE cargo proteins are degraded or recycled.

Linking ISG15 to Cellular Stress Responses: Lessons from Listeria infection.
L. Radoshevich1,2, M. Foecke1, F. Impens3, K. Knobeloch4, P. Cossart1;
1Bacteria Cell Interactions, Institut Pasteur, Paris, France, 2Microbiology, University of Iowa, Iowa City, IA, 3Proteomics Expertise Center, VIB, University of Ghent, Ghent, Belgium, 4Institute of Neuropathology, University Clinic Freiburg, Freiburg, Germany

ISG15 is an interferon-stimulated, ubiquitin-like protein, with anti-viral activity, however its role during bacterial infection had not been addressed. We previously found that ISG15 restricts Listeria monocytogenes infection both in vitro and in vivo and identified ISGylated proteins that could be responsible for the protective effect. Strikingly, infection or overexpression of ISG15 leads to ISGylation of ER and Golgi proteins, which correlates with increased secretion of cytokines known to counteract infection. More recently, we endeavored to map the in vivo ISGylome following Listeria infection to mechanistically understand the function of this pathway in host defense. To do so we combined a genetic approach employing a murine model of hyper-ISGylation with quantitative proteomics of immunoenriched endogenous ISG15 modification sites. In addition, our approach mapped the endogenous ubiquitylome following infection with Listeria in vivo including the identification of several modified bacterial proteins. Interestingly, we detected ISG15 sites in a number of ER and Golgi proteins, which we had previously shown to be ISG15 targets in vitro, as well as proteins known to control cellular stress responses such as ER stress and autophagy. Taken together, this work will open the door to understanding mechanisms of action of an understudied ubiquitin-like protein.

Structural and kinetic analysis of protein degradation by the 26S proteasome.
Y. Lu1;
1Systems Biology, Harvard Medical School, Boston, MA

Controlling the levels of key proteins is achieved through both synthesis and degradation, and failure of this control is implicated in a wide range of human diseases. The ubiquitin-proteasome system(UPS) is central in the regulated protein degradation, playing a key role in most cellular functions, such as cell-cycle progression and protein homeostasis. The supreme regulatory potency of the protein degradation machinery depends on its high specificity for substrates and the ability to efficiently unfold and degrade its targets, which is bestowed by the exquisite structures of the 26S proteasome holoenzyme. Specificity of ubiquitin-mediated protein degradation was thought to be simply determined by the ~600 E3 enzymes in human. However, statistical analysis on published datasets shows insignificant correlation between the steady-state ubiquitylation levels and protein stability in all comparison. We still do not understand the underlying rules by which the proteasome recognizes ubiquitin configurations during the
process of substrate engagement and degradation. Complicating this problem is that many targets of the UPS, including most substrates of the Anaphase-Promoting Complex (APC), carry multiple ubiquitylated lysine residues and therefore possess complex ubiquitin configurations. To understand these rules, we developed single-molecule fluorescent assays with enough precision to distinguish different reaction intermediates, to analyze the kinetics of the degradation of well-characterized APC substrates with defined ubiquitin configurations. Contrary to a prevailing view maintaining that a tetra-ubiquitin chain is the minimal signal for efficient proteasomal degradation, we find that, for all tested substrates, multiple di-ubiquitin chains having the same overall level of ubiquitylation as tetra-ubiquitin chains are more efficient degradation signals. A high-throughput study using proteasome trap further supports this conclusion on a wide range of substrates. Most substrates require ubiquitin chains for proteasomal degradation. We find that the chain structure of ubiquitin on substrates specifically promotes initiation of translocation through the axial channel of the proteasome, while the strength of substrate binding to the proteasome is mainly determined by the total number, but not the chain structure of ubiquitins on a substrate. To understand the molecular mechanism underlying the processive protein degradation, we resolved multiple structures of the human 26S proteasome to near-atomic resolutions using cryo-electron microscopy. Comparative analysis suggests exquisite structural transitions, coupled to the states of nucleotide binding and hydrolysis, in an allosteric network featuring long-rang interactions. Current structural and kinetic s

The ubiquitin-proteasome system regulates degradation of an anti-inflammatory receptor SIGIRR.
L. Li¹, J. WEI¹, S. Li¹, J. Zhao¹, Y. Zhao¹;
¹Department of Medicine and the Acute Lung Injury Center of Excellence, University of Pittsburgh School of Medicine, Pittsburgh, PA

Single Ig IL-1-related receptor (SIGIRR), a receptor for anti-inflammatory cytokine IL-37, negatively regulates inflammatory responses through inhibition of ILR and TLR signaling. However, the role of SIGIRR in lung inflammatory diseases has not been well studied and molecular regulation of SIGIRR stability remains unclear. In this study, we aimed to investigate the regulation of SIGIRR stability in the ubiquitin-dependent system. Consistent with other studies, overexpression of SIGIRR in mouse macrophages attenuated LPS-induced phosphorylation of JNK and Erk, suggesting that SIGIRR plays an anti-inflammatory effect. Intratracheal injection of lipopolysaccharide (LPS) for 24 h or P. aeruginosa (strain PA103) for 4 h significantly reduced SIGIRR protein levels in murine lungs. In mouse lung epithelial cells, SIGIRR degradation was prevented with a proteasome inhibitor MG-132 in a time-dependent manner, while it enhanced by ubiquitin expression. Further, we found that SIGIRR was ubiquitinated by K48-linked polyubiquitin chains on the lysine 163 residue of SIGIRR. SIGIRR lysine 163 mutant (SIGIRRK163R) exhibited an extended half-life compared to SIGIRR wild type. Our data suggest that SIGIRR degradation is mediated by the ubiquitin-proteasome system and is critical for pulmonary inflammation. In the future study, identification of the ubiquitin E3 ligases and deubiquitinating enzymes, which are responsible for regulation of SIGIRR stability, might provide potential therapeutic targets for treating pulmonary inflammatory diseases.

Histone acetyltransferase CBP increases activation of SCF FBXL19 ubiquitin E3 ligase by acetylation and stabilization of FBXL19.
J. WEI1, S. Dong2, R. Bowser1, A. Jacko1, K. Yao1, Y. Zhao1, J. Zhao1;
1Medicine, University of Pittsburgh, Pittsburgh, PA, 2Anesthesia, First Hospital of Jilin University, Changchun, China

Ubiquitin E3 ligases mediate ubiquitination and degradation of intracellular proteins. We have shown that a relatively new SCF (skp, cullin, f-box) E3 ligase subunit, FBXL19, targets cell membrane receptor and small GTPases for their ubiquitination and degradation, while regulation of its stability remains unclear. Here we show that the stability of FBXL19, is mediated by a balance of its ubiquitination and acetylation. FBXL19 is an unstable protein with a half-life around 2.8 h. FBXL19 is polyubiquitinated and a proteasome inhibitor MG132 prolongs FBXL19 stability, suggesting that FBXL19 degradation is mediated by the ubiquitin-proteasome system. Our study reveal that FBXL19 also can be acetylated and enhancing acetylation of FBXL19 by a histone deacetylase inhibitor TSA reduces ubiquitination of FBXL19. Acetylation-mimic FBXL19 mutant exhibits prolonged half-life. Further, we show that an acetyltransferase CBP mediates FBXL19 acetylation. Inhibition of CBP reduces FBXL19 stability, while it is increased in CBP-overexpressed cells. The data indicates that CBP-mediated acetylation reduces ubiquitination and stabilizes FBXL19. Furthermore, ectopically expressed FBXL19 reduces small GTPase Cdc42 protein levels, while the effect is reversed by inhibition of CBP, suggesting that CBP increases activation of SCF-FBXL19 E3 ligase through stabilization of FBXL19. Our study reveals a new molecular model for regulation of SCF E3 ligase activation by acetylation and stabilization of F-box protein.

Accelerated Senescence following DNA Damage upon Loss of a BRCA1 Associated Protein Brap is Mediated through Histone Ubiquitination and Destruction.
Y. Guo1, A.A. Lanctot1, Y. Feng1,2;
1Neurology, Northwestern University School of Medicine, Chicago, IL, 2Biochemistry and Molecular Biology, Uniformed Services University, Bethesda, MD

One of the many outcomes of persistent DNA damage is cellular senescence, a condition that irreversibly arrests the cell cycle and leads to extensive chromatin alteration. While senescence can act as a barrier to carcinogenesis, it also elicits senescence-associated secretory phenotype (SASP) with increased expression of cytokines and proteases that cause inflammation and tissue degeneration. Proper control of cellular senescence would thus protect against cancer and aging associated diseases. However, the mechanism that links DNA damage to senescence remains poorly understood. Here we show that abrogating a BRCA1 associated protein BRAP/Brap can specifically direct cells with DNA damage to senescence. Fibroblasts and neural stem cells isolated from Brap knockout mice showed high levels of DNA damage and rapid growth arrest in culture without increasing apoptosis. In addition to increased SA-b-gal and SASP, Brap deficient cells underwent senescence with massive loss of nuclear contents including core histones and lamin B1. Consistent with our previous finding of Brap’s role as a ubiquitin E3 ligase that acts downstream of Ras-Erk signaling and targets Skp2 to maintain the G1/S CKIs, DNA damage in Brap deficient cells activated p53-p19 (ARF) but did not elevate p21. Furthermore, we found that Brap knockout mice showed significantly increased Brca1 and ubiquitinated histone H2A, a substrate for the Brca1 ubiquitin E3 ligase. The high level of mono- and poly-ubiquitination of H2A in
Brap mutants led to its proteasomal degradation and was correlated with significantly increased autophagy, leading to the loss of not only core histones but also lamin B1 and mitochondrial proteins. These findings suggest that upregulating histone H2A ubiquitination by increased BRCA1 activity in Brap deficient cells can serve as a specific mechanism for tumor suppression through directing cells with unreparable DNA damage to senescence. However, the inflammatory and neurodegenerative phenotype shown by Brap mutant brain also suggest that DNA damage and abnormal histone proteolysis underlie accelerated tissue aging.

E2 and E3 Ubiquitin Ligases in the ERAD Pathway Regulate Neural Receptors in C. elegans.
A. Townsend1, S. Witus2, R. Ulrich3, M. Leytze4, L.L. Dahlberg3;
1Molecular and Cellular Biology, Montana State University, Bozeman, MT, 2Biochemistry, University of Washington, Seattle, WA, 3Biology, Western Washington University, Bellingham, WA

Endoplasmic Reticulum-Associated Degradation (ERAD) is a ubiquitin-dependent process that maintains cellular homeostasis by targeting and removing misfolded proteins from the endoplasmic reticulum (ER). In C. elegans, we have identified homologs for two human ERAD E2 enzymes UBE2J1 and UBE2G2 (ubc-6 and ubc-7 in C. elegans) and three human ERAD E3 ubiquitin ligases HRD-1, GP78/AMFR, and MARCH-6 (hrd-1, hrdl-1, and marc-6 in C. elegans). The genes encoding the E3 ligases have been reported to cooperate in maintaining the overall health of C. elegans during ER stress (Sasagawa, et al., 2012), but the E2 ligases have not been previously described.

We find that two neural proteins, GLR-1 and ODR-10, are regulated by the putative ERAD E2 and E3 ligases. GLR-1 is a tetrameric glutamate receptor and ion channel that is expressed in a subset of interneurons; ODR-10 is a G-protein coupled receptor (GPCR) that is activated by the odorant molecule diacetyl and is expressed in a single pair of olfactory neurons (AWA cells). Compared to wild type controls, the abundance and localization of GLR-1::GFP and ODR-10::GFP change in C. elegans that harbor mutations in the genes encoding ERAD ligases. GLR-1- and ODR-10-dependent behaviors are also impaired in mutant animals. Mutating the three E3 ligases results in phenotypes of different severities, which suggests that those enzymes do not play redundant roles in substrate recognition and targeting in C. elegans. Similarly, mutation of the E2 proteins does not result in identical phenotypes, in correlation with recent work showing that UBC6 and UBC7 in yeast play unique roles in target recognition and ubiquitylation. Our results suggest that distinct cell types and substrates may be differentially regulated by specific ERAD pathways in C. elegans. Future work will focus on defining how the E3 and E2 pathways may differ in diverse neural cell types, and on exploring under what conditions ERAD mechanisms are required for normal neural protein regulation.

KBTBD11, a novel BTB-Kelch protein, is a negative regulator of osteoclastogenesis through controlling Cullin3-mediated ubiquitination.
S. Narahara¹, E. Sakai¹, T. Kadowaki², Y. Yamaguchi¹, H. Narahara¹, K. Okamoto³, Y. Sumita⁴, I. Asahina⁵, T. Tsukuba¹;
¹Department of Dental Pharmacology, Nagasaki University, nagasaki, Japan, ²Department of Frontier Life Science, Nagasaki University, nagasaki, Japan, ³Department of Dental Pharmacology, Okayama University, okayama, Japan, ⁴Basic and Translational Research Center for Hard Tissue Disease, Nagasaki University, nagasaki, Japan, ⁵Department of Regenerative Oral Surgery, Nagasaki University, nagasaki, Japan

Osteoclasts are bone-resorbing giant cells that formed by the fusion of mononuclear monocyte/macrophage progenitor cells. Although osteoclast differentiation is regulated by various factors, the detailed mechanisms remain to elucidated. To investigate genes involved in the osteoclast differentiation, our research group has recently performed DNA microarray analysis of osteoclast differentiation showing that 1,363 were upregulated genes, and 881 were downregulated. Among the upregulated genes, we identified a novel gene, which is possibly implicated in an E3 ubiquitin ligase-mediated event, termed as Kelch repeat and BTB domain containing protein (KBTBD11). Despite the presence of KBTBD11 genes in mammalian genomes, there is no research reports about KBTBD11 at present. In this study, we investigated the role of KBTBD11 in osteoclastogenesis using mouse macrophage-like RAW-D cells by the method of gene knockdown using small interfering RNAs (siRNA) or gene overexpression systems. We found that expression of KBTBD11 increased during osteoclastogenesis. When we performed siRNA-mediated knockdown experiments, KBTBD11 knockdown enhanced osteoclast differentiation than control cells. Upon determining the expression levels of osteoclast marker genes using quantitative RT-PCR analysis, the expression levels of NFATc1, Src, cathepsin K, osteoclast stimulatory transmembrane protein (OC-Stamp), transmembrane 7 superfamily member 4 (DC-STAMP), cathepsin K, and matrix metalloproteinase 9 (MMP9) were all significantly higher in KBTBD11-knockdown osteoclasts than in control cells. On the contrary, KBTBD11 overexpression inhibited osteoclast differentiation. Also, the expression levels of the osteoclast differentiation marker genes in KBTBD11-overexpressing osteoclasts were all decreased compared with control cells. Concerning six major signaling pathways for osteoclast differentiation such as, nuclear factor of activated T cells cytoplasmic-1 (NFATc1), p38 mitogen-activated protein kinase (MAPK), extracellular signal-regulated kinase (ERK), Jun N-terminal kinase (JNK), phosphatidylinositol 3-kinase (PI3K)/Akt, and nuclear factor kappa B (NF-κB), western blot analysis revealed that KBTBD11 predominantly influenced NFATc1 signaling. Moreover, to determine whether KBTBD11 interacts with the E3 ubiquitin ligase Cullin3, immunoprecipitation experiments were performed. Consequently, we found that KBTBD11 specifically interacts with Cullin3. These results indicate that KBTBD11 negatively modulates osteoclast differentiation by interacting with Cullin3. It is likely that the KBTBD11-Cullin3 complex probably mediates ubiquitination of important factors for osteoclast differentiation through the proteasomal-dependent pathway.

Cullin-3 is required for normal skeletal muscle development.

J. Blondelle1, K. Tallapaka2, P. Shapiro1, M. Ghassemian2, J.D. Singer3, S. Lange3;
1Department of Cardiology, University of California, San Diego, La Jolla, CA, 2Biomolecular and Proteomics Mass Spectrometry Facility, University of California, San Diego, La jolla, CA, 3Department of Biology, Portland State University, Portland, OR

E3-ubiquitin ligases are protein complexes that are essential for the recognition and the degradation of specific substrates by the ubiquitin-proteasome pathway. Cullin-RING ligases represent the largest E3-ubiquitin ligase family in mammals. The Cullins constitute the backbone of the E3-ubiquitin ligase complex, and interact with specific substrate adaptors that are necessary for the recruitment of their individual substrates for degradation. While Cullin-RING ligase roles were intensively studied in the context of cancer, very little is known about their functions in muscle biology. Recently, several genes of the BTB-domain family (KBTBD13, KLHL40 and KLHL41) were found mutated in severe and early onset forms of Nemaline Myopathy (NM). Due to their BTB-domains, these proteins are thought to be substrate adaptors for Cullin-3. These findings argue in favor of important and yet uncharacterized roles for Cullin-3 mediated protein turnover for muscle development, maintenance and function.

We have shown the absolute necessity of Cullin E3-ligase activity for the induction of myogenesis, and revealed that treatment of myoblasts with MLN4924, an inhibitor of Cullin-RING ligase activity used in clinical trials for cancer therapy, has a dramatic effect on myoblast differentiation and muscle formation.

Using conditional knockout mice for Cullin-3 in skeletal muscles, we demonstrate the pivotal role of this protein for postnatal life. Indeed, our data reveal that absence of Cullin-3 leads to respiratory defects at birth, associated with a strong skeletal muscle atrophy and neuromuscular junction disorganization, mimicking severe cases of NM. Large-scale proteome analysis of embryonic skeletal muscles that lack Cullin-3 revealed an accumulation of several proteins, presumably representing novel substrates of this E3-ligase. Our results suggest that Cullin-3 mediated protein turnover is required for proper early skeletal muscle development. Future experiments will decipher the molecular mechanisms contributing to the severe myopathy observed in these animals.

The effects of YopJ on respiratory growth due to downregulation of a mitochondria ubiquitin protease in S.cerevisiae.

A.M. Benben1, Y. Wang1;
1Biology, Saint Louis University, St. Louis, MO

YopJ is a virulence factor secreted from Yersinia that inhibits host immune responses and induces apoptosis. Learning more about how YopJ affects eukaryotic cells is crucial to understand how the Black Plague caused one of the worst pandemics in human history. The objective of our study was to examine if YopJ affected ubiquitin proteases in yeast cells. To examine this, we compared the expression of various ubiquitin proteases in both wild type cells and YopJ-expressing cells. We found that a mitochondria-associated ubiquitin protease had decreased level of expression in YopJ cells. To follow-up this result, we tested whether YopJ affected respiratory growth in yeast cells. Specifically, we compared the growth of cells with or without YopJ in the media, which use lactate as the sole carbon source. We found that the growth of YopJ-expressing cells on the lactate plate was significantly diminished when comparing it to wild type cells. Together, our results suggest that the ubiquitin protease that was
diminished in YopJ cells had a significant effect on respiratory growth in the cells and this enzyme may be a new target of YopJ.

Proteasome activity and protein oxidation levels in the skeletal muscles of cultivated rainbow trout.

L. Lysenko¹, N. Kantserova ¹, E. Tushina²;
¹Lab. of Environmental Biochemistry, Institute of Biology, KarRC RAS, Petrozavodsk, Russia, ²Dept of Molecular, Biological Chemistry and Biotechnology, Petrozavodsk State University, Petrozavodsk, Russia

Proteasomes, calpains, and lysosomal cathepsins are the main proteolytic pathways in any eukaryotic cell. In fish, calpain-dependent reactions dominate in the hydrolysis of myofibrillar proteins while a contribution of ubiquitin-proteasome system (UPS) to total protein degradation recognized to be minor. However, UPS is a main path of protein quality control machinery utilizing abnormal proteins including oxidatively damaged ones. Oxidative damage of biomolecules, particularly oxidative post-translational modifications of proteins, affects cell signaling, behavior, and survival. Rainbow trout, Salmo gairdneri, is a typically cold-water species highly susceptible to hypoxia and environmentally-induced oxidative stress followed by high lethality and fish growth depression under rearing conditions. Antioxidant supplementation to fish diet presumably would stimulate fish growth and resistance to stress-inducing factors. In our study we used dihydroquercetin, a polyphenolic flavonoid compound produced from larch raw materials. Dihydroquercetin (Taxifolin, diquertin) widely exploring in medicine, cosmetology and veterinary practice (but not in fish farming yet) behaves as powerful antioxidant and free radical scavenger. To describe oxidative stress manifestation and a possible effect of dihydroquercetin on cultivated rainbow trout growth and viability we have compared (1) a control group of fish fed by a commercial diet and (2) an experimental group fed by commercial diet mixed with dihydroquercetin (50 mg per kg) up to three months. Protein reactive carbonyl products concentration as a marker of oxidative damage and cellular stress in fish has been measured using 2,4-dinitrophenylhydrazine-based assay. Chymotrypsin-like proteasome activity has been assayed in order to evaluate possible correlation between proteasome proteolytic capacity and protein carbonyl content as well as to prove an idea on ubiquitin-proteasome pathway contribution to oxidized protein pool utilization. In the control group, an increase in the protein carbonyl concentration in the muscles associated with proteasome activation has been noted. In the presence of dihydroquercetin, partial decrease in protein oxidation without stimulation of proteasome system has been detected. Significant effect of dihydroquercetin on protein oxidation has developed since a month of experimental diet consumption while decreased proteasome activity has been detected in antioxidant-fed group throughout the experiment. Besides, fish fed by the antioxidant has been characterized by substantial increase in individual growth rate. This work was supported by the Russian Science Foundation, project no. 17-74-20098.

Hyperphosphorylation repurposes the CRL4B E3 ligase to coordinate mitotic progression.

S. Gilberto¹, F. Lampert¹, W. Piwko¹, M. Peter¹;
¹Department of Biology, ETH Zurich, Zurich, Switzerland

Ubiquitylation depends on an enzyme cascade that allows transfer of ubiquitin to a target protein by an E3 ligase. The E3 ligase family Cullin-RING ligases (CRLs) include Cullin-4A (CUL4A) and CUL4B which
together regulate multiple cellular events, in particular chromatin-associated processes such as chromatin remodeling and DNA repair. However, CUL4B mutations result in syndromic X-linked intellectual disability (XLID), never reported for CUL4A, which denotes a non-overlapping function. Through cell cycle analysis in HeLa cells, we discovered that CUL4B is important for mitotic entry. CUL4B is subject to mitotic phosphorylation in its unique N-terminal sequence, mediated by CDK1, PLK1 and possibly other kinases and consequently no longer localizes to the chromatin. Interestingly, proliferation assays and live-cell imaging experiments revealed that the overexpression of the phosphomimetic CUL4B mutant is lethal in HeLa cells due to aberrant metaphase progression and mitotic exit, with a subset of cells failing cytokinesis. While further phenotypic and mechanistic characterization is under investigation, our data suggests that CUL4B phosphorylation repurposes this E3 ligase for a non-chromatin function that is both important for the early mitotic stages and must be abolished by mitotic exit. Our study establishes a clear regulatory distinction between CUL4B and CUL4A, with functional implications, which may aid in clarifying why CUL4A cannot compensate for CUL4B loss in human XLID patients.

Post-translational modification of proteins by ubiquitin (Ub) is a versatile process, highly dynamic, and involved in nearly all aspects of biological functions in eukaryotes. Dysregulation of ubiquitylation has been implicated in plethora of pathological conditions such as developmental abnormalities, neurodegenerative diseases, and cancers. Ub is attached, via isopeptide bonds, to lysine residues in the target protein or to another Ub to form poly-Ub chains. The reversibility, heterogeneity, and diversity of these modifications combined with the lack of suitable tools have made it difficult to properly isolate and characterize poly-ubiquitylated cellular proteins. However, in 2009, a novel technology called TUBEs (Tandem-repeated Ub-Binding Entities) was developed. TUBEs have revolutionized the Ub field by allowing poly-ubiquitylated proteins to be enriched/purified from cellular extracts. Development of TUBEs that selectively bind K48-, K63-, and M1-linked poly-ubiquitylated proteins has helped understand the role of modified proteins in cell physiology. However, the roles of other Ub-linkages remain obscured mainly due to the lack of tools that specifically recognize them. To overcome this, we recently developed a novel microarray platform that facilitates the identification of unique Ub binding domains (UBDs) for rare Ub-linkages. This array contains GST-tagged versions of 140 known and predicted UBDs from over 8 different Ub interacting families. Our initial screen with mono-Ub as well as K48-linked diUb revealed several unique binders. For example, Ub-binding motif (UBM) of REV1L bound uniquely to mono-Ub. On the other hand, Ub-associated (UBA)-like domain of NSFL1C bound preferably to K48-linked diUb. Moreover, UBA domains of RAD23A and RAD23B interacted uniquely with K48-linked diUb, which is concordant with the published data. We also identified several proteins that non-selectively bind mono-Ub and K48-linked diUb, such as the UBA domain of NBR1. The complete array results obtained for mono-Ub and K48-linked diUb will be presented in the poster. We are currently working on to screen the array against other Ub-linkages and we will present data in the poster. To conclude, the array allowed us to identify unique binding partners for mono-Ub and K48-linked diUb, and we strongly believe that our future screens with other Ub-linkages will identify several selective binding partners for rare Ub-linkages. Domains that display selective binding specificity will be utilized to construct linkage-specific TUBEs. The expansion of the TUBE toolkit to include recombinant proteins that can discriminate
between each of the Ub linkages would dramatically accelerate the pace of discovery in this important area of biology.

OTUB1 regulation of E2 ubiquitin conjugating enzyme levels in vivo.
M.E. Morrow¹, N. Pasupala³, A. Ma², C. Wolberger¹;
¹Biophysics and Biophysical Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD,
²Medicine, University of California San Francisco, San Francisco, CA

Ubiquitin signaling plays an essential role in nearly all aspects of biology. Substrate ubiquitination is tightly regulated temporally and in response to different stimuli through the opposing actions of E2/E3 enzymes, which attach mono and polyubiquitin to substrate proteins, and by deubiquitinating enzymes (DUBs), which remove ubiquitin modifications from proteins and cleave polyubiquitin chains. Imbalanced ubiquitin signaling lies at the heart of many cancers and genetic disorders. OTUB1 is an OTU-class DUB that cleaves K48-linked polyubiquitin chains and is one of the most abundant DUBs in human cells. In addition to this deubiquitinating activity, OTUB1 also inhibits the activity of a subset of E2 ubiquitin conjugating enzymes by binding to the charged E2~Ub thioester intermediate and inhibiting ubiquitin transfer both in vitro and in vivo. When the E2 partners of OTUB1 are not charged with ubiquitin, the E2 enzymes stimulate K48 polyubiquitin cleavage by OTUB1 in vitro, although the physiological significance of this is unknown. In order to study the effects of OTUB1-E2 pairs in cells, we searched for potential OTUB1 substrates in OTUB1 knockout MEF cells using tandem mass tag proteomics. Surprisingly, we saw lower protein levels for some E2 conjugating enzymes when OTUB1 was knocked out, specifically isoforms of the Ube2E family, UbcH10, Ube2S, and UbcHSC. We confirmed this result by Western blotting in the OTUB1 knockout MEFs as well as in U2OS cells with a CRISPR knockout or siRNA knockdown. OTUB1 does not affect E2 expression levels by any transcriptional mechanism because RT-PCR results show similar mRNA levels for these E2s in the siRNA knockdown and CRISPR knockout cells. We followed protein levels for Ube2E isoforms in a cycloheximide chase experiment and found that OTUB1 may be affecting the stability of Ube2E isoforms. We are currently exploring whether this is due to OTUB1’s catalytic activity, or through non-catalytic inhibition of Ube2E isoforms. Interestingly, the Ube2E isoform that is most rapidly turned over in cycloheximide chase experiments follows a cell cycle-dependent expression pattern in thymidine release time course experiments as well as by immunofluorescence. We see that OTUB1 knockout causes a delay of entry into mitosis in synchronized HeLa cells both by Western blotting for cyclin B and by live cell imaging. We discuss these findings in light of the known interaction of OTUB1 with E2 enzymes in vivo.

ATG5 deletion results in organelle dysfunction and confers enhanced cytotoxicity following the induction of autophagy.
N.J. Dolman¹, K.M. Chambers¹, S. VanLe¹, S. Leonard¹, B. Samson¹, M.S. Janes¹;
¹Biosciences, Thermo Fisher Scientific, Pittsburgh, PA

The advent of CRISPR-cas9 has revolutionized the ease with which precise manipulations, either insertions or deletions, can be made within a cell’s genome. These approaches are already creating
disease models as well as controls for various pathways and processes. We used one such process, autophagy, and created the gold standard ATG5 knock-out model for autophagy using CRISPR-CAS9. Following deletion, we confirmed successful editing at the protein level through western blot analysis of ATG5 expression levels. Furthermore, we used cell-based assays to show that the ATG5 knock-out cells were deficient in macroautophagy, confirming that no redundant or response mechanism was able to compensate for ATG5 loss. Given the importance of macroautophagy to cellular homeostasis, we sought to understand the dynamic effects of ameliorating this pathway by performing extensive phenotypic profiling in this model using automated, high-throughput imaging. Using cell-based, phenotypic assays, we show that ATG5 knock-out cells display enhanced susceptibility to cytotoxic stressors involved in mTOR signaling and the unfolded protein response. However, general cytotoxic stressors or those that target mitochondrial function or the ubiquitin-proteasome pathway were no more cytotoxic to ATG5 knock-out cells than to wild type cells. We also show perturbation to organelle structure and function, notably mitochondria and lysosomes, following ATG5 knock-out. The above observations are not a function of perturbed general cellular function as analysis of other cellular processes such as proliferation, protein synthesis, reactive oxygen species production, and endocytosis showed no difference between wild type and ATG5 knock-out cells. We present the use of cell-based phenotypic assays as a to probe down-stream effects of gene knockouts using CRISPR-cas9.

Autophagosomal closure is mediated by the ESCRT machinery.

K. Morita¹, I. Koyama-Honda¹, Y. Yamashita², T. Ueno², E. Morita³, H. Mano², N. Mizushima¹;
¹Dept. of Mol. Biol., Grad. Sch. of Med., Univ. of Tokyo, Tokyo, Japan, ²Dept. of Cell. Signal., Grad. Sch. of Med., Univ. of Tokyo, Tokyo, Japan, ³Dept. of Biochem. and Mol. Biol., Fac. of Agric. and Life Sci., Hirosaki Univ., Hirosaki, Japan

Autophagy is an intracellular degradation process that delivers cytoplasmic contents to the lysosome. During the autophagic process, a single-membraned sac termed the isolation membrane elongates, bend, and engulfs a part of the cytoplasm. Finally, the edge of the isolation membrane is closed to form a double-membraned structure, the autophagosome. The autophagosome fuses with lysosomes to degrade its contents. Although many molecules such as ATG proteins are involved in this process, the molecular mechanism of the closure of the autophagosomal edge remains to be elucidated.

In this study, in order to identify novel autophagy-related factors, a genome-wide screen was performed using the CRISPR-Cas9 system and the novel autophagic flux probe GFP-LC3-RFP. As a result, in addition to many conventional ATGs, VPS37A was identified as one of the positive regulators of autophagy. VPS37A is a member of the ESCRT (endosomal sorting complex required for transport) machinery, which is involved in membrane scission processes such as the formation of multivesicular bodies, viral budding, and cytokinesis. Because the autophagosomal closure is also a scission process, we hypothesized that it is mediated by the ESCRT machinery. Our protease protection assays suggested that autophagosomes are not closed when VPS37A as well as other ESCRT proteins were depleted. The endocytosis and lysosomal function may be partially affected but almost normal in VPS37A knockout cells. Furthermore, live-cell imaging showed that ESCRT proteins were recruited to the edge of autophagosomes immediately before spherical change, which is likely the timing of the closure of the autophagosome. In conclusion, we have identified VPS37A as a novel autophagy-related factor by a non-biased forward genetic screen. Our further analysis suggests that the autophagosomal edge is closed by the ESCRT-mediated membrane fission.

Autophagy controls steroid hormone synthesis and developmental timing by regulating cholesterol trafficking in Drosophila melanogaster.
X. Pan1,2, M.B. O'Connor2;
1Molecular, Cellular, Developmental Biology Genetics Program, University of Minnesota, Twin Cities, Minneapolis, MN, 2Department of Genetics, Cell Biology Development, University of Minnesota, Twin Cities, Minneapolis, MN

Autophagy is a common cellular response to nutrient deficiency in a wide spectrum of cell and tissue types. Previous studies show that autophagy occurs in various endocrine organs, but no straight evidence demonstrating the function of autophagy in steroid hormone producing cells has been provided so far. In development of fruit fly Drosophila melanogaster, the timing of metamorphosis is directly controlled by steroid hormone ecdysone (E) which is predominantly produced in larva endocrine organ prothoracic gland (PG). It is well known that both E synthesis in PG and metamorphic timing of animals are finely coordinated with nutritional condition during larva stage, so in this study we try to uncover the potential role that autophagy performs in the PG cells. Firstly, we monitor autophagy in PG under fed and starvation conditions. Autophagy is significantly induced by starvation treatment during early 3rd larva instar (L3) stage, which correlates with the time window that starvation arrests larval development before metamorphosis. Suppression of autophagy results in elevated E level and precocious onset of metamorphosis during starvation, while forced induction of autophagy causes decreased E content and developmental delay/arrest under well fed condition. These results demonstrate that autophagy suppresses E synthesis in PG and consequently blocks metamorphosis. We then study the mechanism on how autophagy attenuates E production and surprisingly find that autophagy regulates cholesterol metabolism in PG cells. In an ex vivo incubation assay we observe that the autophagosomes in PG interact with cholesterol containing lipid droplets. In vivo autophagy induction results in decreased number of lipid droplet, while cholesterol feeding rescues the autophagy induced developmental defects. When testing the interaction between autophagy and endolysosomal pathway, we find that the autophagosomes overlap with Rab7-positive but not LAMP-positive vesicles, suggesting a non-canonical autophagic flux. Further, using live imaging approach we see dynamic formation and mobilization of tubule-like structures marked by Atg8, which to our knowledge is also rarely observed in previous studies. In all, our findings uncover a novel type of autophagic process that controls cholesterol trafficking and hormone synthesis in Drosophila PG cells, which may also represent a common function that autophagy exerts in steroid hormone producing cells.

The Autophagy Conjugation Machinery Specifies The Loading of RNA-Binding Proteins Into Extracellular Microvesicles.  
A.M. Leidal¹, H.H. Huang², T. Solvik¹, J. Ye¹, T. Marsh¹, F. Kai³, J. Goldsmith¹, J.Y. Liu¹, A.P. Wiita², J. Debnath¹;  
¹Pathology, University of California, San Francisco, San Francisco, CA, ²Laboratory Medicine, University of California, San Francisco, San Francisco, CA, ³Surgery, University of California, San Francisco, San Francisco, CA

Autophagy is an autodegrative pathway in which cytoplasmic material is sequestered into double-membrane vesicles and delivered to the lysosome for breakdown. Predominantly viewed as a catabolic mechanism, we are beginning to appreciate that the autophagy pathway also promotes unconventional secretion of proteins lacking N-terminal signal sequences. However, the underlying mechanisms and full repertoire of proteins released via autophagy-dependent secretion remains unknown. To further address the role of autophagy in secretion, we developed a novel strategy using proximity-specific biotinylation to label proteins that engage the autophagy regulator MAP1LC3B (LC3), and subsequently, are secreted outside of the cell. Quantitative proteomic analysis of the LC3-labelled secretome revealed a highly interconnected network enriched in RNA-binding proteins (RBPs) and the cargoes of extracellular microvesicles (EMVs, exosomes). Indicating that specific proteins are loaded into EMVs via secretory autophagy. Focusing on a number of RBP candidates for further mechanistic study, including heterogeneous nuclear ribonucleoprotein K (HNRNPK) and scaffold-attachment factor B (SAFB), we demonstrate these proteins biochemically interact with LC3 and are secreted within EMVs highly enriched with lipidated LC3 (LC3-II). Secretion of LC3-II and LC3-binding RBPs requires essential components of the autophagy conjugation machinery and neutral sphingomyelinase 2 (nSMase2)-mediated ceramide production. Collectively, our data demonstrates a new role for the autophagy pathway in specifying RBPs that are packaged into EMVs and highlights a novel mechanism by which autophagy controls the secretion of RBPs and RNAs outside of the cell.

Stress-Induced Cdk5 Activity Enhances Cytoprotective Basal Autophagy by Phosphorylating Acinus at Serine⁴³⁷.  
H. Kramer¹, N. Nandi¹, L.K. Tyra¹;  
¹Neuroscience, UT Southwestern, Dallas, TX

In the defense against the long-term consequences of accumulating protein aggregates and dysfunctional organelles, neurons rely on basal autophagy. Little is known, however, how the levels of basal, starvation-independent autophagy are adjusted to the specific challenges that neurons face. Here, we explore the role of the Cdk5 kinase in that process. Cdk5, a member of the family of cycling-dependent kinases, has important functions in the post-mitotic maintenance of neuronal health. Cdk5 dysregulation has been linked to multiple neurological diseases, but the various mechanisms by which Cdk5 inhibits and promotes neurodegeneration are still poorly understood. We show that Cdk5 regulates basal autophagy, a key mechanism suppressing neurodegeneration. In a targeted screen in Drosophila, Cdk5 genetically interacted with Acinus (Acn), a primarily nuclear protein, which promotes starvation-independent, basal autophagy. Loss of Cdk5, or its required cofactor p35, reduces S437-Acn phosphorylation, whereas Cdk5 gain-of-function increases pS437-Acn levels. The phospho-mimetic
S437D mutation stabilizes Acn and promotes basal autophagy. In p35 mutant flies, basal autophagy and lifespan are reduced, but restored to near wild-type levels in the presence of activated Acn\textsuperscript{S437D}. Expression of aggregation-prone polyQ-containing proteins or the Amyloid-beta 42 peptide, but not alpha-Synuclein, enhance Cdk5-dependent phosphorylation of S437-Acn. Our data indicate that Cdk5 is required to maintain and adjust the protective role of basal autophagy in the initial responses to a subset of neurodegenerative challenges.

RXR-PPAR-delta agonist therapy achieves neuroprotection by autophagic induction.
M. Arreola-Villanueva\textsuperscript{1}, A.S. Dickey\textsuperscript{1}, A.R. La Spada\textsuperscript{1};
\textsuperscript{1}Pediatrics, University of California, San Diego, La Jolla, CA

Formation of aggregates, a common feature of neurodegenerative disorders, is indicative of insufficient protection provided by the protein quality control system. Improvement of protein quality control has therefore become a strategy to developing therapeutics to ameliorate pathological symptoms and impede neurodegeneration. Recently, our group tested the neuroprotective potential of the Peroxisome-Proliferator-Activated-Receptor-delta (PPARd) agonist KD3010. Preclinical trials of KD3010 resulted in rescue of behavioral symptoms, metabolic deficits, and mitochondrial abnormalities in an aggressive Huntington’s Disease (HD) mouse model with a truncated N-terminal huntingtin (htt) fragment containing a 82 CAG repeat (N171-82Q). Neuropathology indicated reduction of polyQ-expanded htt aggregates in striatal medium spiny neurons, suggesting a role for PPARd in proteostasis. To directly evaluate the effect of PPARd activation on intracellular waste management, we assayed autophagy flux in Neuro2a cells subjected to PPARd shRNA knock-down or PPARd agonist activation, and noted a significant reduction in autophagy flux upon PPARd knock-down, and a significant increase in autophagy flux with PPARd agonist activation. PPARd transcriptional activity is dependent on dimerization with the Retinoic X Receptor (RXR). A preclinical trial of bexarotene in the N171-82Q model gave rise to similar results to those seen with KD3010. Here we evaluated the potential for bexarotene, an FDA approved agonist of RXR, to promote PPARd-RXR dimerization and subsequent activation of autophagy. The ability of bexarotene to induce expression of PPARd target genes was confirmed by qRT-PCR. Repeating the autophagy flux experiments, we found that bexarotene increased autophagy flux similar to that seen with PPARd-specific activation. Spautin-1 inhibition of (macro)autophagy significantly blunted this effect as did ATG7 knockdown, while treatment with lactacystin, a Ubiquitin Proteasome Pathway inhibitor, did not. To determine if PPAR required TFEB to activate autophagy, we measured autophagy flux in HeLa cells lacking TFEB. We detected an increase in autophagy flux upon PPARd agonist treatment in TFEB KO cells comparable to the autophagy flux increase in WT cells, indicating little role for TFEB in PPARd-mediated autophagy activation. Finally, to determine if bexarotene amelioration of mutant htt protein aggregation requires PPARd, we quantified htt-Q104 aggregation in Neuro2a cells treated with bexarotene +/- a PPARd inhibitor. Indeed, PPARd inhibition abrogated bexarotene amelioration of htt protein aggregation. These findings indicate that PPARd activation achieves neuroprotection at least in part by improving proteostasis through autophagy induction.

The Unfolded Protein Response Maintains Lipid Homeostasis by Selective Autophagy during Lipid Perturbation-Induced ER Stress.

J. Koh1, L. Wang2, C. Beaudoin-Chabot1, G. Thibault1;2;1School of Biological Sciences, Nanyang Technological University, Singapore, Singapore; 2Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore

Metabolic disorders such as obesity and nonalcoholic fatty liver disease (NAFLD) are emerging disorders that affect the global population. One facet of the disorders is attributed to the disturbance of membrane lipid homeostasis. Perturbation of endoplasmic reticulum (ER) homeostasis through changes in membrane phospholipid composition results in activation of the unfolded protein response (UPR) and causes dramatic translational and transcriptional changes in cell. To restore cellular homeostasis, the three highly conserved UPR transducers ATF6, IRE1, and PERK mediate cellular processes upon ER stress. The roles of the UPR in proteostatic stress caused by the accumulation of misfolded protein is well understood but lipid perturbation-induced UPR remains elusive. We found that genetically attenuated PC synthesis in C. elegans causes lipid droplets accumulation if not for the intervention of the UPR program. Transcriptional profiling of lipid perturbation-induced ER stress animals shows a unique subset of genes modulated in an UPR-dependent manner that are unaffected by proteostatic stress. Among these, we identified IRE1-modulated autophagy genes that trigger liberation of free fatty acids from excess lipid droplets suggesting a stress release mechanism by which free fatty acids are rechanneling to restore lipid homeostasis. Considering the important role of lipid homeostasis and how its impairment contributes to the pathologies in metabolic diseases, our data uncovers the indispensable role of a fully functional UPR program in regulating lipid homeostasis in the face of chronic ER stress.

Ribosome profiling reveals that autophagy impacts DNA damage repair, cell cycle progression and centrosome maintenance through protein translation regulation.

J. Goldsmith1, S. Asthana2, T. Marsh3, D. Suresh1, A. Olshen2, J. Debnath1; 1Pathology, University of California, San Francisco, San Francisco, CA; 2Department of Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA

Autophagy is a cellular recycling system that degrades large proteins and organelles by delivery to the lysosome. Protein translation is tightly tuned to the metabolic state of the cell by sensing lysosomal amino acid levels and signaling through mTORC1. During metabolic stress, protein translation is abrogated while autophagy is concurrently induced. Accordingly, autophagy is proposed as a principal regulator of the protein translational landscape, especially during starvation, yet to date evidence supporting this hypothesis is lacking. Here, we utilize ribosome profiling to dissect how the autophagy pathway impacts translation, both at baseline and in response to starvation. Although the prevailing viewpoint is that the recycling functions associated with autophagy sustain de novo protein translation, we discovered that in both nutrient replete conditions and in nutrient starvation, global translation rates as well as intracellular levels of most amino acids were intact in autophagy deficient cells. Instead, we observed that specific proteins were translated in an autophagy dependent manner. To identify these products of autophagy-dependent translation, we employed ribosome profiling in autophagy competent vs. deficient fibroblasts, achieved via genetic deletion of the key autophagy regulator ATG12, in both fed and starved conditions. Using biochemical approaches, we
validated that autophagy controls the translation of multiple targets. Most strikingly, we found that basal autophagy is important for the translation of a group of targets involved in centrosome clustering, DNA repair and cell cycle control, including BRCA2, both in vitro and in vivo. While increased DNA damage in autophagy deficient cells has been largely attributed to an increase in defective mitochondria and production of reactive oxygen species, our results reveal translational control as another critical pathway through which autophagy regulates DNA damage levels. We are working to identify how autophagy controls this program of protein translation, hypothesizing that it acts through targeted degradation or sequestration of key RNA binding proteins. The increase in baseline DNA damage and decreased BRCA2 levels means that the autophagy impaired cells have increased sensitivity to various cytotoxic reagents, including PARP inhibitors. These data broach the hypothesis that tumors with high rates of chromosome instability may rely more heavily on autophagy-dependent translation of proteins. Overall, these results expand the functions of autophagy beyond its traditional role as an intracellular degradation pathway, and reveal new roles for autophagy an anabolic pathway that instructs that translation of specific proteins in cell cycle control.

Herbal medicine for resolution of cancers.
Y. Liu
Department of Medical Research; Graduate Institute of Integrated Medicine, China Medical University, Taichung, Taiwan

Cancers such as hepatocellular carcinoma and pancreatic cancer remain the leading cause of mortality with limited therapeutic targets. Herbal medicines have been considered for treating or preventing cancers but require systemic scientific evidence. We conduct in exploration of traditional Chinese herbal medicines, as an attempt to discover new candidates and mechanisms of phytomedicines for treating or preventing cancers. Several in vitro and in vivo gene- and cell-based assays, comparative transcriptional analyses, as well as hepatocellular carcinoma and pancreatic cancer xenografts are employed to validate the pharmacological effects and the underlying mechanisms for the identified bioactive phytomedicines. In addition, how phytomedicines modulate proteostasis to achieve their preventive or therapeutic effects against cancer cell growth are investigated. Furthermore, we identify the molecule targets of bioactive compounds i.e. gallic acid, a secondary metabolite present in most plants, by chemical synthesis in combined with proteomics analyses. Nevertheless, we also investigate phytomedicines, alone or in combination, in sensitizing the chemotherapeutic drugs efficacy in tumor-bearing mice, as a means to evaluate the potential of using natural phytomedicines or compounds in complementary medicine in cancers.

Filamin and Valosin Containing Protein (VCP) interaction in Inclusion Body Myositis.
1Johns Hopkins University School of Medicine, Baltimore, MD, 2National Institute of Arthritis Musculoskeletal Skin Diseases, National Institutes of Health, Bethesda, MD, 3National Human Genome Research Institute, National Institutes of Health, Bethesda, MD, 4National Institute of Environmental Health Sciences, National Institutes of Health, Bethesda, MD, 5Neurological Disorders and Stroke, National Institutes of Health, Bethesda, MD, 6Washington University School of Medicine, St. Louis, MO

Sporadic Inclusion Body Myositis (IBM) is the most common acquired myopathy in individuals over the age of 50, and is characterized by slowly progressive weakness in both proximal and distal muscles. One pressing question in the field is whether IBM is primarily an autoimmune disease or a degenerative disease with secondary inflammation. The association with aging, lack of response to immunotherapy, and presence of pathological features seen in neurodegenerative disease (e.g. protein aggregation) suggest that degeneration may drive disease progression. Furthermore, mutations in valosin-containing protein (VCP) cause inclusion body myopathy with Paget’s disease and frontotemporal dementia (IBMPFD), and recent evidence suggests that VCP variants may cause or be risk factors for developing IBM. However, there is an increased association of IBM with specific HLA haplotypes and other autoimmune diseases. Thus, the relationship between inflammation and protein aggregation in IBM is poorly understood. Recently, we performed whole exome sequencing on a large family with several members that meet diagnostic criteria for sporadic IBM (i.e. autoimmune invasion of CD8+ T cells and typical clinical features). In addition to identifying a known pathogenic VCP variant (R159C), we found a novel variant in the Filamin C (FLNC) gene (F2616S) that cosegregates with disease. Since FLNC mutations are associated with myofibrillar myopathy, we hypothesize that digenic inheritance of VCP and FLNC mutations causes IBM in this family.
To determine whether Filamin C may play a role in IBM pathogenesis, we first investigated FLNC localization in IBM muscle tissue and find that filamin C is mislocalized to large aggregates within human IBM muscle fibers. We next looked for a genetic interaction between FLNC and VCP using a previously characterized Drosophila IBMPFD model (Ritson et al, J Neurosci 2010). Indeed, RNAi-mediated knockdown of Drosophila filamin (cheerio) suppresses muscle degeneration and impaired climbing performance of IBMPFD flies. These data suggest that FLNC may play a role in IBM pathogenesis, potentially through a recently described role in autophagy.

Compartment-specific regulation of neuronal autophagy during homeostasis and stress.
A. Dong1, A. Kulkarni1, V. Kulkarni1, J. Chen1, S. Maday1;
1Neuroscience, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Autophagy is an essential degradative pathway that maintains neuronal homeostasis and prevents axon degeneration, but neuron-specific mechanisms are poorly understood. Here, we use live-cell imaging in mouse hippocampal neurons to establish the compartment-specific mechanisms of autophagy under basal conditions, and during stress induced by nutrient deprivation. We find that at steady state, axonal autophagy is a vectorial process that delivers cargo from the distal axon to the soma. The soma, however, contains multiple populations of autophagosomes at different maturation states, including
input received from the axon combined with locally generated autophagosomes. Once in the soma, autophagosomes are confined within the somatodendritic domain, which likely facilitates cargo degradation by promoting fusion with proteolytically-active lysosomes that are enriched in this region. Surprisingly, canonical autophagy inducers such as starvation or mTOR-inhibition that robustly activate autophagy in other cell types (e.g. hepatocytes and HeLa cells), do not markedly upregulate autophagy in neurons, in either the axonal or somatodendritic compartments. Interestingly, we find that autophagy in glial cells is regulated differently as compared with neurons, suggesting alternative mechanisms of coordinating autophagy in the brain. Together, these observations suggest that the primary physiological function of autophagy in neurons, unlike in other cell types, may not be to mobilize amino acids and other biosynthetic building blocks in response to nutrient deprivation. Rather, constitutive autophagy in neurons may function to maintain cellular homeostasis and regulate the quality of the neuronal proteome by balancing synthesis and degradation, especially within distal axonal processes far removed from the soma.

Regulations during the process of the embryonic development have always been appealing. Since the discovery of cancer stem cells, which are particularly involved in cancer development and recurrence, embryonic stem cells and regulatory mechanisms as well as cancer cells and cancer stem cell control mechanisms have become fundamental research. Aging and aging-related diseases also constitute a major part of today's health problems. Studies that centers on aging related to mTOR and autophagy are available and current research topic in the literature. Autophagy is one of the main mechanisms in eukaryotic cells, for the removal of damaged organelles, macromolecules and the recycling of aminoacids, and with aging, autophagic degradation also reduces resulting with accumulation of damage. In recent years, there have been many studies on how the inhibition of especially mTORC1 is associated with aging. mTORC1 inhibition has both positive and negative effects on age-related diseases. At the same time, it is believed that the reduction of stem cell functions has a role in the pathology of aging and age-related diseases. There is evidence that mTORC1 inhibition can protect stem cell function in many tissues, and even restore this decreased function. Understanding the similarities and differences between somatic cells and cancer cells, which are prospective forms of embryonic stem cells divisions and determinations, led to the rise of medicinal and pharmaceutical sciences. For this purpose, mouse embryonic stem cells (mESC), mouse skin fibroblast cells (MSF) and mouse lung squamous cancer cells (SqLCC) were grown in vitro. We examined autophagy and mTOR related gene expressions; compared them between each groups and support the results with immunofluorescence staining. The study found that mTOR and autophagic regulators are particularly active in embryonic stem cells and generally silent in somatic cells and showing variety in cancer cells. Cellular stabilization mechanisms and damage removal pathways were particularly active in mESCs. Optimum intracellular balance may be in cooperation with protection of embryonic development and preservation of stem cell function. These
results suggest that the normal functioning of the mechanisms of embryonic stem cell regulation results in the formation of somatic tissues whereas that these cells may be the causative agents of cancer as a result of any deterioration.

Systematic analysis of human cells lacking ATG8 proteins uncovers roles for GABARAPs and the CC21/MON1 regulator C18orf8/RMC1 in macro and selective autophagic flux.
L. Pontano Vaites¹, J.A. Paulo¹, E.L. Huttlin², J.W. Harper¹;
¹Department of Cell Biology, Harvard Medical School, Boston, MA

Selective and macro autophagy sequester specific organelles/substrates or bulk cytoplasm, respectively, inside autophagosomes as cargo for delivery to lysosomes. The mammalian ATG8 orthologues (MAP1LC3A/B/C and GABARAP/L1/L2) are ubiquitin (UB)-like proteins conjugated to the autophagosome membrane and are thought to facilitate cargo receptor recruitment, vesicle maturation, and lysosomal fusion. To elucidate the molecular functions of the ATG8 proteins, we engineered cells lacking genes for each subfamily as well as all six mammalian ATG8s. Loss of GABARAPs alone attenuates autophagic flux basally and in response to macro or selective autophagic stimuli including PARKIN-dependent mitophagy, and cells lacking all ATG8 proteins accumulate cytoplasmic UB aggregates, which are resolved following ectopic expression of individual GABARAPs. Autophagosomes from cells lacking GABARAPs exhibit reduced lysosomal content by quantitative proteomics, consistent with fusion defects, but also accumulate regulators of late endosome (LE)/autophagosome maturation. Through interaction proteomics of proteins accumulating in GABARAP/L1/L2-deficient cells, we identified C18orf8/RMC1 as a new subunit of the CC21-MON1 RAB7 guanine exchange factor (GEF) that positively regulates RAB7 recruitment to LE/autophagosomes. This work defines unique roles for GABARAP and LC3 subfamilies in macro and selective autophagy and demonstrates how analysis of autophagic machinery in the absence of flux can identify new regulatory circuits.

Microtubule-Associated Protein 1 Light Chain 3B (LC3B) is Necessary to Maintain Lipid Homeostasis in the Retinal Pigment Epithelium.
A. Dhingra¹, J. Reyes-Reeves¹, D. Alexander¹, R. Sharp¹, A. Swarup², K. Boesze-Battaglia¹;
¹Biochemistry, University of Pennsylvania,, Philadelphia, PA, ²Department of Pathology, Anatomy and Cell Biology,, Thomas Jefferson University, Philadelphia, PA

Objective: Microtubule-associated protein 1 light chain 3 (LC3) is an essential component of selective autophagy including LC3-associated phagocytosis (LAP), a hybrid degradation pathway utilizing components of canonical autophagy and phagocytosis. These autophagy associated processes play an important role in homeostasis of phagocytic cells such as retinal pigment epithelium (RPE) cell that are tasked with a daily burden of degrading lipid rich outer segments from the photoreceptors. LC3 exists as three isoforms in human (LC3A, B, and C), with two of these (LC3A and B) in mouse. Here, we tested the hypothesis that LC3B plays a key role in maintaining lipid homeostasis in the RPE. Methods: LC3BKO and wild-type mice ranging from 2 month to >2 years were used. LC3 isoform expression was analyzed by RT-PCR and immunoblotting. Biopotenig Spectral Domain Optical Coherence Tomography at 840nm was used to image retina. 4-hydroxynonenal (HNE) lipid oxidation adducts were evaluated by ELISA and immunofluorescence. Fixed frozen retinal sections were stained for neutral lipids with Bodipy 493/503,
or immunostained for various antibodies followed by confocal imaging. Lipid turnover as reflected in, β-Hydroxybutyrate (β-HB) released from mouse RPE explants was measured using LiquiColor reagent kit (StanBio). Results: Quantitative RT-PCR experiments showed similar levels of LC3A and LC3B transcripts in the WT mouse RPE. In the LC3B KO, there was no detectable LC3B transcript and the level of LC3A transcript was similar to that in the WT suggesting lack of potential compensatory upregulation in the absence of LC3B. There was an elevation in phagosome numbers for up to 11 h after light onset in the LC3BKO RPE as compared to the a sharp peak within one hour of light onset followed by a decline in the WT. The lipid turn-over, as inferred from mitochondrial ketogenesis was also altered: RPE explants from WT animals show a peak of β-HB at 2 hours after light onset, whereas in LC3BKO, this peak was delayed by 4 hours relative to the WT. Consistent with this, there appeared to be an increase in neutral lipid staining and a decrease in free fatty acids. In addition, there was an accumulation of lipid peroxidation products (HNE-adducts) in the LC3BKO, accompanied by an increase in Iba1 immuno-reactive cells in the sub-retinal space in the LC3B KO mice. The LCBKO RPE also appeared hypertrophic with multinucleated cells in several areas especially in the older mice. Conclusions: Our study provides evidence for a critical role played by LC3B in lipid homeostasis, as lack of LC3B causes defective phagocytosis, leading to metabolic imbalance, lipid deposition, pro-inflammatory microenvironment, and RPE hypertrophy.

Dhh1 regulates autophagy protein expression under long time starvation.
Z. Yao1, X. Liu1, M. Jin1, D. Klionsky1;
1Life Science Institute, University of Michigan, Ann Arbor, MI

Autophagy is an important degradation system that is required for cellular homeostasis in eukaryotes. Fine regulation of autophagy on both transcriptional and translational level is essential to maintain proper autophagy level in cells. Using yeast as a model system, we investigate the role of Dhh1, a cytoplasmic helicase, in the translational control of autophagy proteins (Atg proteins) under long-time starvation. In contrast to function as a post-transcriptional repressor in the early autophagy, Dhh1 serves as a positive regulator in long time starvation. Several Atg proteins showed decreased protein level in the dhh1 mutant under long-time starvation while the mRNA levels remain similar to wild type. As a result, Autophagy level is decreased in the dhh1 mutant during long time starvation. More evidence indicates Dhh1 regulates autophagy via interaction with the translational machinery. Our study reveals a novel role of Dhh1 in regulating autophagy, providing details of translational control of autophagy.

Regulation of autophagy through post-translational modifications.
Y. Feng1,2, D. Klionsky1,2;
1MCDB, University of Michigan Ann Arbor, Ann Arbor, MI, 2Life Sciences Institute, University of Michigan Ann Arbor, Ann Arbor, MI

Macroautophagy/autophagy is primarily a self-eating process that recycles cytosolic components such as misfolded or aggregated proteins and dysfunctional organelles for homeostasis and survival in unfavorable conditions. This highly conserved and constitutive pathway has to be tightly regulated; either too much or too little autophagy can be detrimental. Dysregulation of this pathway is related to various diseases that include neurodegeneration, cancer and infection, as well as aging-related disorders. Autophagy is stringently regulated at different levels: Transcriptionally, post-transcriptionally,
translationally and post-translationally. A thorough understanding of the mechanisms involved is crucial to allow the manipulation of autophagy for the treatment of diseases. Although 41 autophagy-related (ATG) genes have been identified, we have a limited understanding of the complex network of regulatory factors that control this process. Post-translational modifications (PTMs) represent a subset of regulatory mechanisms that are critical for modulating autophagy in order to adapt to different types of environmental stress. Recent studies have reported a function of the CUL3-KLHL20 ubiquitin ligase in feedback regulation, leading to the downregulation of autophagy through the degradation of the ULK1 and PIK3C3/VPS34 complexes. Based on a large-scale analysis predicting that yeast Atg9 is ubiquitinated, we studied the regulation of Atg9 through PTM. Atg9 is the only transmembrane protein in the core autophagy machinery, which is absolutely required for autophagosome biogenesis and autophagy activity. Unlike other Atg proteins, Atg9 has a distinctive feature with regard to its subcellular localization: This protein travels between peripheral sites and the phagophore assembly site (PAS) where the autophagosome is formed, presumably delivering membranes from different donors to the PAS for autophagosome biogenesis. In this study, we show that Atg9 is ubiquitinated and targeted for degradation in a proteasome-dependent manner during nutrient-rich conditions, therefore limiting autophagy to a basal level. However, when cells are nutritionally deprived, autophagy is highly induced, necessitating an increase in the amount of Atg9. During these conditions, we show that the proteasome-dependent reduction of Atg9 protein levels is reduced. Thus, the post-translational ubiquitination of Atg9 provides an additional mechanism that allows cells to maintain appropriate levels of autophagy, and to rapidly respond and adapt to environmental stresses.

**Natural genetic variation modifies polyglutamine aggregation via an imbalance in autophagy.**

J.J. Alexander-Floyd¹, A. Entezari¹, M. Ying², S. Haroon², T. Gidalevitz³;

¹Biological Sciences, Drexel University, Philadelphia, PA, ²Department of Pathology and Laboratory Medicine, Children’s Hospital of Philadelphia, Philadelphia, PA

Many late-onset neurodegenerative diseases, such as Huntington’s disease (HD), are caused by aggregation of misfolded proteins. Individuals stricken with these diseases succumb to the detrimental symptoms associated with them. Discovering the cellular and genetic pathways that are protective against protein aggregation will improve our understanding of potential treatments for these diseases. Huntington’s disease (HD) is associated with aggregation of mutant huntingtin protein, containing an expanded polyglutamine tract. In HD patients, individual’s genetic backgrounds can modulate the severity of the disease. However, the variants responsible for modulating disease phenotypes are not known. To ask what natural variant(s) play a role in modifying protein aggregation, we use a *Caenorhabditis elegans* polyglutamine model expressing a fluorescent 40-glutamine expansion (Q40-YFP) in muscle cells. We have shown that introduction of Q40-YFP into genetically diverse wild strains of *C. elegans* results in a wide range of phenotypes, from suppression to strong enhancement of Q40-YFP aggregation and toxicity. Here, we have identified a 400kb genetic interval derived from one of the wild strains (DR1350) that contains variants that increase polyglutamine aggregation. A RNAi survey of 24 candidate genes in that interval identified *atg-5*, an important component necessary for the proper formation of autophagic vesicles (autophagosomes) during autophagy. When *atg-5* is knocked down we observed a 33% decrease in polyglutamine aggregation. Interestingly, genome sequencing identified 2 variants within the 3’UTR of *atg-5* in the DR1350-derived interval. Animals carrying this interval have increased ATG-5 expression and deficient autophagosome formation. Because autophagy is important for degradation of protein aggregates, we hypothesize that natural variants in the DR1350 genetic
of background increase polyglutamine aggregation by causing increased levels of ATG-5 expression and thus misregulating autophagosome formation.

Decoupling global biases and local interactions between cell biological variables.
A. Zaritsky\textsuperscript{1,2,3}, U. Obolski\textsuperscript{4}, Z. Gan\textsuperscript{2,3}, C.R. Reis\textsuperscript{3}, Y. Du\textsuperscript{3}, S.L. Schmid\textsuperscript{3}, G. Danuser\textsuperscript{2,3};\textsuperscript{1}\textsuperscript{1}Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, \textsuperscript{2}Bioinformatics, UT Southwestern Medical Center, Dallas, TX, \textsuperscript{3}Cell Biology, UT Southwestern Medical Center, Dallas, TX, \textsuperscript{4}Department of Zoology, University of Oxford, Oxford, United Kingdom

Analysis of coupled variables is a core concept of cell biological inference, with co-localization of two molecules as a proxy for protein interaction being a ubiquitous example. However, external effectors may influence the observed co-localization independently from the local interaction of two proteins. Such global bias, although biologically meaningful, is often neglected when interpreting co-localization. Here, we describe DeBias, a computational method to quantify and decouple global bias from local interactions between variables by modeling the observed co-localization as the cumulative contribution of a global and a local component. We showcase five applications of DeBias in different areas of cell biology, and demonstrate that the global bias encapsulates fundamental mechanistic insight into cellular behavior. The DeBias software package is freely accessible online via a web-server at https://debias.biohpc.swmed.edu.

Inferring cell state by quantitative motility analysis reveals a dynamic state system and broken detailed balance.
J.C. Kimmel\textsuperscript{1}, A.Y. Chang\textsuperscript{1}, A.S. Brack\textsuperscript{2}, W.F. Marshall\textsuperscript{1};\textsuperscript{1}Biochemistry and Biophysics, Univeristy of California San Francisco, San Francisco, CA, \textsuperscript{2}Orthapedic Surgery, Univeristy of California San Francisco, San Francisco, CA

Cell populations display heterogeneous phenotypic states at multiple scales. Similar to molecular features commonly used to explore cell heterogeneity, cell behavior is a rich phenotypic space that may allow for identification of relevant cell states. Inference of cell state from cell behavior across a time course may enable the investigation of dynamics of transitions between heterogeneous cell states, a task difficult to perform with destructive molecular observations. Cell motility is one such easily observed cell behavior with known biomedical relevance. To investigate cell heterogeneity through the lens of cell behavior, we developed Heteromotility, a software tool to extract quantitative motility features from timelapse cell images. In mouse embryonic fibroblasts (MEFs), myoblasts, and muscle stem cells (MuSCs), Heteromotility analysis identifies multiple motility phenotypes within the population. In all three systems, the motility state identity of individual cells is dynamic. Quantification of state transitions reveals that MuSCs undergoing activation transition through progressive motility states toward the myoblast phenotype. By probability flux analysis, we find that this MuSC motility state system breaks detailed balance, while the MEF and myoblast systems do not. Our data indicate that the system regulating cell behavior can be decomposed into a set of attractor states which depend on the identity of the cell, together with a set of transitions between states governed by inputs from signaling.

Sunday-442
pathways such as oncogenes and growth factors. Within one state, equilibrium formalisms can capture variation in behavior, while switching between states violates equilibrium conditions and would require an external driving force. These results support a conceptual view of the cell as a non-deterministic state automaton, responding to inputs from signaling pathways and generating outputs in the form of observable motile behaviors.

Identification of gene expression variability with phenotypic consequences using Luria-Delbrück-seq.

S.M. Shaffer¹, B. Emert¹, R. Gupta¹, A. Raj¹;

¹Bioengineering, University of Pennsylvania, Philadelphia, PA

Single cell gene expression measurements have shown that individual cells can have highly variable levels of mRNA for many genes. In cancer, even a single cell expanded in a culture dish can show tremendous plasticity such that the resulting population of cells will drastically different gene expression patterns at the single cell level. It is also known that individual cancer cells can exhibit different phenotypes, such as proliferation rates and drug sensitivities, and these phenotypes are thought to underlie important transformations in cancer including drug resistance and metastasis. However, making the direct connection between gene expression variability and phenotypes at the single cell level has been huge challenge in this field. Specifically, it largely unknown how to separate meaningful biological variability from “noise” in gene expression.

We hypothesized that variable genes associated with different behaviors at the single cell level would show memory of gene expression across cellular division, as genes with this behavior would be part of a coherent “cell state”. Thus, we developed an unbiased method for quantifying single cell gene expression memory by using the design of Luria and Delbrück’s “fluctuation analysis” and combining it with RNA sequencing. Specifically, we isolated individual cells, allowed them to expand, and then performed RNA sequencing on each of the single-cell derived cultures. For genes with uniform expression in every cell, all the samples should have similar RNA sequencing counts; however, for genes that occasionally turn on in a subset of cells, the RNA sequencing counts across all cultures should show high variability. By looking at the coefficient of variation for each gene across all of the samples, we have a metric for the heritability of each gene.

We applied this method to two melanoma cell lines and one triple negative breast cancer cell line, and identified sets of hundreds of genes in each cell line with transcriptional memory. We next used single molecule RNA FISH and time-lapse imaging to directly demonstrate that the genes with transcriptional memory are indeed expressed in related cells. In melanoma, we identified a gene expression program present in a rare subpopulation of cells and found that these cells are more resistant to targeted therapy. Similarly, in breast cancer, we identified subpopulation of cells expressing a different transcriptional program that confers resistance to chemotherapy. Taken together, Luria-Delbruck-seq is a method for quantification of genome-wide transcriptional memory which can enable de novo identification of functionally important rare subpopulations with differential sensitivities to therapy.

Monte Carlo simulations of *Listeria monocytogenes* cell-cell spread predict a stratified spreading behavior crucial for survival in the intestinal epithelium.
F.E. Ortega\(^1\), E.F. Koslover\(^2\), J.A. Theriot\(^{1,3,4}\);
\(^1\)Biochemistry, Stanford School of Medicine, Stanford, CA, \(^2\)Physics, University of California San Diego, San Diego, CA, \(^3\)Microbiology and Immunology, Stanford School of Medicine, Stanford, CA, \(^4\)Howard Hughes Medical Institute, Stanford, CA

Bacterial pathogens use diverse mechanisms to colonize their hosts. After invading an intestinal epithelial cell during an oral infection, the pathogenic bacterium *Listeria monocytogenes* can spread to neighboring cells without exposing itself to the bactericidal extracellular milieu. This mechanism, known as cell-cell spread, enables *L. monocytogenes* to breach epithelial and endothelial barriers, and to reach distant organs such as the liver, placenta, and brain. To learn about the dynamics of *L. monocytogenes* cell-cell spread, we established a live microscopy system which allowed us to track fluorescent intracellular *L. monocytogenes* as they spread through polarized epithelial monolayers. Qualitatively, we observed that the dynamics of *L. monocytogenes* cell-cell spread resembled those of a random walk. To test whether a random walk alone could explain bacterial movement during cell-cell spread, we performed a Monte Carlo simulation in which these movements were modeled based on the Normal distribution. Surprisingly, we discovered that the observed speed of spread in our experimental data was higher than that predicted by our simulated data, suggesting that we cannot use a random walk alone to model *L. monocytogenes* cell-cell spread. However, Monte Carlo data generated by simulating stratified spread, a form of spread characterized by stochastic dispersal events over longer distances, agreed well with our experimental data. Importantly, further simulation demonstrated that stratified spread increases the probability that *L. monocytogenes* will mount a successful infection of the epithelium, which depends on the bacterium’s ability to spread and replicate efficiently without killing the host cell.

Semi-automatic Segmentation and Frequency Mapping of Murine Hair Cells in Multi-Channel Light Microscopy Images.
T. Lancon\(^1\), N. Paz\(^2\), B. Holmes\(^2\);
\(^1\)Materials Structural Analysis, Thermo Fisher Scientific, Waltham, TX, \(^2\)Decibel Therapeutics, Boston, MA

A place-frequency map correlates the location along the cochlea to the frequencies interpreted by inner and outer hair cells (IHC, OHC) at that location. This map can be generated from microscopy images showing the organ of Corti. Current solutions for creating the place-frequency map depend on researchers manually tracing a line through the basal membrane in a microscopy image. Here we propose a workflow to automate this manual tracing step in Amira 6.4 (Thermo Fisher Scientific, Waltham, MA, USA) and thus accelerate the throughput of images. **The ultimate goal of this on-going research is to achieve semi-automatic segmentation of the basilar membrane, IHC, and OHC to correlate hair cell characteristics to given frequencies of the murine cochlear map.**

The whole volume of each cochlea is imaged in 2-8 sections using multi-channel fluorescent microscopy. Each section implies a piece of the basal membrane, so that the traced line must continue through all sections as one continuous object from the most basal to the most apical location.

Sunday-444
Membrane binarization begins with a difference of boxes filter and Otsu thresholding to extract highly-expressed areas in a single channel. The entire section’s structure is masked using morphological operations. The binarized structures surrounding the implied membrane are grown together using a watershed algorithm, creating a map of “boundaries” expressing potential membrane space. This membrane space is masked by the whole section’s volume and filtered by measurements (volume, surface area, etc.) to exclude all structures except the true membrane. A line is then extracted and smoothed from the binary voxel map to define the frequency map.

IHCs and OHCs are segmented from appropriately-stained channels using Otsu criteria and morphologically cleaned before being separated using watershed. False positives are removed from potential cell candidates using thresholded maximum intensity projections from each channel as a mask. The centroid from each unique cell is then correlated to the closest point along the extracted frequency line. Qualitative evaluation of the frequency line segmentation routine shows agreeable results in test images. Relevant IHC and OHC are shown to be successfully thresholded and individually labelled. Determination of the points describing the frequency line throughout the cochlea allows successful correlation to the centroid of each segmented cell which, in turn, allows correlation of any measurement calculated for any cell to a given frequency according to the species-specific place-frequency function. Future work includes testing processing routines against ground truth segmentation and improving the morphological cleaning to allow more robust detection of the frequency line.

Dealing with SNP’s - a Hurdle in Renin and ACE Inhibition.
R. Razi1, M. Ahmed1;
1Microbiology and Molecular Genetics, University of the Punjab, Lahore, Pakistan

Hypertension refers to the consistent and chronic blood pressure elevations which result in a pathological state of the body. Blood pressure remains less than 120/80 mmHg under normal conditions. However, in hypertension it rises up to 140/90 mmHg or even above. According to WHO, around 18% of Pakistani population suffering from hypertension which tragically is not considered as a problem by majority of the public. Many genes have been found to play their role in regulation of the blood pressure and hence, mutation in any of them may directly or indirectly result in hypertension. Nonetheless, certain genes are considered more significant than the others and the two targets (Renin and Angiotensin-Converting Enzyme (ACE)) selected in this study were among such critical blood pressure regulators. Amino acid sequences and the 3D structures of selected proteins were retrieved from PDB database. Three dimensionastructural structures of active ingredients present in 05 FDA approved drugs (targeting renin and ACE) and 40 phytochemicals (source plants used in herbal medicines) were retrieved from commonly used ligand databases. Efficiency of ligands was determined in term of docking scores and binding energies. Mutated forms of renin were generated focusing the SNP’s influencing the amino acid residues of their target sites. Molecular docking among normal targets and mutated forms of renin with respective ligands including antihypertensive phytochemicals and synthetic drugs was performed. Substantial binding affinity was found among the phytochemicals and the selected targets even stronger than that of their respective in use synthetic drugs. Chinese isoliensinnine was found to be more than 10% effective against renin; whereas, tannin was more than 40% effective against ACE, as compared to their respective drugs. Furthermore, the tested FDA approved drugs showed significantly less (~20%) binding energy with mutated proteins as compared to selected phytochemicals. Theobromine and Allicin showed ~20% higher binding scores as compared to respective drugs in all ten mutated proteins. Some compounds were found better to be used in case of certain
SNPs. Hence, genetic data should be considered while treating hypertension, moreover, plants can also be considered as a cheaper source of cure.

**Rational design of anti-diabetic agent.**
T. Redij\(^1\), R. Chaudhari\(^2\), Z. Li\(^3\), Z. Li\(^{1,2}\);
\(^1\)Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA, \(^2\)Chemistry and Biochemistry, University of the Sciences in Philadelphia, Philadelphia, PA, \(^3\)Pharmaceutical Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

Glucagon Like Peptide-1 Receptor (GLP-1R) is the major drug target in the treatment of Type II Diabetes (T2D). The failure of injectable insulin or Glucagon Like Peptide -1 (GLP-1) mimetic to cure T2D is believed to underlie the high incidences of T2D worldwide. Moreover, the discovery of small molecule drugs remains a challenge due to the nature of the orthosteric binding site in GLP-1R. Therefore using the allostERIC sites of GLP-1R to design drugs represents a novel approach to the discovery of anti-diabetic agents. Allosteric sites in G-Protein Coupled Receptors (GPCRs) are less conserved than the orthosteric site, show spatiotemporal specificity, saturation and exhibit the noncompetitive inhibitory effect. We hypothesize that if we design small molecule positive allosteric modulator (PAM) targeting GLP-1R, then the synergy between PAM and endogenous GLP-1 would enhance insulin production. For this study, in house homology modeling method and Sitemap was used to predict the GLP-1R model and allosteric site in model respectively. In order to find an anti-diabetic small molecule, we generated a library of 5689 compounds and docked in the predicted allosteric site using computational tools. Based on the docking scores, top 9 molecules were screened in vitro using luciferase assay. From the preliminary screening, we found two GLP-1R agonists. Furthermore, synergistic studies confirmed that one of the two GLP-1R agonists bind to the allosteric site in GLP-1R. This study has identified novel small molecules PAM of GLP-1R. In future, we will perform rational design to improve the binding affinity and absorption, distribution, metabolism and excretion (ADME) properties of the hit compound. The innovative aspect of this work is the structure based small molecule allosteric drug designing for GLP-1R activation. The significance of this work to public health is getting an anti-diabetic oral molecule that would induce insulin production in the presence of low levels of an endogenous GLP-1 in T2D patients.

**Computational analysis of the membrane targeting domains of the phospholipase D family in Arabidopsis thaliana.**
C. Barreto\(^1\), K. Begum\(^1\), A. Cataldo\(^1\), S.M. Singh\(^1\);
\(^1\)Biology, Brooklyn College, City University of New York, Brooklyn, NY

The phospholipase D (PLD) class of enzymes is key to several cellular functions that require an association with the cellular membranes, including cell signaling, growth, vesicular trafficking, secretion, and endocytosis. Although well studied in animals, the mechanism and behavior of the membrane targeting domains that mediate these interactions is largely unknown in plants. To this end, we have characterized the structure of membrane targeting domains of the six classes of PLD isoforms in the model organism, *Arabidopsis thaliana*. Utilizing sequence and structural analysis including template based modeling, electrostatics analysis, and docking studies, we have analyzed the membrane binding mechanism for the different PLD classes in *Arabidopsis thaliana*. Domain architecture analysis has
revealed the presence of C2 domains coupled with the catalytic domains of the alpha, beta, gamma, delta, and epsilon isoforms. Only one class of PLDs in Arabidopsis contain Pleckstrin Homology (PH) and Phox homology (PX) domains coupled with their catalytic domains similar to the animal PLDs. Our results show that Arabidopsis PLDs largely control their localization via C2 domains that appear to be structurally analogous to their mammalian counterparts in other protein families. Here we present the modeled membrane targeting domains of all the six classes and elaborate their membrane targeting behavior discerning differences within individual members of this expanded PLD family and compare them with mammalian PLDs. The results from this study lay the foundation for understanding the detailed membrane targeting behavior of the plant PLDs and the consequences of the expansion of this gene family in plants.

Incoherent Inputs Enhance the Robustness of Biological Oscillators.
Z. Li¹, Q. Yang²;
¹Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI,
²Department of Biophysics, University of Michigan, Ann Arbor, MI

Robust biological oscillators retain the critical ability to function in the presence of environmental perturbations. Although central architectures that support robust oscillations have been extensively studied, networks containing the same core vary drastically in their potential to oscillate, and it remains elusive what peripheral modifications to the core contribute to this functional variation. Here, we have generated a complete atlas of two- and three-node oscillators computationally, then systematically analyzed the association between network structure and robustness. We found that, while certain core topologies are essential for producing a robust oscillator, local structures can substantially modulate the robustness of oscillations. Notably, local nodes receiving incoherent or coherent inputs respectively promote or attenuate the overall network robustness in an additive manner. We validated these relationships in larger-scale networks reflective of real biological oscillators. In addition, we built Xenopus extract droplet system to track cell cycle circuit in parallel while manipulating molecular circuit to verify our hypothesis. Our findings provide an explanation for why auxiliary structures not required for oscillation are evolutionarily conserved and suggest simple ways to evolve or design robust oscillators.

3D Computational Modeling of Bleb Initiation Dynamics.
W. Strychalski¹;
¹Mathematics, Applied Mathematics, and Statistics, Case Western Reserve University, Cleveland, OH

Blebbing occurs in cells under high cortical tension when the membrane locally detaches from the actin cortex, resulting in pressure-driven flow of the cytosol and membrane expansion. Some cells use blebs as leading edge protrusions during cell migration, particularly in 3D environments. Blebs can be initiated through either a localized loss of membrane-cortex adhesion or ablation of the cortex in a region. Bleb morphologies resulting from different initiation mechanisms have not been studied in detail, either experimentally or with theoretical models. Results from experiments have suggested that cytoplasmic elasticity is important for limiting bleb size. A 3D dynamic computational model of the cell is presented that includes mechanics of and the interactions among the cytoplasm, the actin cortex, the cell
membrane, and the cytoskeleton. The model is used to quantify bleb expansion dynamics and shapes that result from simulations using different initiation mechanisms. The cytoplasm is modeled as a viscous fluid and as a poroelastic material. Results from simulations using a viscous fluid cytoplasm model show much smaller and broader blebs when they are initiated via cortical ablation than when they are initiated by removing membrane-cortex adhesion. Simulation results using the poroelastic model of the cytoplasm provide qualitatively similar bleb morphologies regardless of the initiation mechanism. The resulting cell shapes also are qualitatively similar to those from experimental data.

Mathematical models are important to guide synthetic biology experiments, including those using Phage-Assisted Continuous Evolution (PACE). Our aim was to use PACE to evolve a riboswitch sequence in an M13 phage, selecting for the ability of the riboswitch to bind to a new small molecule. We modeled random mutations in the phage, accounting for lethal mutations (in functional noncoding regions such as promoters), non-lethal mutations (in nonessential genes and unannotated regions of the phage genome, as well as synonymous mutations in coding regions) and potentially lethal mutations (nonsynonymous mutations in coding regions). The lethality probability of a nonsynonymous mutation in a coding region is a user input to the model. We calculated the expected value and 90% confidence interval for the number of phage required to observe all possible single, double and triple base substitutions in the riboswitch sequence of the M13 phage, after removing from the population all phage with one or more lethal mutations. This probability model was used to ensure that the spatial and temporal scale of the wet lab experiment was sufficient to explore the extremely large sample space of all possible riboswitch sequences of a given length. Further, we used differential equations to predict the time required for the small molecule anhydrotetracycline (aTc) to reach each of its target concentrations, and for negative selection host cells to dominate the population in each compartment of the PACE chemostat. Generalized versions of our probability and differential equation models were coded into web tools that biologists can use for future experimentation.

Graph Fingerprints of Mitochondria and Mitochondrial-Like Networks.
G.R. Lewis¹, W.F. Marshall¹;
¹Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA

Mitochondria are the respiratory powerhouses of eukaryotic cells. These organelles form a variety of physical networks in many biological contexts, ranging from multi-cell structures in skeletal muscle tissue to highly-fused networks in single cells of S. cerevisiae. Though mitochondrial networks are quite common, the reason for maintaining a network structure is unclear. Here we begin to test mathematically the similarity between mitochondrial networks in S. cerevisiae and network structures that have been optimized for a variety of tasks, such as for macromolecular transport and rejection of
low-quality components. To do this, I develop a “fingerprint” using a variety of mathematical signatures of a target graph, which characterizes the major properties of the graph. Preliminary data suggest that this fingerprint is quite different for graphs that are superficially similar, though built using distinct sets of construction rules. By computationally simulating mitochondrial-like networks incorporating different types of construction rules, then comparing their fingerprints, I will be able to differentiate between networks optimized for different tasks. I will then compare these fingerprints to those of true mitochondrial networks in S. cerevisiae. Through analyzing fingerprints for time-courses of mitochondrial networks, I will be able to determine conserved characteristics of true mitochondrial networks, allowing a more acute approach toward understanding the properties for which these networks are optimized.

Protein docking and molecular dynamics simulations of the extracellular domain of Na⁺,K⁺-ATPase β₁ subunit reveals a reliable binding model for epithelial Na⁺,K⁺-ATPases on adjacent cells.  
O. Paez¹, L. Shoshani¹, M. Martínez-Archundia², J. Correa-Basurto²; ¹Physiology, CINVESTAV-IPN, Mexico city, Mexico, ²Pharmacology, ESM-IPN, Mexico city, Mexico

In addition to its ion transporting function, Na⁺,K⁺-ATPase (sodium pump) acts as a homotypic epithelial cell adhesion molecule via its glycosylated β₁ subunit ¹,². The β subunit extracellular domain is not homologous to any other family of cell adhesion molecules and, when expressed as a soluble recombinant ectodomain, maintains its adhesive properties. We have performed Molecular Dynamics (MD) simulations and protein-protein docking of the truncated β₁ subunit ectodomain (ED) in order to gain insight into the recognition mode between Na⁺,K⁺-ATPase β₁ subunits. Our MD results show that the N-terminal half of β₁ subunit ED suffers important structural rearrangements, probably as a result of loss of interactions with Na⁺,K⁺-ATPase alpha subunit but nonetheless the C-terminal half of β₁ subunit ED remains stable during the simulations thanks to its β-sheet sandwich structure imposing movement restrictions in the ectodomain. We submitted several conformers to directed protein-protein docking and have obtained a robust model of β₁ ectodomain binding. In such a model two Na⁺,K⁺-ATPase recognize each other via its β₁ subunit by means of a large, complex interface in which one of the three N-glycosylation sites is involved. Our model reconciles experimental data suggesting that both N-glycans and loop residues are involved in the trans dimerization of Na⁺,K⁺-ATPase in epithelia ³,⁴.

Structural and functional analysis of key proteins involved in ESX-1 protein secretion system of M. tuberculosis: novel targets for drug developments.  
V.K. Kashyap¹, R. Sharma¹, A.K. Saxena¹; ¹School of Life Sciences, Jawaharlal Nehru University, New Delhi, India

Tuberculosis is a chronic infectious disease caused by M. tuberculosis. M. tuberculosis contains ESX protein secretion system for the transport of intracellular proteins across their highly impermeable cell wall. Out of five ESX pathways, ESX-1 and ESX-3 are essential for virulence and growth of M.
tuberculosis. ESX-1 pathway contains at least 10 genes that encode T-cell antigens as well as AAA-ATPases. Proper functioning of ESX-1 pathway requires the knowledge of structure and interaction of multiple ESX-1 substrates and other component proteins prior to their secretion. We have expressed, purified and determined the X-ray structure of M. tuberculosis EspR protein. EspR is a transcriptional activator that promotes ESX-1 secretion by activating transcription of espACD operon immediately upon macrophage infection. Currently, we are involved in structure analysis of complexes of EspR with promoter DNA sequences and specifically designed molecular inhibitors. EspC is small protein that strongly recognized by T cells isolated from patients with M. tuberculosis. EspC is immunodominant in active and latent tuberculosis infection. The high immunodominance characteristics of EspC, makes it an attractive vaccine candidate for M. tuberculosis. We have expressed, purified and crystallized and looking for x-ray structure of M. tuberculosis EspC and EccA1 proteins. We have also characterized the biological activities and mechanism of interaction between EspC and EccA1. The structure-function analysis of EspR and EspC/EccA1 complex proteins will contribute significantly in understanding the mechanism of ESX-1 secretion pathway and drug development against M. tuberculosis.

\(^1\)Biology, Gustavus Adolphus College, Saint Peter, MN

Genomic sequencing is the cutting-edge in advancing technology and the understanding of how the world functions through DNA, specifically how gene interactions and function lead to successful cell functioning and survival. Currently, 10% of open reading frames (ORFs) in Saccharomyces cerevisiae, remain uncharacterized after many years of analysis. The purpose of this study is aimed at analyzing and gaining data surrounding currently uncharacterized ORFs (ORFans) within S. cerevisiae. Two such ORFan proteins of interest are YGL101W and YLR407W. YGL101W is a yeast protein of unknown function that interacts with DNA Helicase Hpr5p and has a paralog from whole genome duplication, YBR242W, and YLR407W has been observed to include an abnormal phenotype of elongated buds and containment of a single nucleus among mutants. The ORFan proteins were first tested for sequence similarity comparisons utilizing the BLAST algorithm to determine the presence of a viable protein. Structure based evidence was then accumulated and multiple sequence alignment searches were run to formulate predictions on function through homology between the ORFan proteins and different protein families and motifs. Cellular localization data algorithms were used to predict protein membrane topology and cellular localization. The yeast deletion collection and ORFan protein-deleted genetic and physical interaction and expression data were also for any viable information to further characterize protein function. Through these analyses, it has been revealed that YGL101W may function as a phosphohydrolase with homology to the HD domain, while YLR407W contains a nuclear localization signal, an ER membrane retention-like signal, and the appearance of a peroxisomal targeting sequence. This information leads towards the cytoplasm as the cellular location of YLR407W. Both proteins may be involved in cell proliferation, however, further analysis using GFP tagging and knockout-experimentation is required to determine the validity of this hypothesis.

Pigment epithelium derived factor facilitates cornea limbal regeneration in a mouse model through the activation of STAT3 and sonic hedgehog (SHH) signaling.
Y. Tsao1;
1Ophthalmology, Mackay Memorial Hospital, Taipei, Taiwan

We previously reported the mitogenic effect of pigment epithelium derived factor (PEDF) on limbal epithelial stem cells (LSCs) and further demonstrated that PEDF successfully induced limbal regeneration in rabbit partial limbal deficiency. This study was conducted to investigate the mechanism of PEDF-mediated limbal regeneration. In the present study, 120 degree limbal excision of mice was followed by synthetic 44-mer PEDF treatment. Compared with the control, 44-mer PEDF promoted limbus repair with evidence of expression of △P63α and Lrig1 positive cells within limbal wound at 2 weeks and accelerating central corneal epithelium healing after wound challenging. Inhibitors for sonic hedgehog (SHH) and STAT3 significantly decreased the PEDF effect on △P63α and Lrig1 expression in mice as well as the LSC expansion in cell study. Using organ culture and cell study, PEDF sustained the upregulation of SHH activity accompanied with nuclear translocation of Gli3 at least for 6 hours. STAT3 inhibitor blocked the SHH-Gli signaling sustained by PEDF. Together, we demonstrate that LSC expansion and limbal regeneration promoted by PEDF was mediated by STAT3 and SHH-Gli signaling pathway. We hypothesize that limbal regeneration was dependent on the sustained SHH-Gli pathway activity through phosphorylation of STAT3 promoted by PEDF.

The physical microenvironment influences plexus self-assembly in a 3D in vitro model of vasculogenesis.
J. Shirazi1, J.T. Morgan1, E.M. Comber1, J.P. Gleghorn1;
1Biomedical Engineering, University of Delaware, Newark, DE

Developing large-scale tissue grafts for soft tissue defects remains an ongoing challenge in bioengineering largely due to an inability to fully vascularize these constructs. The current standard of care is to use autologous grafts; however, critical flaws include donor-site trauma and volume reduction due to ischemia and slow revascularization. Thus, an engineered graft is ideal. Current bioengineered approaches mainly rely on the fabrication of patterned structures; however, they are difficult to endothelialize and prone to collapse. Our approach instead relies on the de novo formation of a 3D, perfusable, stable vascular plexus within a collagen gel in a process termed vasculogenesis. Although vasculogenesis-based approaches do not lend themselves to controlling vessel phenotype, altering the physical properties of the collagen scaffold allows us to influence cell behavior and dictate the morphology of the resulting network. Engineered vascular plexuses were formed by seeding human umbilical vein endothelial cells at a range of cell densities into collagen gels of varying mechanical properties and allowing them to self-assemble into networks over seven days of culture. The collagen gels were then fixed, stained, and imaged via confocal microscopy. Custom MATLAB algorithms were used to segment the images and quantification of the vascular network phenotype was characterized by vessel diameter, vessel length between junctions, and network connectivity via vessel lumens. To understand how the physical variables tested affect plexus self-assembly, we developed a quantitative
framework equivalent to a “state diagram” where emergent properties of the morphology could be mapped from the variable space. Additional experiments modulating cell contractility via nonmuscle myosin II and ROCK inhibition were performed, and the resulting phenotypes were also mapped onto this framework. Using this framework to understand the role of collagen density, collagen stiffness, cell density, and cell contractility, we can generate lumenized vascular plexuses to fill collagen gels in a variety of regular and irregular shapes and sizes with networks that span centimeters in length. Vessel perfusion was confirmed by flowing fluorescent microspheres throughout the self-assembled architecture. The platform and quantitative framework discussed herein has several advantages, including versatility, stability, and ease of fabrication. By adjusting physical parameters, a fully interconnected, perfusable vascular network with a desired morphology could be incorporated into large-scale grafts via self-assembly and presents an opportunity to implant fully vascularized constructs with minimal risk of volume reduction.

T.A. McGaughey¹, K.M. Fischer¹;
¹Biology, Hampden-Sydney College, Hampden-Sydney, VA

Patients that have lost major sections of tissue from events like major trauma, may require clinical intervention including amputation, skin grafting, transplantation, or, the most interesting option that is not available to doctors yet, tissue engineering (TE), growing a new section of tissue in vitro [1]. TE methods grow cells well in flat sheets, but when the sheets are layered the center mass is poorly diffused decreasing cell viability. If pores were introduced into the hydrogel, then the cell viability will increase, while the introduction of tension and over the counter muscle supplements will increase maturation rates to better mimic native tissue. A 10% (w/v) gelatin solution was used for the experiments [2]. Microbial transglutaminase (mTG) at a concentration of 1% (w/v) was used as a cross-linking agent for the hydrogels. Chloroform was added (0.02% v/v) to sanitize the hydrogels [2]. The hydrogel scaffolds maintained their 3D shape for two weeks after successful cross-linking in PBS at 37°C. Pores were induced with nails, 3D printed structures, and stainless-steel (ss) wire with the ss wire being the most effective. Several different pin configurations were tested including squares, circles, and triangles. There is a dilemma between inducing more pores to increase diffusion without weakening the gel to the point it cannot stretch without tearing; a triangle formation seemed to be the most effective. C2C12 cells with randomly incorporated mCherry fluorescent tags were used for this investigation. C2C12 cells were embedded in the hydrogel at a concentration of 1 million cells/well. The cells were imaged every three days for two weeks. Overall, a viable porous cross-linked hydrogel scaffold was developed; however, the cells failed to orient themselves properly in the hydrogel. Ongoing research includes applying tension to the C2C12-gelatin scaffold to help the myoblasts orient in a unified direction. Additionally, over-the-counter muscle supplements marketed as having the ability to improve muscle growth during workouts are being investigated on decreasing time to cell maturation in vitro. The ability to rapidly grow thick and viable skeletal muscle for introduction will help patients have an increased quality of life by restoring function to their injured muscle.

Acss2 controls mode of acetate utilization.
N. Puthillathu1,2,3,4, R. Vengilote1,2,3,4, J.R. Moffett1,2,3,4, A. Peethambaram1, G. Sukumaran3,4, J. Singh3,4, C.L. Dalgaard1,2,3,4, r. Wilkerson3,4, j. te3,4, A.M. Namboodiri1,2,3,4;
1Anatomy, Physiology and Genetics, Uniformed Services University of the Health Sciences, Bethesda, MD, 2School of Medicine, USUHS, Uniformed Services University school of Medicine, bethesda, MD, 3School of Medicine, USUHS, The American Genome Center, Bethesda, MD, 4School of Medicine, USUHS, Collaborative Helath Research Initiative (CHIRP), bethesda, MD

The current knowledge of Acss2 (acyl-CoA short chain synthetase-2) is expanding and has taken center stage in acetate metabolism. In mammals, cytoplasmic and nuclear acetyl-CoA are replenished by ATP-citrate lyase (Acly) and Acss2. Up until recently, Acly was alone thought to be the major source of extramitochondrial acetyl-CoA but accumulating data indicate that both enzymes are critically involved in acetate metabolism. Acss2 -/- mice develop and reproduce normally, but exhibit behavioral differences from wild type mice. Acss2 has been implicated in lipid synthesis, but additional functions of Acss2 remain mostly unexplored. Therefore we examined gene expression changes in the liver and brain under conditions in which exogenous acetate is increased (acetate loading by oral GTA) vs. when endogenous acetate and ketone bodies are increased (48 hour starvation) and compared the responses between wild type and Acss2 -/- mice. Initial bioinformatics analysis of the data indicates that endogenous and exogenous increases in acetate are not equivalent, and in fact, result in vastly different changes in gene expression. Following acetate loading, wild type and Acss2 -/- mice exhibited significant differences in the expression of 151 genes in the liver. In contrast, 48 hr fasting resulted in the differential expression of 2675 genes in the liver. Interestingly, when GTA fed mice were compared to 48 hour fasted Acss2 -/- mice, the number of differentially expressed genes in liver increased to 4768. In brain, the main pathways perturbed were PI3K-AKT and serotonergic responses. Alcohol induced organ damage showed strong correlation to the gene function loss. Previously unknown roles for Acss2 such as cell signaling cascades, specific chromosomal regulatory networks, cell cycle, immune regulation, apoptosis and others were uncovered indicating the diverse functional roles played by Acss2, particularly during nutrient deprivation and negative nitrogen balance. The Integration of Cellular and Subcellular Dynamics for Cell Migration.
T. Lan1, S. Hung1, X. Su1, S. Wong2, Y. Tseng1;
1Chemical Engineering, University of Florida, Gainesville, FL, 2Department of Statistics, University of Florida, Gainesville, FL

Integrated biology requires real-time cell information to establish comprehensive cellular-molecular connections. The lack of appropriate cellular assessments will hinder a systematic understanding of cell physiology. Hence, we develop a novel cellular signature — the CN correlation profile — to quantify the contributions of the momentary subcellular migratory activities in the cell migration pattern of a cell type. We found that the CN correlation profile can uniquely and consistently represent the cell migration pattern of the cell types probed. The effects of molecular perturbations, such as Y27632 and Cdc42 knockdown, also can be clearly revealed on each subcellular migratory activity. As a result, the CN correlation approach can effectively promote integrated biology through bridging cell dynamics and
migration pattern with their underlying subcellular migratory activities and elucidated molecular mechanisms.

Coupled control of mRNA and protein variability in single mammalian cells.
D. Popovic1, L. Pelkmans1;
1Department of Molecular Life Sciences, University of Zurich, Zurich, Switzerland

Central dogma of biology is an intriguing question since decades, mainly due to the lack of clarity concerning the stochastic or deterministic nature of single cell variability in both, mRNA and protein level. While various bulk approaches tried to address to which extend do the mRNA levels predict the protein levels, the variability within single cell population that can lead to a different time scale regulation of mRNA production and translation remained vaguely addressed. We have recently shown that cytoplasmic transcript abundance in single mammalian cells is minimally stochastic, and absolute mRNA quantities are largely predictable by the cellular features. Now, using ~20 mammalian cell lines where gene of interest has been tagged on all alleles with mEGFP by CRISPR/Cas9 or ZnF technology combined with antibody staining approach, we provide very accurate measurements of both protein and mRNA (using single molecule mRNA FISH), together with ~200 single cell features (cell size/shape, nucleus size/shape, DNA content, total protein content, neighbor relations and activity...) and ~35 features that describe mRNA spatial patterns (distance from the nucleus, plasma membrane, each other, relation to the neighboring cells...). Importantly, pairwise correlations of mRNA and protein for all genes across thousands of measured single cells are very high, irrespective of the expression distribution that is gene-specific (uni- or multimodal, multimodal-inducible). mRNA content largely explains the variance in the measured protein levels, however, when cellular features are taken into account, we are able to further map the cells that deviate in their kinetics from the bulk of the population. Using mathematical modelling we can accurately predict protein levels of all single cells, pointing that the kinetics of the translation/transcription processes is determined by a particular cell cycle stage, cellular phenotype or mRNA pattern, and is also gene-specific. Contribution of the mRNA patterning to the explained variance of the protein levels further suggests cytoplasmic compartmentalization (apart from nuclear retention) as one of the mechanisms by which cells buffer the transcriptional and translational noise, by directly modulating kinetics of mRNA stability and translation.

Chemotropism in yeast.
D. Ghose1, D.J. Lew2, T.C. Elston3;
1Computational Biology and Bioinformatics, Duke University, Durham, NC, 2Pharmacology and Cancer Biology, Duke University, Durham, NC, 3Pharmacology, University of North Carolina, Chapel Hill, Chapel Hill, NC

Eukaryotic cells like migrating cancer cells, developing neurons, and mating yeast move (chemotaxis) or grow (chemotropism) in a specific direction by using a chemical gradient for directional reference. Existing models for how eukaryotic cells sense chemical gradients generally involve comparing concentrations of ligand-bound receptors across the cell surface to infer the gradient. However, our studies, using yeast chemotropism mating as a model, suggest that cells may sense a chemical gradient with a pheromone-sensing patch of the cell cortex (a "nose") that is mobile. The nose is set up by
polarity factors and moves in response to vesicle traffic. We have modeled the dynamics of this moving nose with stochastically perturbed reaction-diffusion equations. In this study, we show that an in silico cell based on this computational model can track pheromone gradients. However, the model is much worse at tracking shallow gradients than yeast cells in in vivo experiments. Interestingly, an additional pathway, linking receptor-coupled G-alpha to a formin, was implicated in gradient sensing in yeast. When we incorporate the potential effects of this pathway into our mathematical model, the model's ability to track pheromone gradients improves significantly if, and only if, we assume that G-alpha (unexpectedly) inhibits the formin. Furthermore, we experimentally demonstrate that the change in the moving nose's dynamics in G-alpha mutants recapitulate the mathematical model's predictions. In summary, we propose a mechanistic basis for a novel pathway that improves the accuracy of gradient tracking in yeast.

Visualizing and controlling calcium signaling dynamics after wounding in engineered stromal microtissues.
S. Ghilardi\textsuperscript{1,2}, J. Eyckmans\textsuperscript{1,2,3}, A.E. Sgro\textsuperscript{1,2};
\textsuperscript{1}Biological Design Center, Boston University, Boston, MA, \textsuperscript{2}Department of Biomedical Engineering, Boston University, Boston, MA, \textsuperscript{3}Wyss Institute for Biologically Inspired Engineering, Harvard University, Boston, MA

How cellular populations coordinate their behaviors to drive tissue morphogenesis and organ function has been a long-standing question. The most familiar paradigm is having a group of control cells, such as pacemaker cells in a beating heart, that dictate the tissue's action. However, in the context of wound healing, no specific ``pacemaker'' cells driving tissue closure have been identified. Instead, the cells need to communicate and coordinate the tissue response after injury. In a wounded tissue, the multicellular response is driven by several key signaling molecules, the earliest of which is calcium. In 2D scratch assays the calcium response has been characterized as an initial wave followed by periodic oscillations and it has been demonstrated that these periodic oscillations change based on the mechanical environment. As the mechanical environment in 3D tissues is complex and changes in these mechanics are critical to the wound closure process, we hypothesize that the calcium response is different and that these differences could be amplified down the signaling cascade, ultimately leading to a different healing response. To address this hypothesis, we have implemented a toolbox of genetically-encoded fluorescent calcium sensors and optogenetic calcium actuators to permit the visualization and control of calcium signaling in 3D microtissues composed of fibroblasts and collagen type I matrix. We have found that some cells in these 3D tissues display calcium oscillations prior to wounding and that the oscillations after wounding are faster than those observed in 2D scratch assays, both of which we believe are due to the different forces cells experience in these microtissues. Using our actuators, we have begun to manipulate calcium signaling to test our hypothesis that these differences in the initial calcium signaling dynamics manipulate the downstream healing response. This toolbox will allow us to causally link signaling dynamics to their mechanical environment and the downstream responses they control, both permitting us to potentially reprogram cellular communication to optimize the wound healing response and more generally understand how non-hierarchical cellular populations make decisions.

Using phage assisted continuous evolution (PACE) to evolve riboswitches that function reliably in vivo.
S.R. Bilby¹, L.D. Doolan¹, C.C. Mackley¹, C. Watson¹, S.S. Bent², I.G. Cuellar², F.C. Enriquez², M.O. Hunter², H.S. Sinks³, A. Tutar³, L.J. Heyer³, A.M. Campbell², J. Poet⁴, T.T. Ekedahl¹;

Phage assisted continuous evolution (PACE) is a method first developed by the David Liu laboratory at Harvard University. PACE uses both positive and negative selection of filamentous phage M13 that infect E. coli. A chemostat is used to direct mutations to phage populations instead of E. coli host cells. A two-campus team of Missouri Western State University and Davidson College undergraduates adapted PACE to evolve a new riboswitch that functions reliably in vivo. Riboswitches are RNA elements within mRNAs that control protein production by binding ligands of interest and regulating either transcription or translation. Discovering new riboswitches that work in vivo has proven to be very difficult, and incorporating a published aptamer into existing riboswitches rarely succeeds. Our PACE experiments aimed to evolve transcriptional and translational riboswitches known to bind theophylline into xanthine-specific riboswitches. We carried out positive selection in the presence of xanthine, and negative selection in the presence of theophylline. After PACE, a variant of the translational theophylline riboswitch, which contained a seven base pair deletion in the aptamer, dominated the phage population. This variant was tested to ascertain the effect of the mutation on riboswitch function. Populations of new riboswitches taken from different M13 samples after PACE were subjected to next generation sequencing to obtain a library of variants that had evolved over the course of PACE. The populations will be tested further to determine if xanthine-specific riboswitches evolved through PACE.

Tunig DNA- and Membrane-binding proteins to sense cellular geometry.
C.W. Sandlin¹, M.C. Good¹;
¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Adenocarcinoma samples from the Penn Medicine BioBank show evidence of oversized cells. These cells may affect cancer progression. However, testing whether large cells are relevant to pathology in a mouse requires a way to target only oversized cells. Targeting this subpopulation cannot be accomplished with drugs or any other existing method. Therefore, we are building synthetic genetic circuits to target only oversized cells. This synthesis approach has another benefit: it teaches us about the evolutionary constraints upon size-sensing proteins. To synthesize size-sensing, I am building proteins to sense cellular geometry. I describe how DNA- and membrane lipids titrate with cell volume, and simulate binding of a protein to DNA or membranes as a function of volume. Simulations of this “binding-with-volume” predict an increase the free activity of a protein at larger cell sizes. This effect could be employed to activate a cell-death program. To account for nuclear transport effects on binding, I solve partial differential equations for nuclear binding and transport as a function of size. The results show that altering import and export rates of a DNA-binding protein will shift its binding curve. Overall, increasing any of the parameters of KD, binding specificity, protein concentration, or nuclear export all shift size-response curves to smaller sizes.
I apply this theory to experiments in cell-sized droplets by showing binding vs. volume of HMG proteins to DNA-coated beads, and an amphipathic helix to phospholipids. As expected, protein fluorescence in the lumen of droplets is depleted at smaller sizes. To show this behavior is relevant in cells, I demonstrate the binding-with-volume effect in cell-like compartments containing Xenopus laevis oocyte extracts and reconstituted sperm nuclei. Finally, I describe the differences between theory and experiment and differences between the buffer and extract-based system.

Optogenetic control of protein activity in cell-like compartments.  
R.M. Caldwell¹, J.G. Bermudez², D.G. Thai¹, M.C. Good¹²;  
¹Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA,  
²Department of Bioengineering, University of Pennsylvania, Philadelphia, PA

The spatial organization and temporal activation of proteins are critical for cellular function. For example, the Rho family of GTPases act as spatiotemporal ‘switches’ to control organelle development, cell motility, and cytoskeletal dynamics. To characterize the organizing principles that guide intracellular signaling, it is necessary to control initiation and spatial patterning of these pathways. To this end, we previously developed cell-like compartments that enable broad control of cellular contents and dimensions. However, this minimal system lacked tools to control subcellular localization and spatiotemporal triggering of enzymatic activities. We chose light as an optimal trigger to augment our system because the area of illumination can be precisely controlled and because it circumvents the difficulty of diffusing small molecules through the continuous phase into water-in-oil emulsions. To introduce optogenetic control, we employed cTMP paired to Halo-DHFR and dRAP coupled with FRB-FKBP. We implemented these photocaged dimerization systems with split proteins to enable reconstitution of biochemical activity with light. Here, we demonstrate this scheme by activating split tripartite GFP with light through the cTMP-Halo system and by reconstituting split TEV (Tobacco Etch Virus) protease with light through the dRap and FRB/FKBP system. In pairing split proteins with light inducible dimerization systems, we demonstrate the potential for a myriad of light-inducible protein activities using previously-developed split proteins inside of synthetic cell-like compartments. These novel optogonetic tools can aide in studies linking cell geometry, subcellular localization, and signaling within synthetic cells.

Controllable phase separation and modular recruitment to form synthetic membraneless organelles.  
B.S. Schuster¹, M. Good¹, D.A. Hammer¹;  
¹University of Pennsylvania, Philadelphia, PA

Many intrinsically disordered proteins (IDPs) self-assemble intracellularly into liquid droplets that function as membraneless organelles. Because of their importance in biology and unique chemical characteristics, these protein compartments represent a compelling target for synthetic biology research. Here, we manipulated the intrinsically disordered, arginine/glycine-rich RGG domain from the P granule protein LAF-1, to demonstrate controllable phase separation and cargo recruitment to a synthetic membraneless compartment. First, we demonstrated methods to control phase behavior, externally triggering droplet assembly and disassembly by using specific proteases to manipulate the...
valency of IDP domains and presence of solubility-enhancing domains. Second, we characterized permeability of these compartments to soluble macromolecules and devised strategies to target and colocalize cargo molecules into the droplets. Cargos were recruited using either RGG domains or coiled-coiled interaction domains as recruitment modules, and cargo release was triggered by proteolytic removal of the recruitment domains. Droplet assembly and cargo recruitment were robust and occurred in cytoplasm. Our results using this platform suggest it is now possible to recruit multiple enzymes and substrates to stimulus-responsive membraneless organelles. This system provides a much-needed experimental framework to investigate the biochemical consequences of localizing enzymes and substrates to membraneless organelles and to harness IDP compartments for synthetic biology applications.

A forward genetic screen identifies host factors that influence the lysis-lysogeny decision in phage lambda.
N.T. Quach1, K. Bodner1, A. Miguel1, Y. Tanouchi1, M.R. Silvis2, C.A. Gross2, K.C. Huang1, M.W. Covert1, D.A. Van Valen1,2,3,1Bioengineering, Stanford University, Stanford, CA, 2Microbiology and Immunology, University of California, San Francisco, San Francisco, CA, 3Biology and Bioengineering, California Institute of Technology, Pasadena, CA

The lysis-lysogeny decision made by bacteriophage lambda is one of the classic problems of molecular biology. Shortly after infecting a cell, the virus can either go down the lytic pathway and make more viruses, or go down the lysogenic pathway and integrate itself into the host genome. While much is known about how this decision takes place, the extent to which host physiology influences this decision and the mechanisms by which this influence takes place has remained mysterious. To answer this question, we performed a forward genetic screen to systematically identify all of the genes in E. coli that influence the lysis-lysogeny decision. Our results demonstrate previously unknown links between host physiology and viral decision making and shed new light on this classic system.

Characterization of the Gain-of-function Toxicity of Optineurin in Yeast.
M. Islam1, S. Chen1, Y. Kim1, S. Ju1, Q. Zhong1; 1Biological Sciences, Wright State University, Dayton, OH, 2Brandeis University, Waltham, MA

Optineurin is an autophagy adaptor protein associated with two distinct types of neurodegenerative diseases: Normal Tension Glaucoma (NTG) (Rezaie et al., 2002) and Amyotrophic Lateral Sclerosis (ALS) (Maruyama et al., 2010). NTG is a sub-type of Glaucoma, which may lead to complete blindness following progressive optic nerve degeneration. ALS is a fatal neurodegenerative disorder, attacking mainly the upper and lower motor neurons. Although overexpression (Chi et al., 2010) and deletion (Ito et al., 2016) of optineurin were shown to induce degenerative phenotypes in mice similar to those observed in disease, the underlying mechanisms remain unclear. Overexpression of optineurin leads to growth defects in yeast (Kryndushkin et al., 2012). Using yeast genetic approaches, the human homolog of a yeast gene, MKK1, was identified as a potential drug target that suppresses the toxicity of optineurin in mammalian cells and in zebra fish models (Jo et al., 2017). Overexpression of Ypt1, the yeast homolog of a human interactor protein of optineurin, Rab8, also alleviates optineurin mediated...
toxicity (Kryndushkin et al., 2012). We found that Ypt1 is an interacting protein of optineurin (Zhong et al., 2016). Based on this observation, we hypothesized that other interacting proteins of optineurin in yeast could be involved in its toxicity. We therefore expressed the wild-type and six mutated forms of optineurin in yeast. Each allele alters a specific interaction domain of optineurin: the NTG-associated E50K allele in the Nemo-like domain, the ALS-associated V295F and E478G alleles in the coiled-coil and the ubiquitin-binding domains, the F178W and F178A alleles specifically altering the binding motif of the autophagy protein ATG8/LC3 and the C555X allele truncating the Zinc finger domain. We determined overexpression phenotypes of optineurin alleles and systematically tested these alleles against ~6000 yeast proteins for interactions using the yeast two-hybrid method. We identified 128 interactors including three reported suppressors of the optineurin induced toxicity, Ypt1, Btn2 and Mdv1 (Kryndushkin et al., 2012, Jo et al., 2017). The mapped interaction network reflects the interplay of multiple cellular processes including autophagy, protein trafficking and mitochondrial functions. Different optineurin alleles change the interaction network differently. Strikingly, the ALS-associated E478G allele appears to gain a large number of new interactions. Our current work focuses on examining the modifier effect of each optineurin interactor protein on its toxicity. Such allele-specific physical and genetic interaction networks, if demonstrated to be conserved in human, may provide new insights in optineurin-associated neurodegenerative processes.

Causes and consequences of slow-cycling cells within isogenic populations.
M. Min¹, S.L. Spencer¹;
¹Department of Chemistry and Biochemistry, University of Colorado-Boulder, Boulder, CO

The subpopulation of slow-cycling cells has been well characterized in bacteria, which often give rise to antibiotic resistance. In mammalian cells, it has been proposed that cancer drug resistance is mainly conferred by a small subpopulation of slow-cycling cells, also referred as dormant cancer cells. Yet, a clear connection between slow growth and adaptability to drug environment has not been established, mainly due to the lack of tools to identify and follow this small subset of slow-cycling cells throughout the process. The Spencer lab has recently developed several live-cell sensors to distinguish quiescent cells from proliferating cells. These tools enable flow-cytometry-based isolation of naturally slow-cycling cells within a heterogeneous population, as well as tracking the dynamics of slow-cycling cells at the single-cell level. By profiling the sorted slow-cycling cells by RNA-seq, we present the molecular network underlying the slow-cycling subpopulation. Using dynamical and systems-level information, we show that stress is the fundamental cause of spontaneous entry into the slow-cycling state and that, in turn, the slow-cycling state may protect cells from future stress.

Mathematical models for tissue structure based on asymmetric cell division.
B.M. Boman¹, T. Dinh², K. Decker², B. Emerick², C. Raymond², J.Z. Fields¹, G. Schleiniger²;
¹Cancer Research, CATX Inc, Princeton, NJ, ²Center for Applications of Mathematics in Medicine, University of Delaware, Newark, DE

While the life of any multicellular organism is dependent on maintaining organization of its tissues, the laws that govern the organization of cells in tissues have not been elucidated. Hypothesis: Simple mathematical laws involving temporal and spatial rules explain how the organization of tissues is
maintained during tissue regeneration. Our goal was to discover the code that regulates normal tissue renewal and organization. Models (discrete and continuous) of asymmetric cell division were used to determine rules that explain, at the cellular scale, how tissues maintain their organization in an emergent fashion. Five mathematical rules were found to generate symmetric geometric patterns having self-renewing branches with cell numbers as described by generalized Fibonacci-recursive sequences. The dynamics of the system are described by rate equations, rate constant values for division of mature and immature cells in the system population, eigenvalues and eigenvectors. Our discrete, asymmetric cell division model involving simple mathematical laws based on temporal and spatial rules generates symmetric patterns of cell populations that maintain their organization while continuing to self-renew. This model provides a first step toward understanding how rules that regulate organization of healthy tissues might be modified in diseases of tissue disorganization such as cancer.

Optogenetic platform to probe cytokinesis signaling in vitro.
J.G. Bermudez1, M. Good1,2; 1Bioengineering, University of Pennsylvania, Philadelphia, PA, 2Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

While proper cell division is critical to the development of living cells, the timing and mechanistic details of this dynamic process remain unresolved. To gain fundamental insights on disease and development, we must first understand how intracellular signals that direct cell division are organized in space and time. Here we present a minimal in vitro platform to decode the molecular mechanisms that link spindle positioning and cell cycle progression. This simplified system and the perturbations it enables offer benefits over the complexity of living cells and in vivo genetic studies which preclude the analysis of short, dynamic processes. Precise spatial regulation of the mitotic spindle – a macromolecular machine that separates chromosomes - is necessary for proper cell division, particularly during the rapid cell cycles present in early embryo development. Once positioned, the spindle initiates other mitotic events such as cytokinesis through cleavage furrow signaling. By engineering proteins that can sense activity of key regulators of cell division, as well as proteins that can localized by light, we can reconstitute and observe many of these complex processes. Our goal is to reconstitute these mitotic processes in vitro by encapsulating Xenopus egg extract along with these engineered proteins within a synthetic boundary and tuning compartment geometries. By doing so it should be possible to investigate how cell geometry affects the transport and activation of cell cycle signals. Currently, we are developing optogenetic tools to enable us to position proteins of interest as well as proteins that interact with microtubule ends of spindles formed in vitro. Here I describe our progress toward these goals. We have expressed and purified protein pairs that dimerize upon illumination by blue light. By merging optogenetic recruitment with a boundary tethering mechanism, we are poised to recruit proteins to specific regions of the cell-like compartment. We plan to characterize how known key players in cytokinesis, such as small GTPase RhoA, are spatially activated throughout the cell. With this platform, we can determine how the rates of signaling vary in cells with extreme geometries and further examine link between spindle positioning and the molecular pathways associated with cell division.
Vascularization of engineered tissue constructs is crucial to recapitulating fluid flow and transport necessary for cell survival and to create accurate in vitro disease models for drug discovery applications. Methods to engineer vasculature currently rely on either self-assembly or microfabrication approaches which are often limited in their ability to generate vasculature with repeatable and controlled architecture or to generate 3D biomimetic networks respectively. To overcome these limitations, we developed and implemented laser-based hydrogel degradation to recapitulate the native architecture of in vivo microvasculature in engineered hydrogels. We also demonstrate the ability to quantify transport between two adjacent and intertwining microfluidic channels, similar to transport between the cardiovascular and lymphatic systems in vivo, and to fabricate planar vascular constructs to study interstitial and luminal fluid flow within tissue constructs. By tracking particle movement through vascular networks, we can replicate physiologically relevant capillary wall shear stress of 45 dyne/cm2. Our hydrogels are housed within larger pre-fabricated microfluidic (PFM) devices to conveniently enable pump-driven or pressure-driven fluid flow. For culture of microvascular endothelial cells, channel networks are created in both synthetic (poly(ethylene glycol) diacrylate; PEGDA) and natural (collagen) hydrogels, with channels ranging from 3.3 to 100 μm in diameter. Due to differing degradation mechanisms (photodegradation via plasma ionization and photocavitation in PEGDA, and via multiphoton ionization in collagen), networks can be generated two times faster in collagen than in PEGDA, albeit with similar resolution. For these studies, PEGDA hydrogels were photopolymerized within PFM devices and functionalized with AF633 for visualization and RGDS peptide for cell adhesion. Rat tail collagen type 1 at 2.5 mg/mL was incubated at 37 °C to induce polymerization within AIM Biotech PFM devices. Using a 20X(NA1.0) water immersion objective, virtual masks guide the position of a 140 fs pulsed Ti:S laser operating at 790 nm at 37.7 nJ/μm2 to induce PEGDA degradation, and 900 nm at 18.0 nJ/μm2 to induce collagen degradation. Channels were seeded with mouse brain endothelial cells, human umbilical vein endothelial cells, or human lung microvascular endothelial cells and stained and immunofluorescently labeled for nuclei, actin, and VE-cadherin. Applicable to both synthetic and natural hydrogels, laser-based degradation can be used to generate fluidic networks with controlled and engineered vascular architecture and cellular microenvironment. Currently, we are applying these techniques to study circulating tumor cell lodging in, and extravasation from, capillaries.

Germ Cells, Gametogenesis, and Fertilization

In some rare Australian species like Solanum asymmetriphylum, two types of flowers are found: one with only male reproductive structures, or male flowers, and another with both male and female structures, or hermaphroditic flowers. Pollen grains have apertures in their cell walls to facilitate
initiation of the pollen tube, which enables pollination. Grains (pollen) from the androecium of hermaphroditic flowers are inaperturate, therefore the flowers are functionally pistillate (making species with these breeding systems functionally dioecious). We propose a molecular study of the differences between pollen grains from the male flowers and the hermaphroditic flowers in two different dioecious taxa: S. ossicruetem and S. dioicum, which have male and female flowers on separate plants and we compare these to one andromonoecious taxon, S. ultraspinosum, which has inflorescences that produce one hermaphroditic flower and several male flowers. Since we know that the structure of pollen grains is different between the two breeding systems, we will use protein quantification to compare the amount of total protein in each population. We aim to quantify the differences in protein concentration between the two pollen types in the Solanum genus. After protein quantification, protein extraction will allow us to perform 2-dimensional gel electrophoresis technique (2D-GE). 2D-GE will facilitate the determination of a protein expression profile for each of the pollen grains. This analysis will give a new insight into this unusual reproductive condition.

Proteomics of phosphorylation and protein dynamics during fertilization, activation, and meiotic exit in the Xenopus egg.
M. Presler1, E. Van Itallie1, A.M. Klein1, R. Kunz2, P. Coughlin1, L. Peshkin1, S.P. Gygi2, M.H. Wühr1,2,3, M.W. Kirschner1;
1Systems Biology, Harvard Medical School, Boston, MA, 2Department of Cell Biology, Harvard Medical School, Boston, MA, 3Department of Molecular Biology, The Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ

Fertilization triggers release from meiotic arrest and initiates events that prepare the egg for the ensuing developmental program. Protein degradation and phosphorylation are known to regulate protein activity during this process, especially for meiotic exit. However, the full extent of protein loss and phospho-regulation is still unknown. We examined absolute protein and phospho-site dynamics after fertilization by mass spectrometry-based proteomics at high temporal resolution. To do this, we developed a new approach for calculating the stoichiometry of phospho-sites from multiplexed proteomics for improved interpretability of the data. We measure the endogenous degradation rates of known cell cycle proteins (e.g., Cyclin B, securin, EMI2) and identified two putative degradation targets. Overall, the data suggest that degradation is limited to a few low abundance proteins in the egg. However, this degradation promotes extensive dephosphorylation that occurs over a wide range (~1,000 fold) of abundances during meiotic exit. One specific observation is the differential dephosphorylation rates of several nucleoporins which corresponds to the proposed sequence of nuclear pore complex reassembly. This gives insight to the post-translational mechanisms that may regulate the post-mitotic reassembly of the nuclear pore. The data also reveal insights related to fertilization and egg activation. We show that eggs release a large amount of protein into the medium just after fertilization, with ~1% of the non-yolk protein mass lost within minutes. This is most likely related to the blocks to polyspermy. There is also a substantial increase in phosphorylation, likely tied to calcium activated kinases, in parallel to the cell cycle-related dephosphorylation. The analytical approaches demonstrated here are broadly applicable to studies of dynamic biological systems.

Cell cycle–coupled changes of redistribution of inositol 1,4,5-trisphosphate receptor-1 and Ca2+- oscillatory activity in mouse zygotes.
Y. Chang1, R. Fissore2, S. Yoon3;
1Industry Academic Cooperation Foundation, CHA university, Seongnam-si, Korea, South, 2Veterinary and Animal Sciences, University of Massachusetts, Amherst, MA, 3College of Life Science, CHA university, Seoul, Korea, South

BACKGROUND Ca2+ oscillations during fertilization induce eggs activation and embryonic development in mammalian eggs. The type 1 inositol 1,4,5-trisphosphate receptor (IP3R1) is in charge of Ca2+ oscillations for the release of stored Ca2+ from the endoplasmic reticulum. The capacity of this oscillation is obtained during egg maturation and corresponds with an increase in the sensitivity of the IP3R1 and their localization in cytoplasm. Cluster formation of IP3R1 in the egg cortex is important to initiation of Ca2+ oscillations during egg and sperm fusion. In this study, we investigated that cell cycle–coupled changes of redistribution of IP3R1 and Ca2+- oscillatory activity in mouse zygotes. MATERIALS AND METHODS Metaphase II arrested eggs were collected from CD-1 female mouse after super ovulation induction. At 14 hr post hCG, MII eggs were collected, and artificially activated in Ca2+ free CZB medium with 10mM SrCl2 for 2 hrs. Pronuclear zygotes (PN) were collected from Strontium activated eggs at 8 hr post activation, and the first mitotic eggs were collected at 16~17 hr post activation. To identify cell cycle coupled IP3R1 redistribution, MII eggs, zygotes, and first mitotic eggs were fixed for immunostaining with anti-IP3R1antibody (CT-1) and observed on CLSM. Ca2+-oscillatory activity was monitored with fluorescence microscope with fura 2 AM after injection of cRNA of mouse phospholipase C zeta (mPLCZ). To evaluate the phosphorylation of IP3R1, anti-MPM2 and anti-IP3R1 were used for western blotting. RESULT IP3R1 were exhibited clusters with 1-2 um in diameter, near cortex area of ovulated MII eggs and highly phosphorylated, and these MII eggs represent high Ca2+ oscillatory activity more than 6 spikes per 60 min by mPLCZ injection. However, IP3R1 clusters were disappeared in PN eggs and these eggs showed very low Ca2+-oscillatory activity by mPLCZ. In mitosis I stage eggs, clusters of IP3R1 were appeared and Ca2+-oscillatory activity was reactivated slightly (2 spikes per 60 min). Less phosphorylation of IP3R1 in PN and mitosis I eggs than in MII eggs were observed. CONCLUSIONS This study introduced the redistribution of IP3R1 clusters were occurred in egg activation according to cell cycle dependent manner. Also, functional modification of IP3R1 was associated with cortical clustering of IP3R1 in cell cycle coupled Ca2+ oscillatory activity. ACKNOWLEDGEMENT This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education (NRF-2014R1A1A2056914/2017R1D1A1B03028155).

A proteomics approach identifies novel protein components of the Balbiani body.
A. Jamieson-Lucy1, M.C. Mullins1;
1Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Oocytes maintain precise cytoplasmic organization, making them an excellent system for studying cell polarity. Oocyte polarity defines the pole of the egg that is fertilized in mouse, frog, and fish, and establishes the anterior-posterior axis of frog and fish embryos. In zebrafish, oocyte polarity is initiated by the Balbiani body, a transient aggregate of mRNA, ribonucleoprotein particles (RNP), mitochondria
and other membrane bound organelles. The Balbiani body carries the germ line determinants and polarized mRNAs from the nucleus to the cortex, defining the vegetal half of the developing oocyte. The Balbiani body is conserved across many vertebrate and invertebrate species including the mouse and the fly, but its components remain poorly characterized. Only a handful of resident Balbiani body proteins have previously been identified. Analysis of these resident proteins is insufficient to explain how the Balbiani body forms and polarizes the oocyte. We isolated Balbiani bodies from zebrafish oocytes and performed mass spectrometry to define the Balbiani body proteome. Using this technique, we successfully identified over 70 replicable hits representing Balbiani body protein components. Our list includes known Balbiani body proteins and many novel proteins. This library of Balbiani body proteins is a prerequisite for a comprehensive mechanism for Balbiani body function at a protein level. Furthermore, the number of proteins identified indicates that the Balbiani body is a complex structure that requires many proteins working in concert to generate oocyte polarity. We have validated selected proteins from our proteomics library by injecting mRNAs encoding fluorescently tagged fusion proteins directly into stage I oocytes. These proteins localize to the Balbiani body, supporting our proteomics results. The ability to easily inject very early stage oocytes with mRNAs and other reagents gives us an opportunity to test additional Balbiani body properties. By injecting fluorescently tagged dextran molecules of different sizes, we found that the Balbiani body has a partial size exclusion barrier, which we speculate could aid in mRNA cargo selection. In the future, we will use this oocyte injection assay to perform structural analysis of known and novel Balbiani body proteins and to continue validating our proteomics library.

Determining the function and regulation of polymers of nucleotide biosynthetic enzymes during Drosophila oogenesis.
J.C. Simonet1, S.A. Anthony2, A.M. O'Reilly1, J.R. Peterson1;
1Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA, 2Drexel School of Medicine, Philadelphia, PA

CTP synthase (CTPS) and inosine monophosphate dehydrogenase (IMPDH) are two rate-limiting enzymes in de novo pyrimidine and purine nucleotide biosynthesis, respectively. They have been found to polymerize into filaments under conditions of nucleotide depletion or elevated demand for nucleotides in many different species and cell types. For example, these enzymes polymerize in nutrient-starved mammalian cell lines and CTPS polymerizes during normal Drosophila oogenesis, where germ cells undergo rapid cycles of endoreplication and rRNA synthesis. Our lab and other have demonstrated that CTPS assemblies are present during Drosophila egg development and we are using this model system to understand their function and regulation. We also recently reported that, IMPDH filament assembly has no effect on its biosynthetic activity, either as a purified protein or cultured cells. By contrast, others have found that filament assembly of CTPS can either inhibit or enhance activity of the enzyme, depending on the species. We hypothesize that assembly of these enzymes into filaments may regulate some other aspect of their biological function unrelated to their catalytic activity. We are currently examining this question in different ways for each of these two enzymes. For IMPDH, I am utilizing transgenic flies expressing human IMPDH2 constructs that either inhibit or promote filament assembly without altering enzyme activity to functionally rescue mutants of the Drosophila IMPDH gene. Human IMPDH rescues the impaired fertility of Drosophila IMPDH mutant flies equally whether it can form filaments or not, which means that its ability to form filaments is not necessary for its role in Drosophila egg development. Along with our recent discovery that IMPDH mutants that cannot form filaments have similar catalytic activity to those that do, this indicates that both in vitro and in vivo
filament formation has no effect on the catalytic activity of IMPDH. For CTPS we are screening genes involved in nucleotide biosynthesis, endoreplication, cell proliferation, and growth to find regulators of CTPS filament formation during Drosophila oogenesis in order to understand how CTPS assembly and disassembly is regulated and what is its biological function during oogenesis.

Membrane rafts regulate acrosome reaction via glucose signaling pathways in chicken sperm.
A. Ushiyama¹, A. Tajima², N. Ishikawa², A. Asano²;
¹Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan, ²Faculty of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan

Sperm possess compartmentalized metabolic and signaling pathways in specific regions of cells poised to function when needed. However, little is known about how multiple different pathways are orchestrated to function in different spatial and temporal scales for achieving fertilization. Previous studies of ours and others demonstrated in mammalian sperm that membrane rafts play roles in the multistage process of fertilization, including acrosome reaction. Beyond class, we recently demonstrated the presence of membrane rafts in sperm head region of avian sperm. This motivated us to perform quantitative proteome comparison between rafts and non-rafts in chicken sperm, which enabled us to find prominent association of glucose transporter 3 (GLUT3) with membrane rafts. In fact, glucose has been known to be beneficial to sperm of some mammalian species for supporting flagellar motility and optimal acrosome reaction. However, the effect of glucose on these functions are not known in any avian sperm. These combined with the fact of extremely high glucose content in chicken uterine fluid, led us to investigate the roles of glucose in regulation of chicken sperm functions with focus on the functional interaction of GLUT3 with membrane rafts. Localization and western blot experiments showed the presence of GLUT3 in the flagellum and acrosomal region. Sharp association of GLUT3 with membrane rafts was confirmed by comparison of low density detergent-resistant membrane protein from sperm depleted with/without sterols. Characterization of the roles of glucose on sperm functions showed that glucose stimulated acrosome reaction in response to inner peri-vitelline layer treatment by taken-up via glucose transporter(s) while flagellar motility was not influenced. However, glucose uptake was significantly inhibited by AMPK inhibitor treatment or alteration of membrane rafts by sterol depletion treatment, which resulted in diminution of acrosome reaction. APMKα is known to be abundant in the midpiece and acrosomal regions. To gain mechanistic insight into the regulation of AMPK activity, comparison of phosphorylation status of AMPKα(Thr172) was performed following by treatment with several stimulators and inhibitors under the presence of glucose, showing that glucose uptake occurs via glucose transporter(s) associated with membrane rafts and it stimulates phosphorylation of AMPKα. These results demonstrate in chicken sperm that membrane rafts regulate glucose uptake, thereby stimulating acrosome reaction via AMPK signaling pathway, and suggest its possible involvement in GLUT3 regulation. Our results provide new insight into avian sperm function as well as the roles of membrane rafts in sperm.

Intercellular communication in the mouse ovarian follicle analyzed by serial section electron microscopy.  
V. Baena¹, M. Terasaki¹;  
¹Cell Biology, University of Connecticut Health Center, Bristol, CT

Somatic cells in the mammalian ovarian follicle are intimately connected to the oocyte throughout follicular development through gap junctions. As the oocyte grows in response to gonadotropin hormones, the zona pellucida is deposited, creating a physical barrier 3-4 um-thick between the oocyte and the surrounding cells. Cumulus cells maintain their connection with the oocyte through cytoplasmic projections known as transzonal projections (TZPs), which transverse the zona pellucida and make gap junctions and adherens junctions with the oocyte surface. We used serial section electron microscopy to analyze TZPs and their relationship to other structures in mouse preovulatory follicles. We found that TZPs frequently interact with each other, and with oocyte microvilli. On average, each cumulus cell sends 9 TZPs that connect to the oocyte and 33 that are free-ended. Interestingly, cumulus cells send most of their cytoplasmic projections toward the oocyte, and virtually none away from it. Additionally, we found that mural granulosa cells in preovulatory follicles have cytoplasmic projections that resemble TZPs morphologically but are oriented toward other mural granulosa cells with no apparent preferred orientation. These projections are thin (76.1 nm in diameter), short, of approximately the width of the zona pellucida (3.3 um in length), and abundant (24 per cell). They often end on the surface or inside invaginations of neighboring cells, and can make gap junctions or annular junctions at the endings. In cell culture, mural granulosa and cumulus cells can interconvert depending on their proximity to an oocyte. We suggest that the somatic cells of the follicle use filopodia that are ~3-4 um in length to determine where they are in relation to the oocyte. The default state is the mural granulosa cell. If the cell contacts the oocyte, it directs its filopodia towards the oocyte and acquires the characteristic phenotype of the cumulus cell.

Guidance of stem cell niche assembly, position, and architecture.  
L. Anllo¹, L. Wingert¹, S. DiNardo¹;  
¹Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Stem cells are required for renewal and regeneration of damaged or aging tissue. Intricate signaling between the niche and its resident stem cells is necessary to accomplish these tasks. Signaling requires intimate contact with a well-designed niche: one positioned accurately in the tissue, and with its constituent cells well-organized. Unfortunately, there are few cases where niche morphogenesis can be studied at the necessary resolution. **For this reason I have chosen to study niche morphogenesis in the Drosophila male gonad.** The eventual function of this niche is well defined, and has served as a paradigm in niche-stem cell biology. Furthermore, our lab recently pioneered live-imaging morphogenesis of the niche during embryogenesis. We capitalized on visualizing niche assembly to uncover candidate tissues that could be the source for signals that organize niche formation. Imaging revealed that the niche was located near the trachea, an alary muscle, and the visceral mesoderm, all of which are known to send developmental regulatory signals. We genetically ablated each of these tissues in turn, and discovered that the visceral mesoderm (Vm) was the tissue producing a guidance cue. To identify the potential guidance signal, I screened an extant database (http://fly-fish.ccbr.utoronto.ca/)
for signaling genes expressed within the Vm, and identified candidates such as Netrin, Wunen, and Neurotrophic factor. I am currently engineering strains that will allow me to knockdown these candidates to test for roles in guiding niche placement. In summary, I have identified a tissue source that guides niche assembly, and I have identified candidate signals that might be used for this purpose. This research represents the first work describing how the stem cell niche is positioned correctly during its development, and thus will bridge an important gap in our knowledge of stem cell-niche biology.

The Misshapen kinase is Essential for Normal Expansion and Stability of the Germline Ring Canals in the Developing Drosophila Egg Chamber.
A.N. Kline, T. Curry, L. Lewellyn;
1Biological Sciences, Butler University, Indianapolis, IN

Intercellular bridges allow for the transfer of materials between neighboring cells. These connections are essential for the normal development of gametes in organisms from fruit flies to vertebrates; defects in intercellular bridges can lead to infertility. The developing Drosophila egg is an excellent model system to study intercellular bridges. Each fly egg develops from a multicellular structure called an egg chamber; the egg chambers is composed of a central cluster of germ cells surrounded by a layer of somatic epithelial cells. The germ cell cluster contains 16 cells (1 oocyte and 15 nurse cells) that are connected to each other through intercellular bridges called ring canals. Ring canals are actin-rich structures that arise through incomplete cytokinesis during formation of the germ cell cluster, and they are essential to allow the transfer of materials from the nurse cells to the developing oocyte. During stage 11 of oogenesis, the nurse cells rapidly transfer their cytoplasmic contents to the oocyte, doubling its volume in 30 minutes. To accommodate this transfer, the ring canals undergo a significant expansion to reach a final diameter of ~10 µm. Although a number of structural and regulatory components have been identified, there is still much to be learned about ring canal formation, stabilization, and expansion. We have identified a novel role for the Misshapen (Msn) kinase in regulating the growth and stability of the ring canals. Depletion of Msn by RNAi leads to over-expansion and instability/collapse of the ring canals without disrupting the recruitment of other ring canal components, such as Cheerio, Hts-RC, and Kelch. Over-expression of Msn leads to reduced ring canal diameters, whereas over-expression of a membrane-tethered form of Msn leads to ring canal collapse and the formation of multinucleate nurse cells. Therefore, regulation of Msn levels and localization are essential for the stability and expansion of the germline ring canals. Future studies will determine whether Msn acts with other known ring canal components to promote proper growth and stability of these intercellular bridges.

Mitochondrial protein ATAD-3 facilitates germ granule formation in C. elegans embryo.
X. Fan, Y. Wu, E.E. Griffin;
1Biological Sciences, Dartmouth College, Hanover, NH

Germ granules are RNA/protein assemblages that contribute to the specification and proliferation of germ cells in animals (Voronina, 2011). Germ granules are not membrane bound, are enriched in intrinsically disordered proteins and exhibit properties of phase separated liquid droplets (Brangwynne, 2009). Interestingly, germ granules are commonly found in association mitochondria and the
endoplasmic reticulum, although neither the molecular basis nor the importance of these associations are understood (Voronina, 2011; Kloc 2014). In the C. elegans zygote, germ granules (called P granules in C. elegans) concentrate in the posterior cytoplasm due to their disassembly in the anterior and assembly/stabilization in the posterior (Brangwynne, 2009; Gallo, 2010). In order to begin to dissect the relationship between P granules and the ER and mitochondria, we followed the dynamics of these organelles in live embryos using both spinning disk confocal microscopy and lattice light sheet microscopy (at the Janelia Farm Advance Imaging Center). We find that P granules are persistently associated with and move in accordance with both mitochondria and the ER in the zygotic cytoplasm. Through a candidate RNAi screen, we identified the conserved mitochondrial AAA+ ATPase, ATAD-3, as a regulator of P granule dynamics. Mammalian ATAD-3 spans both the inner and outer mitochondrial membranes exposing a ~50 amino acid, intrinsically disordered N-terminal domain to the cytoplasm, where it has been proposed to mediate interactions with the ER (Gilquin, 2010; Issop, 2014). We find that endogenously tagged ATAD-3::OLLAS is uniformly distributed on mitochondria in the worm zygote. In atad-3(rna) embryos, we find that both the number and size of P granules are significantly reduced. ATAD-3 was previously shown to co-precipitate with MBK-2 (Chen, 2016), a kinase that stimulates the disassembly of P granules (Smith, 2016; Wang, 2014). Mutation of a predicted MBK-2 phosphorylation site in the N-terminus of ATAD-3 (T12A) results in a significant increase in the size and number of P granules and causes their distribution to spread further towards the anterior relative to wildtype embryos. Strikingly, when expressed as a transgene, the ATAD-3 N-terminus (ATAD-3(aa1-46)::mKate) is diffusely cytoplasmic in wild-type embryos but concentrates on the ER in mbk-2(rna) embryos. Based on these findings, we conclude that the mitochondrial protein ATAD-3 promotes the growth/stabilization of P granules and speculate that this activity may be inhibited by MBK-2 phosphorylation. We are currently testing whether ATAD-3 regulates P granule dynamics through direct interaction with P granule components and/or by mediating ER/mitochondrial contacts that could, in turn, help stabilize P granules.

Utilization of the auxin-degradation system to eliminate P granules in C. elegans.
E.A. Marnik¹, C. Sharp¹, D. Updike¹;
¹MDI Biological Laboratory, Bar Harbor, ME

In C. elegans, germ granules, known as P granules, play a critical role in maintaining germline pluripotency. However, much remains unknown about how P granules carry out this function. One limitation has been the ability to deplete P granules completely due to redundancy in P granule proteins and technical limitations of RNAi. Recently our lab has tried to circumvent this issue by using the auxin-degradation system to degrade essential P granule proteins in C. elegans. Normally, in plants, Auxin combines with TIR1 to degrade any proteins with a degron sequence. For our research, we obtained a C. elegans strain with Tir1 under the control of a germline promoter. Then, using CRISPR, we engineered degron sequences onto critical P granule genes. Degradation of targeted P granule proteins was seen within four hours of auxin exposure, confirming that the auxin-degradation system can be used to target P granules in the germline of C. elegans. This technique now enables us to improve our research into how P granules help maintain germline pluripotency.
Ovaries from diabetic mice exhibit loss of follicles leading to reproductive failure.
E. De Jong1, C. Hart3, E. Yong3, A. Becker3, J. Fellmeth1;
1Biology, Hamilton College, Clinton, NY

Non-insulin dependent (type 2) diabetes is characterized by a cell’s inability to efficiently process insulin, which results in high blood glucose levels, also known as hyperglycemia. While glucose is necessary for the maturation of oocytes, high glucose concentrations accelerate maturation of the oocyte (Chang, Dale and Moley, 2005). These increased, yet fluctuating, glucose levels impair meiotic development and cause lower rates of ovulation by inhibiting extracellular communication (Colton, Pieper and Downs, 2002). Diabetes has been shown to affect the meiotic maturation of oocytes during folliculogenesis, resulting in reduced preimplantation embryo development and increased rates of infertility (Chang, Dale and Moley, 2005).

In the ovarian follicle, both granulosa cells and cumulus cells surround the developing oocyte. Granulosa cells support oocyte growth by secreting hormones through paracrine signaling and gap junctions within the follicle. Decreases in oocyte-granulosa cell communication impair oocyte maturation (Chang, Dale and Moley, 2005). Cumulus cells aid in glycolysis by metabolizing glucose into products that promote oocyte maturation such as pyruvate and ATP (Wang, Chi, and Moley, 2012). These products are transferred to the oocytes via gap junctions, but when there are insufficient amounts of these byproducts, oocyte development is impaired. Previous studies have shown that hyperglycemia induces mitochondrial dysfunction and apoptosis within oocytes via cumulus cells; in the ovaries of diabetic mice, less pyruvate and ATP is produced by the cumulus cells (Wang et al., 2010). The decrease in glucose uptake from the cumulus cells has been associated with meiotic defects in oocytes such as spindle abnormalities, chromosome misalignment, and double strand breaks (Blasiak et al., 2004). These genetic breakages trigger the apoptosis of the cells, which reduces the ovulation rate and decreases fertility. This study examines the correlation between non-insulin dependent diabetes and the formation of oocytes by comparing the number and size of follicles in both wild type and diabetic mice.

Through histological analysis of whole mount ovaries, we have observed gross morphological defects at the organ level in diabetic ovaries compared to control littermates. Upon closer examination, we also identified a significant loss of primordial follicles (often referred to as the fertility pool) in diabetic mice. Future studies aim to look at earlier time points in hopes of identifying the stage where the oocytes are lost.

Only Sertoli cells cultured at high density mimic in vivo conditions.
A. Sriram1, H. Huynh1, J. Shadarevian1, D. Djaksigulova1;
1Cellular Physiological Sciences, University of British Columbia, Vancouver, BC

The seminiferous epithelium lining the seminiferous tubules of mammalian testes is comprised of Sertoli cells and germ cells. Sertoli cells are tall, columnar cells that extend from the base of the seminiferous epithelium to the tubule lumen. They play a key role in spermatogenesis by providing support and nourishment for the developing spermatogenic cells. We have been working to establish a primary culture system for studying junction turnover in morphologically differentiated Sertoli cells. The purpose of this study is to determine the optimal density of Sertoli cells in vitro for co-culture with spermatogenic cells. Sertoli cells were enzymatically dissociated from the testes of four 20-day-old
Sprague-Dawley rats and plated at low (1.3 x 10^5 cells/cm²), medium (4.1 x 10^5 cells/cm²) or high (1.3x10^6 cells/cm²) cell densities on Matrigel-coated Transwell® culture inserts. Sertoli cells were cultured in serum-free defined media (SFDM) containing hormones (FSH and testosterone), vitamins and antibiotics, and incubated at 34°C in 95% air and 5% CO₂ for a week. The cultured cells were treated with a brief hypotonic wash after two days to lyse any residual germ cells. The culture media was replenished every 48 hours. Finally, the cells were fixed and processed for TEM to determine if the Sertoli cells had a differentiated morphology as indicated by the presence of polarized cells with basally located junctions. Primary cultures of Sertoli cells cultured at high density in vitro formed a confluent layer within 24-48 hours with cells having a cuboidal to columnar shape. These cells formed areas with a monolayer interrupted by areas where cells formed focal clumps. Sertoli cells within this culture system were polarized with nuclei and junction networks located basally. The presence of ectoplasmic specializations and tight junctions as part of basal junction complexes indicated Sertoli cell differentiation in vitro. Sertoli cells cultured at low or medium cell densities formed clumps, but did not have cells between the clumps. These results suggest that a high Sertoli cell density is required for the cells to form a confluent monolayer with specialized junctions that closely mimic the blood-testis barrier in vivo.

Positive and Negative Regulation of Cell Fusion in Budding Yeast.
M.D. Rose¹,², A.E. Hall³, J.A. Smith¹,²;¹Biology, Georgetown University, Washington, DC, ²Molecular Biology, Princeton University, Princeton, NJ, ³Biology, UNC, Chapel Hill, NC

Cell fusion is ubiquitous in eukaryotic organisms. We are studying cell fusion during mating of the budding yeast, S. cerevisiae. Haploid yeast cells detect each other by pheromone signaling, polarize growth toward the partner, and then fuse to form a diploid zygote. Fusion requires removal of the cell wall between the mating cells to allow plasma membrane fusion. Because premature or mislocalized cell wall removal would lead to lysis and death, the initiation of cell fusion must be highly regulated. The signal(s) that regulates when and where cell wall degradation occurs has not been identified. Rho-like GTPases regulate cell fusion in many systems, including myoblast fusion. In yeast, the highly conserved Cdc42p promotes yeast fusion via binding to Fus2p/Rvs161p, a pheromone-induced heterodimeric amphipath. Early in mating, Cdc42p functions in pheromone signaling and morphogenesis, independent of Fus2p, and the proteins do not colocalize. Later, in prezygotes, Fus2p recruits Cdc42p to a novel focus at the center of the zone of cell fusion (ZCF). After fusion, the proteins remain colocalized on the edge of the eroding ZCF remnant. Recruitment of Cdc42p by Fus2p was dependent on the flatness of the ZCF. In fps1 mutants mating to wild-type, increased osmotic pressure caused the ZCF to be curved and Cdc42p was mislocalized. In fps1 matings to fps1, the osmotic pressure was balanced, the ZCF was flat, and Cdc42p was localized. These observations suggest that Fus2p/Rvs161p recruits Cdc42p specifically to the flattened area of the ZCF that forms between two mating cells, promoting cell wall degradation and fusion.

On the other hand, evidence suggests that the cell wall integrity (CWI) pathway negatively regulates cell fusion. Five transmembrane sensors (Wsc1-3p, Mid2p, and Mtl1p) monitor cell wall damage and activate CWI signaling. Pheromone-induced morphogenesis activates CWI signaling, and activation of the downstream kinase, Pkc1p, blocks cell fusion. Loss of one CWI-sensor, Mid2p, causes death in response to pheromone. We hypothesize that, during mating, cell-cell contact must relieve CWI signaling to allow cell wall degradation. In support, we find pheromone caused mid2 death by loss of cell wall and plasma membrane integrity at the tip of the mating projection. In mid2, Cdc42p was recruited to a focus at the tip of the shmoo, dependent on Fus2p. Mutations in cell fusion genes (FUS1, FUS2,

**Finding required genes for proper sp-ut valve function in *C. elegans***

P.G. Castaneda¹, E. Cram¹

¹Biology, Northeastern University, Boston, MA

The *Caenorhabditis elegans* (*C. elegans*) spermatheca, the site for embryo fertilization, is a tube composed of a single layer of cells that undergo cyclic stretching, constriction, and relaxation as ~150 oocytes pass through the gonad and into the spermatheca. This feature makes the *C. elegans* spermatheca an ideal model in which to explore mechanotransduction machinery in smooth muscle-like cells. The spermatheca is made up of three regions: the distal constriction, the bag, and the spermatheca-uterine (sp-ut) valve. Immediately after oocyte entry, the sp-ut valve constricts. After ~10 minutes, the bag begins to constrict, and the valve relaxes allowing the fertilized embryo to exit the spermatheca and enter the uterus. Although we have identified several genes required for transit of oocytes through the spermatheca, very little is known about the genes required for proper sp-ut valve function. To address this, we created a sp-ut valve specific RNAi strain by expressing rde-1 under a sp-ut valve specific promoter (tag-312). Additionally, we co-expressed GCaMP, a genetically-encoded calcium sensor in the sp-ut valve, to analyze calcium dynamics. Using this strain, we have conducted a candidate RNAi screen, in which we tested possible required genes and analyzed for defects in dilation or constriction timing in the sp-ut valve. We've identified several genes necessary for sp-ut valve function, including cytoskeletal regulators, gap junction proteins, and signal transduction proteins. This work will help us better understand communication between different cell types in tissue.

**Complexes regulating *C. elegans* eggshell formation and egg activation are scaffolded by a common protein.**

D. Gonzalez¹, H. Lamb¹, D. Partida¹, Z. Wilson¹, J. Prieto¹, S.K. Olson¹

¹Biology, Pomona College, Claremont, CA

Fertilization triggers rapid remodeling of the zygote surface to create an extracellular barrier that protects the developing embryo and prevents polyspermic fertilization. In nematodes, this barrier is a multi-layered eggshell that assembles in a hierarchical manner. The outermost layer of the eggshell is called the vitelline layer, which is present on the oocyte before fertilization. Immediately following fertilization, the vitelline layer lifts off the zygote and initiates remodeling of the extracellular surface. Despite its importance, little is known about the composition of the vitelline layer or how it is remodeled to form the outermost eggshell layer. A previous RNAi screen in the nematode *C. elegans* identified PERM-2 and PERM-4 as proteins required for eggshell formation. PERM-2 and PERM-4 localize to the vitelline layer and are co-dependent for proper localization based on RNAi and CRISPR null allele studies. PERM-2 and PERM-4 localization also depends on CBD-1, a protein previously shown to stabilize the EGG/CHS-1/MBK-2 complex involved in the oocyte-to-embryo transition. Interestingly, CBD-1 appears to scaffold the PERM complex and the EGG/CHS/MBK complex independently, suggesting dual roles for...
CBD-1 in eggshell formation and regulation of egg activation. Depletion of PERM-2/4 compromises the structural integrity of the outermost vitelline layer of the eggshell, but also disrupts subsequent assembly of the innermost permeability barrier that serves as the major line of defense in protecting the newly fertilized embryo.

Comparison of fertilization in the invasive zebra and quagga mussels.
M.J. Misamore1, E. Couch1, H. Quinn1;
1Biology, Texas Christian University, Fort Worth, TX

The zebra mussel (*Dreissena polymorpha*) and quagga mussel (*Dreissena rostriformis bugensis*) are two invasive freshwater mussels infesting many waterways of the eastern, central, and southwestern United States. Key to their remarkable spreading is their reproductive strategy. Unlike most North American freshwater bivalves, dreissenid mussels broadcast spawn gametes directly into the water column where fertilization and larval development occurs – a strategy common among marine bivalves. This objective of this study is a direct comparison of fertilization and early development between these two closely related species. Light, fluorescent, and electron microscopy techniques are used to observe the various stages of early development. Reproductive features compared include egg and sperm morphology, sperm-egg binding, sperm entry and egg activation, pronuclear formation, cleavage and early larval development. As previously reported, there are observable differences in sperm morphology, particularly the curved cell body of quagga mussel sperm. We observed numerous differences in egg morphology as well, including egg surface carbohydrates, cortical granules, and egg jelly layer. Sperm binding occurs perpendicular to and uniformly across the egg surface in both species. Sperm rotation occurs during entry with quagga mussels exhibiting a more dramatic wobble along the perpendicular axis due to their curved sperm morphology. Sperm entry and rotation within the egg cortex is similar. A microtubule bundle is observed linking the polar body with the female pronucleus. Timing of pronuclear formation and early cleavage events is reported. The question of hybridization potential between the species is also addressed. Fertilization and early development had many similarities between these two congeneric species, however, several prominent morphological and mechanistic differences were also observed.

Localization of N-terminally arginylated beta-actin in mouse oocytes.
S. Kurosaka1, T. Mitani1, Y. Hosoi1;
1Institute of Advanced Technology, Kindai University, Kainan, Japan

Protein arginylation is a posttranslational modification mediated by arginylationtransferase (Ate1), and plays essential roles in functions of cells, tissues, and organs. Gametogenesis is not an exception. In conditional knockout studies, Ate1 depletion affected the reproductive ability of mice (Leu et al., PLoS One, 2009; Brower et al., PLoS One, 2009; Liu et al., J Biol Chem, 2016). While it is reported that male infertility is due to apoptosis in Ate1-depleted germ cells (Liu et al. J Biol Chem, 2016), the effect of Ate1-depletion on female germ cells is still unknown, though it is suggested that premeiotic depletion of Ate1 causes the production of defective gametes (Leu et al. PLoS One, 2009). A hypothesis is that arginylation play a role in female gametogenesis via cytoskeleton for following reasons: 1) abnormal chromosome segregation during the first meiosis is the major cause for uneuploidy in oocytes, 2) While
microtubule is the main component of meiotic spindle, actin filament has an important role in meiosis as well, 3) lack of arginylation affects actin cytoskeleton in mouse embryonic fibroblast (MEF) (Karakozova et al., Science, 2005), and 4) aneuploidy occurs frequently in Ate1 knockout MEF, suggesting that arginylation affects chromosome segregation machinery (Rai et al., Oncogene, 2015). Here, for the first step to investigate the role of arginylation in female gametogenesis, we assessed the expression and localization of Ate1 and arginylated beta-actin (R-b-Actin) are by immunocytochemistry in oocytes at germinal vesicle (GV), metaphase I (MI), and metaphase II (MII) stages. Diffusing signal for Ate1 is detected in the entire cytoplasm of oocytes at all stages examined, suggesting that proteins can be arginylated in oocytes at these stages. Short filamentous signal for R-b-actin is detected in the entire cytoplasm of GV stage oocytes, as well as non-arginylated beta actin. At MI stage, the R-b-actin signal accumulated and formed spindle shape around chromosomes, and this localization at the spindle is more dramatic compared to non-arginylated beta-actin, strongly suggests that R-b-actin has a distinctive role at the first meiosis. At MII stage, diffusing and non-filamentous signal for R-b-actin was observed in entire cytoplasm, and accumulation at meiotic spindles was not as clear as M1 stage. These results suggest that protein arginylation is involved in the mechanisms for normal chromosome segregation during first meiosis in oocytes, and could be the initial step of novel understanding of germ cell research toward arginylation-based treatment for female infertility and improvement of animal production.

Sugar Cane Extract (SCE) influence steroidogenesis in the testicular interstitial cell of Japanese quail.

S. Pu¹,², M. Mizu³, T. Furuta³, K. Nagaoka¹,², G. Watanabe¹,²;
¹United Graduate School of Veterinarian Sciences, Gifu University, Gifu, Japan, ²Department of Veterinary Medicine, Tokyo University of Agriculture and Technology, Tokyo, Japan, ³Research Development Division, Mitsui Sugar Co., Ltd., Tokyo, Japan

Sugar Cane Extract (SCE) is the residue after removing glucose, fructose and sucrose from molasses, which has been proved wide range of biological effects, including deodorization, anti-inflammatory and anti-oxidative, and already used in animal feed. Our pervious studies found SCE feed decrease male quail testis weight and cloaca gland size, however the mechanism underlying this phenomenon is still unknown. Here we show the effects of SCE on gonad function in male quails with testosterone concentration in serum decreased, and corticosterone increased. Steroidogenic enzymes P450c17, 17βHSD and 3βHSD expression in the testis showed dose dependent decrease. Immunofluorescence staining showed decreased aromatase and 3β-HSD after feeding SCE in the testis. Later, testicular interstitial cells were isolated and cultured with SCE and oLH; testosterone secretion as well as 3βHSD gene expression was suppressed by SCE. We propose a model in which SCE influences male quail gonadal function by suppressing the expression of 3β-HSD in testicular interstitial cells.
Patagonian blenny (Eleginops maclovinus) spermatozoa characterization and quality markers evaluation under chilling storage.

P. Ulloa¹, P. Contreras², K. Dumorne¹, M. Lee-Estevez¹, E. Figueroa², I. Valdebenito³, J. Risopatron², J.G. Farias¹;
¹Chemistry Engineering, Universidad de La Frontera, Temuco, Chile, ²Center of Biotechnology in Reproduction (CEBIOR-BIOREN), Universidad de La Frontera, Temuco, Chile, ³School of Aquaculture, Catholic University of Temuco, Temuco, Chile

Patagonian blenny (Eleginops maclovinus; known in Chile as robalo) population has been decreasing due to overexploitation. Little is known about the reproduction behavior of robalo, and even less about its reproduction biology. Fish sperm of several other teleost are described in literature, but research regarding fish sperm from native species from Chile is only beginning. Understanding the ability for Patagonian blenny sperm to sustain short-term storage is a key step to carry out artificial propagation of this species. In this aspect, characterization of the spermatozoon, evaluation of sperm function markers (membrane and DNA integrity; reactive oxygen species generation; mitochondrial membrane potential; dynamics of the ATP content; oxygen consumption), and also evaluation of the pH and osmolarity of the extracellular medium during chilling storage could be highly helpful for designing an in vitro management protocol for Patagonian blenny. The objective of this study was first to characterize the male gametes of this marine fish species with potential for aquaculture and then to evaluate the sperm function markers under chilling storage. Patagonian blenny spermatozoon structure and ultrastructure are consistent with spermatozoon from modern teleost with external fertilization, measuring ~40 μM length, a head of ~0.8 μM diameter, and containing 3 to 5 spherical mitochondria. Semen contains ~15×10⁹ spz mL⁻¹, an osmolarity of ~345 mOsm kg⁻¹ and pH of ~7.5. Analyses of sperm function were done during 14 day cold storage, under diluted (1:1 with Cortland solution) and undiluted conditions. The use of Cortland solution do improve the storage time from 3 to 7 days approximately, allowing better gas exchange, preventing desiccation and keeping membrane integrity better. Factors that affect most the storage time are reactive oxygen species (ROS) generation and unwanted motility process activation during storage, produced probably by osmolarity and ion content differences. In conclusion, Patagonian blenny semen is obtainable and manageable in vitro without sacrificing males, and can be stored to aid aquaculture of this species. Tools used in this research are useful for fish sperm analysis to include new species to aquaculture.

A universal feature of early oocyte differentiation is formation of the Balbiani body (Bb), a large prion-like amyloid aggregate of specific mRNA-protein (mRNP) granules and organelles. The zebrafish Bb
establishes oocyte animal-vegetal polarity by specifying the oocyte vegetal pole. The Bb has been observed for two centuries, but how it forms and is asymmetrically positioned was unknown. Using quantitative image analysis, we traced oocyte symmetry breaking to a nuclear asymmetry at the onset of meiosis called the chromosomal bouquet. The bouquet is a universal feature of meiosis where all telomeres cluster to one pole on the nuclear envelope (NE). Telomere movements and clustering on the NE facilitate chromosomal pairing and meiotic recombination. We show that Bb granules first localize with the centrosome to the cytoplasm apposing the bouquet telomere cluster. They then aggregate around the centrosome in a specialized nuclear cleft that we identified, assembling the early Bb. We found that the bouquet nuclear events and the cytoplasmic Bb granule localization are mechanistically coordinated by microtubule. Thus, the animal-vegetal axis of the oocyte is aligned to the nuclear axis of the bouquet. This symmetry breaking lays upstream to Bucky ball, the only known regulator of Bb formation. However, Bucky ball, a prion-like protein, is then required for Bb granule nucleation around the centrosome, forming the mature Bb, and showing that oocyte polarization utilizes prion-like mechanisms. We link two universal features of oogenesis, the Bb and the chromosomal bouquet, to oocyte polarization, and propose that the bouquet centrosome functions as a cellular organizer that we term the Centrosome Organizing Center (COC), coupling meiosis and oocyte patterning and controlling prion-like nucleation. We next revealed that oocytes are organized in cysts with synchronized COCs. We discovered bouquet specific primary cilia that may synchronize and mechanically regulate cyst COCs. Moreover, the COC localizes near cytoplasmic bridges that connect sister cyst oocytes, suggesting its positioning by a previous mitotic division plane. These results link oocyte polarity to cyst organization. We uncovered a cellular organizer that integrates multiple processes of mitosis, meiosis, cilia biology and prion-like mechanisms in the early differentiating oocyte.

High saturated-fat diet induces hypercholesterolemia and impairs sperm motility in the Mongolian gerbil.

A.C. Negrin¹, M. Marcielo De Jesus¹, M.E. Pinto-Fochi², R.M. Gões¹,²;

¹Department of Structural and Functional Biology, University of Campinas (IB/UNICAMP), Campinas, Brazil, ²Department of Biology, State University of São Paulo (IBILCE/UNESP), Sao Jose do Rio Preto, Brazil

Long term high-fat diet consumption leads to hyperlipidemia and obesity. Clinical and experimental data have shown that high fat intake or obesity alters steroid hormones and affects sperm motility and reproductive capacity. However, the influence of a particular lipid composition on testicular function is largely unknown. The present study investigated the effects of a high-saturated-fat diet (HSF) on the sperm parameters and steroidogenic function of gerbils (Meriones unguiculatus) and their relationship with metabolic alterations. Male gerbils (4w old, n=10 animals/group) were fed a balanced diet (C group) or a HSF containing 31% of lard (D group), for 12 weeks. The main endpoints evaluated were the adiposity index, blood lipid profile, serum and intratesticular testosterone (T) and 17β-estradiol (E₂) levels, sperm parameters, testicular apoptosis index and testicular expression of liver X receptor α (LXRα) and peroxisome proliferation activated receptor γ (PPARγ). HSF raised body weight by about 7% and the adiposity index by 26%. These alterations were due to an increase in retroperitoneal (C: 794±300; D: 1015±351mg) and visceral (C: 140±67; D: 213±122mg) fat deposits. HSF also altered the lipid profile, increasing total cholesterol and non-HDL cholesterol levels (C: 60.8±11.5; D: 99±15.3mg/dL and C: 25.5±5.2; D: 53.1±14mg/dL, respectively). No changes were detected in serum T and E₂ levels. However, intratesticular T level was lower (C: 6.4±2.7; D: 3.9±1pg/mL) and intratesticular E₂ level was

---

Sunday-475
higher in D group (C: 18.2±11; D: 33.3±9.9). HSF did not affect daily sperm production nor sperm reserve in the cauda of the epididymis, but impaired sperm motility, reducing the number of spermatozoa with progressive movement (C: 60.7±5.7; D: 48.9±5.8) and increasing the number of spermatozoa with non-progressive movement (C: 17.5±3.7; D: 25.7±5.8) and immotile spermatozoa (C: 19.9±5.4; D: 25.4±4.4). The number of apoptotic cells in the testes increased in D group (C: 2.7±0.4; D: 3.7±0.5cells/mm²). Additionally, HSF did not alter the testicular expression of PPARγ but enhanced LXRα by about 63%, an important regulator of lipid homeostasis and cholesterol uptake. These findings suggest that other mechanisms are involved in steroidogenesis regulation under HSF that not those mediated by PPARγ and LXRα. In conclusion, HSF causes perturbations in testicular steroidogenesis of the gerbil, favoring estrogen production without impacting on circulating steroid levels. Moreover, HSF does not alter sperm production in this rodent but impairs sperm motility, an important parameter of semen quality, indicating that alterations in cholesterol metabolism are prejudicial to reproductive capacity. Focal adhesion proteins, vinculin and integrin β5, during early pregnancy in rat uterine epithelial cells: Anastrozole favors their normal distribution.
A. Mwakikunga¹, G.A. Adefolaju², L. Schepartz¹, M. Hosie¹,³;
¹Anatomical Sciences, University of the Witwatersrand, Johannesburg, South Africa, ²Pre-Clinical Sciences, University of Limpopo, Pietersburg, South Africa, ³Anatomy, Newcastle University Medicine, Johor, Malaysia

An alternative superovulator to replace clomiphene citrate is needed as clomiphene citrate is associated with low pregnancy rates. Anastrozole is an effective superovulator, but it has not been well researched. In order to determine the effectiveness of anastrozole as a superovulator and to compare it with clomiphene citrate in similar situations, this study ascertained the effects of these drugs on the expression of the focal adhesion proteins, vinculin and integrin β5, which are uterine receptivity markers, in the uterine epithelial cells of day 1 and day 6 pregnant Wistar rats. The results show that vinculin and integrin β5 are co-localized at the base of the uterine epithelium at day 1 of pregnancy whereas at day 6, they disassemble from the basal focal adhesions and co-localize and significantly increase their expression apically (p<0.0001). Moreover, there is a significant difference in the protein expression levels of vinculin and integrin β5 in uterine luminal epithelial cells between untreated (control) and clomiphene citrate treated rats (p<0.0001), anastrozole and clomiphene citrate treated rats at day 6 (p<0.0001) suggesting the interpretation that anastrozole seems to enhance their expression in order to perhaps assist in the implantation process of the blastocyst. The immunofluorescence experiments agree with the vinculin and integrin β5 gene expression findings in which at day 6 of pregnancy, vinculin and integrin β5 gene expression are significantly up-regulated in uterine luminal epithelial cells in the anastrozole treated group relative to the calibrator sample (p<0.0001). These findings suggest that anastrozole is implantation friendly.

Role of integrin-linked kinase in melanocyte development.
M. Crawford1, L. Dagnino1;
1Physiology and Pharmacology, University of Western Ontario, London, ON

Integrin linked kinase (ILK) is a scaffold protein essential for epidermal integrity and permeability barrier function, as well as hair follicle development. However, the role of ILK in other epidermal cell types, such as melanocytes, remains unexplored. To determine the roles of ILK in melanocytic lineage cells, we generated a reporter mouse model that allows conditional Ilk gene inactivation in melanocytic cells, and their identification through green fluorescent protein (GFP) expression. During mouse embryogenesis, melanocyte precursors, termed melanoblasts, are formed from neural crest cells which begin to migrate towards the skin around embryonic day (E) 9. By E16.5, melanoblasts have homed to the epidermis and to developing hair follicles. To investigate if ILK is necessary for melanoblast migration and homing to the skin, we purified and quantified cutaneous melanoblasts from E15.5 embryos, using fluorescence activated cell sorting. We found a 60% reduction in the number of ILK-deficient melanoblasts compared to the abundance of ILK-expressing cells. Similarly, analysis of interfollicular epidermis in E17.5 embryos revealed a 50% decrease in the number of ILK-deficient cells relative to ILK-expressing melanoblasts. Significantly, ILK-deficient melanocytes were virtually undetectable in the interfollicular epidermis of E20.5 animals, indicating that ILK is implicated in embryonic melanoblast proliferation, migration, and/or survival. To further explore this possibility, we used primary melanocyte cultures to determine the effects of Ilk gene inactivation on proliferation and motility. ILK deficiency results in a decrease in the fraction of melanocytes that express the proliferation marker Ki67, from 45% in normal melanocytes, to 17% in ILK-deficient cells. Using live-cell videomicroscopy to assess motility over a 16-h interval, we determined that ILK-deficient cells exhibited a 3.5-fold decrease in distance travelled and speed, compared to ILK-expressing cells. Melanocytes respond to integrin stimulation by laminin-332 by forming dendrites, which are necessary for the transfer of melanin granules to adjacent cells. In the presence of laminin-332, 83% of ILK-expressing cells formed dendrites, with an average of 4 dendrites/cell. In contrast, 60% of ILK-deficient cells were dendritic, but with an average of 2 dendrites/cell. Together, our results show that ILK is essential for normal migration and/or maintenance of embryonic melanoblast populations in vivo, and for postnatal melanocyte proliferation, motility, and ability to respond to laminin-332.

The role of Wolf-Hirschhorn Syndrome related genes in Xenopus development.
A. Mills1, R. Cella1, F. Kim1, M. Selig1, L.A. Lowery1, S. Lee1;
1Biology, Boston College, Chestnut Hill, MA

Wolf-Hirschhorn Syndrome (WHS) is a neurodevelopmental disorder caused by a deletion or microduplication on the short arm of human chromosome 4. Mutations within this critical region result in craniofacial malformations, heart and skeletal defects, intellectual deficits, seizures, and microcephaly. Five genes are contained within this region; TACC3, NELFA, WHSC1, LETM1 and FGFR3. While the function of many of these genes has already been characterized, their role in early embryonic development and in relation to WHS still remain unknown. In order to investigate the function of each gene we have designed knockdown strategies to reduce gene function and observe phenotypic
differences in the context of neurodevelopment using Xenopus laevis. First, we performed whole-mount in situ hybridization in order to show the localization of each gene during different developmental stages. Here, we demonstrate that these five genes show variable expression during embryonic development with enrichment in the pharyngeal arches, craniofacial region and neural tube. Previously, we hypothesized that several of the symptoms associated with WHS may be due to disrupted neural crest cell migration, leading to the craniofacial abnormalities seen in WHS patients. Thus far, we have found that knockdown of each individual gene causes variable craniofacial malformations, as well as aberrant neural crest cell migration. We have also previously characterized the function of TACC3 as a microtubule plus TIP (+TIP), which promotes axon elongation and regulates microtubule dynamics, and unpublished work from our lab suggests that TACC3 may also function during neural crest cell migration. Further, we have also performed whole-mount immunohistochemistry in order to observe brain morphology and we have found that knockdown of WHSC1, TACC3, and NELFA results in decreased forebrain size. Together, these results help to further characterize the role of these five genes during early embryonic development, as well as elucidate their role in relation to Wolf-Hirschhorn Syndrome and neural crest cell migration.

Using Drosophila denticles as a model system to investigate the role of cytoskeletal proteins in the formation of actin-based protrusions.
H. Majer1, B. Allen1, J.L. Sallee1; 1Biology, North Central College, Naperville, IL

The formation of actin-based protrusions, such as the denticles in Drosophila melanogaster, requires the coordination of extensive actin-associated proteins to crosslink and bundle actin filaments. Mutations in such proteins can cause defects in the shape, structure, and function of actin-based protrusions and provide us with information on the molecular mechanisms of their function. Our goal was to establish a method for systematically examining denticle size and shape in order to compare the function of a variety of genes in the formation of these protrusions. Here, we examined the mutants of several genes known to cause bristle and wing hair defects for their effect on denticle morphology. Cuticle preps of late stage embryos from loss of function alleles of singed, forked, twinfilin, flare, and ck/MyoVIIA were examined for their overall denticle morphology (shape) as well as for the height and widths of the denticles. Single mutants, ck; twinfilin and ck; flare double mutants, and snf; ck triple mutants were compared to determine if combinations of the genes might show genetic interactions. Although severe phenotypes were observed in bristles and wing hairs, singed, forked, twinfilin and flare mutants showed mild denticle defects suggesting that the stage of development and potential interactors present at that stage might influence the effect on the actin-based protrusions. Combination of the alleles with the loss of ck did not enhance all of the phenotypes and denticles of multiple mutants often looked similar to ck mutants.
The patterns of earliest cell divisions in a vertebrate embryo define later developmental events such as gastrulation, organogenesis, and the establishment of an overall body plan. Thus, understanding how early division patterns are regulated is critical for the study of vertebrate development. Here, we utilized an easily tractable vertebrate model, zebrafish, for single cell lineage tracing to examine the role of spindle placement in embryonic cellular patterning. Our studies identified a relationship between cell size and spindle positioning that regulates cell placement. We first found that embryonic cells decrease in size by approximately half following each round of division for the first six cell cycles post-fertilization. Throughout these divisions, spindle size remains relatively constant. We found this to be conserved in an invertebrate embryo, C. elegans, where cell diameter decreased to a greater degree compared to spindle length during the first ten cell divisions. We then found that during the first five rounds of zebrafish cell division a 2-D pattern of one-tiered cell arrays are formed. These cells are primarily elongated along the X-Y axis, which the spindles align to, with minimal elongation along the Z-axis. However during the sixth round of division, spindles position along the cells’ Z-axis, resulting in a two-tiered cell structure. During the sixth round, the cellular X-Y axis is no longer elongated compared to the Z-axis. Thus, our studies suggest a shape-sensing mechanism realigns the spindle from an X-Y axis alignment to the Z-axis. We find that astral microtubules, microtubules that extend from mitotic spindle poles towards the cell cortex, play a pivotal role in this process. A metaphase cell astral microtubules do not contact the cell cortex during the first five-rounds of division, but as the cell diameter decreases, astral microtubules from one mitotic spindle pole asymmetrically contacts the cell cortex closer to the yolk. These studies suggest that asymmetric astral microtubule contact at the cell cortex allows for spindle orientation away from the yolk boundary creating a two-tiered cell array.

Fundamental mechanisms of spindle assembly and subcellular scaling have been elucidated using cell-free extracts prepared from Xenopus eggs and embryos. By generating hybrids between related but different-sized Xenopus species, we are also investigating size control mechanisms at the cellular and organismal levels, as well as the barriers that lead to hybrid inviability. X. laevis (~10 cm adult body length) are larger than X. borealis (~7 cm), but both possess diploid genomes of 36 chromosomes. In contrast, X. tropicalis has 20 chromosomes and is significantly smaller (~4 cm adults). Scaling at the organismal and genome levels is accompanied by differences in the size of the egg as well as nuclei and spindles formed in egg extracts. Despite these size differences, the close phylogenetic relationship among these species allows the production of hybrid embryos by cross-fertilization. While the hybrid produced when X. laevis eggs are fertilized by X. tropicalis sperm (l×t) is viable, the reverse hybrid (t×l) is inviable and dies at the late blastula stage. Similarly, while the hybrid produced when X. borealis eggs are fertilized by X. tropicalis sperm (b×t) is viable, the reverse hybrid (t×b) is inviable. Cross-
fertilizations between *X. laevis* and *X. borealis* are viable in both directions. We applied cell biological tools and high-throughput methods to study the mechanisms underlying hybrid inviability. Strikingly, we observed mitotic defects in both *t*.xl* and *t*.xb* hybrids starting early in development that include chromosome bridges and lagging chromosomes in anaphase. Using egg extracts, we found that paternal genomes do not impair spindle assembly. Instead, DNA sequencing revealed that specific paternal chromosomes are incompatible with the *X. tropicalis* cytoplasm and are mis-segregated during mitosis in *t*.xl* and *t*.xb* hybrids. Remarkably, these chromosomes differ between the *X. laevis* and the *X. borealis* genomes. In *t*.xl* hybrid embryos, we found that specific chromosomal loss leads to death due to unbalanced gene expression at the maternal to zygotic transition, resulting in a metabolic crisis and cell-autonomous cell death. In contrast, the different chromosomal loss in *t*.xb* hybrid embryos does not impair metabolism, but leads to exogastrulation. Mechanisms underlying chromosome loss are currently under investigation.

**DDX3 induces neural crest through activation of an Akt-Wnt signaling axis.**

M. Perfetto1,2, J. Li2,3, S. Wei1;  
1Biological Sciences, University of Delaware, Newark, DE, 2Biology, West Virginia University, Morgantown, WV, 3Clinical Laboratory, Kunming University, Kunming, China

DDX3 is a DEAD-box RNA helicase critical for normal development. Recently, mutations in DDX3 were found to be associated with multiple abnormalities including cleft lip/palate, phenotypes that are often caused by aberrant neural crest development. Here we show that knockdown of DDX3 inhibits neural crest induction in Xenopus embryos. This is accompanied by reduction in Akt activity and canonical Wnt signaling. Blocking Akt activity phenocopies DDX3 loss of function in inhibiting Wnt signaling and neural crest induction, and a constitutively active mutant of Akt rescues the neural crest induction phenotypes caused by DDX3 knockdown. These results show for the first time that a DDX3-Akt-Wnt axis is required for neural crest induction.

**Vg1 ortholog Gdf3 is required for Nodal dependent developmental processes in zebrafish.**

J.L. Pelliccia1, G.A. Jindal2,3, R.D. Burdine1;  
1Molecular Biology, Princeton University, Princeton, NJ, 2Chemical and Biological Engineering, Princeton University, Princeton, NJ, 3The Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ

The formation of mesendoderm and the placement of organs are conserved events within vertebrates that depend on the proper temporal and spatial activation of the Nodal signaling pathway—a Smad2/3 based pathway activated by the TGFβ superfamily member Nodal. In zebrafish, the two *nodal* orthologs *squint* (*sqt*, or *nodal-related 1*) and *cycllops* (*cyc*, or *nodal-related 2*) are required during blastula and gastrula stages for proper mesendoderm formation. Expression of a third *nodal* ortholog, *southpaw* (*spaw*), in the left-lateral plate mesoderm during somitogenesis is required for the proper asymmetric organization of organs such as the heart and liver. Here, we present evidence that another TGFβ ligand, Growth differentiation factor 3 (*Gdf3* or *Vg1*) is required for proper Nodal signaling during mesendoderm formation and left-right patterning in zebrafish. Using CRISPR/Cas9 techniques we have generated several mutant alleles of *gdf3*. *gdf3* is maternally supplied with restricted zygotic expression
domains emerging during gastrulation and somitogenesis. However, our gdf3 mutants demonstrate that maternally supplied gdf3 is capable of functioning for both mesendoderm and left-right patterning without being spatially restricted. Embryos lacking maternal and zygotic gdf3 lack most mesendodermal structures, resembling the phenotypes observed in cyc; sqt double mutants, or mutants lacking the Nodal coreceptor one-eyed pinhead (oeo, or EGF-CFC). While these results show Gdf3 is required for robust Nodal signaling, we show Nodal signaling is not completely abrogated, but severely attenuated. Utilizing mutants and morpholinos, we demonstrate that Gdf3 is also required for proper development of the laterality organ in zebrafish called Kupffer’s vesicle and for robust expression of spaw during left-right patterning. Collectively, our data indicate that gdf3 is important for multiple Nodal dependent developmental processes in the zebrafish embryo. We hypothesize that Gdf3:Nodal heterodimers are more potent signaling molecules than Nodal or Gdf3 homodimers.

*Drosophila Importin-7 is required for proper muscle attachment site formation.*

M.G. Zych¹, E.R. Geisbrecht¹, C. Liu², N. Odell², T. Sadikot³;

¹Department of Biochemistry and Molecular Biophysics, Kansas State University, Manhattan, KS,

²Department of Cell Biology and Biophysics, University of Missouri-Kansas City, Kansas City, MO,

³Department of Biology, Washburn University, Topeka, KS

The proper localization of proteins within cells is essential for tissue formation during the development of all organisms. Mutations that prevent or alter this normal subcellular localization may affect organismal survival and/or fitness. For example, the attachment of muscles to epidermally-derived tendon cells in embryogenesis requires the deposition of extracellular matrix (ECM) components tethered to integral complexes on the opposing surface of muscle and tendon cells. Incorrect formation these muscle attachment sites (MASs) results in muscle detachment, a loss of locomotor ability, and lethality. We previously published that embryos with mutations in moleskin (msk), which encodes for Drosophila Importin 7 (Dim7), exhibit defects in muscle-tendon attachment. Dim7 is a dynamic protein that regulates the nucleocytoplasmic shuttling of proteins in the early embryo, but also accumulates at MASs later during the process of myogenesis. Dim7 has an N-terminal Importin-beta, (IBNN) domain, an internal exportin Cse1-like (Cse1) domain, followed by an uncharacterized C-terminal region with no identifiable domains. To determine how Dim7 gets recruited into the nucleus or MAS, we generated YFP-tagged deletion mutants that remove regions of Dim7. Briefly, the Dim7-YFP deletion constructs under UAS control (UAS-Dim7ΔA-F) were recombined into a msk mutant background and examined for the distribution of Dim7 in muscle tissue under the mef2 promoter. Expression of the IBNN domain (Dim7ΔA) alone in msk mutants resulted in the strong nuclear accumulation of Dim7 without apparent muscle attachment defects. Removal of the entire N-terminus, including the IBN_N and Cse1 domains (Dim7ΔE) did not alter the overall distribution of Dim7 in muscles, but reduced the ability of the attachment site to form. These data, taken together suggest that the nuclear function of Msk may be sufficient to initiate muscle-tendon attachment, possibly through the previously identified epidermal growth factor (Egf) signaling pathway. Future experiments will test this idea by preventing the nuclear translocation of Dim7.

Using Xenopus laevis as a model for characterizing the function of C16orf52 during early embryonic development.
M.C. Lasser¹, J. Tiber¹, C. Monahan¹, S. Lee¹, A. Ostojic¹, L. Pizzo², S. Girirajan², L.A. Lowery³; ¹Biology, Boston College, Chestnut Hill, MA, ²Biochemistry and Molecular Biology, Penn State University, State College, PA

The various processes that occur during early embryonic development are extremely complex and require thousands of different genes, each of which encodes for a protein that has a distinct function. Due to the vast amount of genes within the genome, many still have not yet been characterized in the context of early embryonic development. One such gene is C16orf52, which is a protein coding gene located specifically at 16p12.1. The cell type specific functions of this gene still have not been investigated in relation to development. In order to elucidate the function of this uncharacterized gene, we have created an antisense morpholino oligonucleotide to knock down this genes function and observe phenotypic differences in Xenopus laevis. Importantly, this gene is highly conserved between humans and Xenopus laevis, making it an ideal model organism to understand the developmental mechanisms of this gene. Here, we investigate the functions of C16orf52 by knocking it down and quantifying phenotypic differences in terms of craniofacial morphology, brain morphology, and axon outgrowth patterns. Thus far, we have found that reduction of this gene results in severe craniofacial and cartilage defects, such as abnormal pigmentation, smaller eyes, smaller face, as well as abnormal mouth and nostril formation. Additionally, the knockdown of this gene results in aberrant axon outgrowth by decreasing axon length and velocity, and increasing axon retraction. Further, we have also performed whole-mount in situ hybridization to show the localization of this gene during different stages of development, as well as whole-mount immunohistochemistry to see whether the reduction of this gene alters brain morphology. Together, our results suggest that this gene may play a significant role during early embryonic development and future studies will focus on the mechanisms by which this gene regulates different aspects of craniofacial morphology, brain morphology, and axon outgrowth patterns.

Little is known about the maternal factors that function in body axis formation during vertebrate embryonic development. To identify these factors, a recessive maternal-effect mutagenesis screen was performed in the zebrafish Danio rerio. A number of mutants with defects in early developmental processes, including early morphogenesis and body axis formation were identified. One such mutant, split top exhibits a dorsalization of the embryonic axis. Clutches of embryos from split top mutant mothers are characterized by the five classic dorsalized phenotypic classes, as well as some additional defects. The mutant embryos show an expansion of dorsal markers and a corresponding reduction in ventral markers during gastrulation indicative of dorsalization. The dorsalization defects can be rescued by misexpression of either BMP2 or BMP7 ligands, or by derepression of BMP signaling by knockdown of BMP antagonists. The additional defects appear to be the result of altered morphogenesis, including
defects in epiboly progression, the process by which the blastoderm cells migrate over and surround the yolk. Mutant embryos display altered microtubule and actin cytoskeletal networks in the yolk cell, which can account for the epiboly defects observed. split top mutant embryos also appear to be defective in the cell movement process of convergence and extension. We mapped the split top mutation to chromosome 17, and identified cathepsin B, a through RNA-Seq and traditional positional cloning methods as the gene disrupted in split top mutants. This work was supported by NIH grant R01-GM56326, NIH training grant T32HD007516, the PENN-PORT training program, and by the Mississippi INBRE, funded by an Institutional Development Award (IDeA) from the National Institute of General Medical Sciences of the National Institutes of Health under grant number P20GM103476.

NLRP7's Key Role in Primate Trophoblast Differentiation.
A. Garipcan¹, B. Ozcimen², T. Onder², N. Ozoren¹;
¹Molecular Biology and Genetics, Bogazici University, Istanbul, Turkey, ²School of Medicine, Koc University, Istanbul, Turkey

Hydatidiform mole (HM), a gestational trophoblastic disease, can be explained as a pregnancy with no or improper embryo development and abnormal trophoblast proliferation. NLRP7, a member of NOD Like receptor family, which takes part in innate immunity, was identified as the first causative gene of recurrent HM. Very little is known about the function of NLRP7 in inflammation whereas its mechanistic contribution in HM formation is still unknown. To elucidate NLRP7's function in HM, we generated induced pluripotent stem cells (iPSC) from a patient who carries a heterozygous NLRP7 and NLRP2 deletion (NLRP7+2Δ). This strategy allows us to overcome the ethical considerations in working with human embryonic tissues and primary trophoblast cells and we also circumvent the inability to perform in vivo animal experiments since rodents lack NLRP7. Patient’s primary fibroblast cells were successfully converted to iPSCs using non-integrating episomal strategy and iPSCs were differentiated to trophoblast cells upon BMP-4 exposure together with inhibitors of ACTIVIN and FGF2 pathways. We demonstrated that under BMP-4 conditions, cells begin to express several trophoblast markers; CDX2, CGB, HLA-G, PGF whereas they lose expression of pluripotency markers; POU5F1 and NANOG. iPSCs derived from NLRP7+2Δ have a tendency to differentiate faster and more into trophoblast cells compared to wild type cells, which is possibly the root of HM. This idea is further supported by recovery experiments showing that introduction of NLRP7 decelerates this differentiation process. In conclusion, NLRP7 appears to have a critical contribution in trophoblast differentiation during early embryo development and is an essential regulator of primate embryogenesis.

microRNA cross regulation of gene regulatory network and signaling pathways.
J.L. Song¹, N.A. Stepicheva¹;
¹Biological Sciences, University of Delaware, Newark, DE

The microRNAs are small non-coding RNAs that repress the translation and reduce the stability of target mRNAs in animal cells. microRNA-31 (miR-31) has been found to play a role in cancer, bone formation, and lymphatic development. However, the function of miR-31 in embryogenesis is not well described. We examined the role of miR-31 in early development, using the sea urchin embryo as a model. We
found that miR-31 is expressed in all stages of development and its knockdown (KD) resulted in defects in the patterning and function of the skeletogenic primary mesenchyme cells (PMCs). Using bioinformatics and luciferase reporter constructs, we identified miR-31 to repress genes within the PMC gene regulatory network (GRN). The majority of the mislocalized PMCs in miR-31 KD embryos did not express VegfR10, indicating that miR-31 regulates the ability of PMCs to respond to positioning cues. We also found that miR-31 directly suppresses Eve and indirectly regulates Vegf3 in the ectoderm. These results indicate that miR-31 coordinate suppresses genes within the GRN of PMCs and in the ectoderm to impact PMC patterning and skeletogenesis. To understand the function of miR-31 at a systems level, we used miR-31 pull down assays to identify its direct targets. This study will reveal how miR-31 cross-regulates GRNs and signaling pathways to ensure proper development. Since miR-31, GRNs, and signaling pathways are highly conserved in animals, this study will enhance the understanding of fundamental mechanisms used by a developing embryo to build its precise organization.

MicroRNA regulation of Dishevelled in early embryonic development.
N.F. Sampilo1, N. Stepicheva2, S. Zaidi3, L. Wang2, W. Wu1, A. Wikramanayake2, J.L. Song1; 1Biological Sciences, University of Delaware, Newark, DE, 2Biological Sciences, University of Miami, Miami, FL

MicroRNAs (miRNAs) are highly conserved, small non-coding RNAs that regulate gene expressions by binding to the 3’ UTR of target mRNAs and silence translation. MiRNAs are key regulators of the Wnt signaling pathway that are known to affect cell proliferation, migration, polarity and other developmental processes. This study investigates miRNA regulation of different isoforms of Dishevelled (Dsh/Dvl), an important signaling protein located upstream of β-catenin. At least three isoforms of Dvl are found in the sea urchin embryo, where they have similar spatial localization in early development but later show distinct ciliary staining in select isoforms. Using luciferase assays and site-directed mutagenesis, we demonstrated that the different isoforms of Dvl are directly regulated by miRNAs. By blocking miRNA regulation of all Dvl isoforms using miRNA target protector morpholino oligonucleotides (miRNA TP MASO), we observed dose-dependent defects of the embryonic skeleton, patterning of the skeletogenic primary mesenchyme cells, and morphological defects in the gut. We will identify the molecular mechanism of how miRNA regulation of Dvl impacts early development.

Histone Abundance Adjusts the Timing of the Zygotic Genome Activation in Drosophila.
H. Wilky1, S. Chari1, A. Amodeo1; 1LSI, Princeton University, Princeton, NJ

The mid-blastula transition (MBT) is a crucial period during embryogenesis where the embryos of many species including flies, fish, and frogs switch from fast cell cycles driven by maternal components to slower cycles dependent on zygotic transcripts. Prior to the MBT zygotic transcription is repressed and major zygotic transcription is activated during this transition. The timing of the MBT is sensitive to changes in the ratio of DNA to cytoplasm which is exponentially increasing as cells complete repeated rounds of DNA replication without growth. This lead to the hypothesis that titration of a maternally provided component against the increasing quantity of DNA may serve as a trigger to activate many downstream events. Our previous work suggests that histones may be this titrated component. Here
show that in Drosophila quantitative overexpression of the early embryonic histone pool leads to delayed cell cycle slowing and delayed gastrulation. Similarly, histone-overexpressing embryos activate transcription of many early genes more weakly and in later cell cycles than controls. Conversely, transcription is initiated more strongly and earlier in histone depleted embryos. Furthermore we explore the relationship between these changes in transcriptional levels and nucleosome occupancy on the genome. This work opens the door for more detailed molecular analysis of the interaction between histone levels, transcription factors, and the cell cycle machinery during early development.

Identifying functional domains in the histone anchor Jabba.

R.A. Stephenson¹, L. Chen¹, M. Johnson¹, M. Beller², M.A. Welte¹;
¹Department of Biology, University of Rochester, Rochester, NY, ²Institute for Mathematical Modeling of Biological Systems, Heinrich Heine University Duesseldorf, Duesseldorf, Germany

Because both excess and dearth of histones result in widespread cellular defects, histone synthesis and turnover are typically tightly controlled. Early Drosophila embryos employ a unique sequestration mechanism to regulate histone availability: histones H2B, H2A, and H2Av are transiently recruited to lipid droplets (LDs), fat storage organelles in the cytoplasm. This sequestration mediates both storage of excess histones and short-term buffering of the histone supply. A key player is the protein Jabba, which anchors histones to LDs. However, its molecular mechanism remains unknown.

We have generated a genomic Jabba transgene that restores Jabba expression to wild-type levels. It rescues histone localization to LDs, short-term H2Av buffering, and the developmental defects associated with lack of Jabba. This sets the stage for a structure-function analysis of Jabba.

To identify functional domains in Jabba, we employ two strategies: characterizing Jabba isoforms in vivo and Jabba deletion constructs in cultured cells. Using RNAseq and RT-PCR, we find that in embryos Jabba expression is dominated by three of seven predicted isoforms, namely B, G, and H. We have generated embryos expressing solely mCherry-tagged JabbaB or JabbaG fusion proteins in a Jabba null background. Both constructs localize to LDs and are sufficient to recruit histones. These results suggest that LD localization and histone recruitment are mediated by Jabba’s common N-terminal 316aa.

Using imaging and a luciferase complementation assay, we have identified distinct Jabba regions that mediate targeting to LDs and interactions with histones in Kc167 cells, respectively: Jabba[1-108] localizes to LDs, but does not interact with histones; Jabba[193-320] interacts with histones, but is diffusely distributed throughout the cell. In addition, deleting amino acids 223-248 abolishes histone binding, without compromising LD targeting.

To determine in vivo relevance, we are now testing various Jabba transgenes in flies. Jabba[1-192] and Jabba(delta223-248) localize to embryonic LDs as expected. Jabba[193-320] is undetectable in embryos, but expressed in ovaries, where it is highly enriched in the nuclei of nurse cells. Similar nuclear localization of Jabba[193-320] is observed in fat body, salivary glands, and Kc167 cells. During normal development, the cytoplasm of nurse cells is transferred to the oocyte, while their nuclei degenerate via apoptosis. We propose that Jabba localization to LDs retains histones in the cytoplasm and thus promotes their transport from nurse cells to oocyte.

The functional and structural analysis of Drosophila robo2 in axon guidance.
L.J. Howard1, T.A. Evans1;
1Biological Sciences, University of Arkansas, Fayetteville, AR

No matter the complexity of bilateral animals, axons are posed with the central problem of whether or not they should cross the midline. Roundabout (Robo) family proteins regulate many axon guidance decisions in the Drosophila embryonic central nervous system. Robo1 and Robo2 facilitate midline repulsion in response to Slit, while Robo2 and Robo3 define the lateral position of longitudinal axon pathways. In addition to these shared roles, Robo2 can also promote midline crossing of axons, an activity that is not shared by the other Drosophila Robos. My project will give me insight on molecular mechanisms of Robo2’s functional diversity as a transmembrane receptor and therefore also may apply to vertebrate species. Drosophila Robo2 plays at least three distinct roles in axon guidance in the fly embryo (midline repulsion, pro-midline crossing, and lateral positioning). Previous gain of function and genetic rescue studies suggest that the different roles of Robo2 are specified by individual immunoglobulin-like (Ig) domains within the receptor. Ig2 is required for Robo2’s pro-crossing function, while Ig1 and Ig3 are thought to regulate lateral positioning. It has been assumed (but not directly demonstrated) that Robo2 acts as a canonical cell-autonomous Slit receptor to signal midline repulsion; if so, this activity would likely require the Slit-binding Ig1 domain of Robo2.
We are using a CRISPR/Cas9-based gene replacement approach to investigate which domains of Robo2 (Ig & Fn) are required for each of its axon guidance activities. By replacing the robo2 coding region with epitope-tagged cDNAs, in which individual domains have been deleted, we are examining the contributions of each domain to receptor localization, regulation, and Robo2-dependent axon guidance outcomes. We observed a mislocalization of protein when looking at Robo2 without its Ig1 and Ig3 domains. We are also currently examining the roles of the cytoplasmic domains of Robo2 with a similar approach. Our results promise to increase our understanding of how individual receptors can contribute to multiple axon guidance outcomes during developmental wiring of the nervous system.

The role of MNL1 during neural crest cell developmental defects in mice.
H. Noh1, H. Kweon1, S. Seo1, M. Lee1, G. Oh1;
1Life science, Ewha womans university, Seoul, South Korea

MNL1 is required for development in several species and associated with human diseases having development defects. Previously, we demonstrated that mice lacking MNL1 displayed several development defects during embryonic days, especially in development defects of peripheral nerve. In addition, MNL1 (conventional) deficiency mice showed hypopigmentation on their belly and limbs. This phenotype is caused by a depletion of melanocytes that are differentiated in the neural crest (NC) cells. In this connection, the transcription factor microphthalmia-associated transcription factor (MITF) occurs the primary regulator of melanocyte and regulates the development of melanocytes from the NC. Neural crest (NC) cells are transient group of cells unusual to vertebrates that occur in the embryonic ectoderm cell layer and produce a variety cell lineage including melanocytes, peripheral and intestinal neurons, and glia cells. Here, we used neural crest (NC) specific deleted MNL1 (conditional) mice to determine precise effects of MNL1 in NC cells. To produce deletion of MNL1 in NC cells, we used floxed
version of MNL1 which has subsequently been crossed with Wnt1-cre which expresses in the NC precursor cells. We confirmed the expression of MNL1 in NC cells during embryonic days to determine that deletion of MNL1 occurred in NC cells. We observed that the expression of MNL1 was disappeared. As a result, hypopigmentation observed in Neural crest-specific deletion of MNL1. Also, the hydrocephaly, postnatal lethality and abnormalities during embryonic days were observed in Neural crest-specific deletion of MNL1. In addition, we further studied Sox10 which plays an important role in NC development, MITF and its down-regulation genes in neural crest-specific deletion of MNL1. Thus, we demonstrated that decreased levels of these genes reduces melanocyte development. In conclusion, our data report that MNL1 plays an important role in hypopigmentation.

Role of Peptidylglycine α-Amidating Monooxygenase in the Adaptive Plasticity of Embryonic Hatching in Zebrafish.
R.T. Thomason1,2, D. Kumar3,4, J. Sloan2, J.D. Gitlin2, R.E. Mains3,5, B.A. Eipper3,5;
1University of Virginia, Charlottesville, VA, 2Eugene Bell Center for Regenerative Biology and Tissue Engineering, Marine Biological Laboratory, Woods Hole, MA, 3Molecular Biology and Biophysics, University of Connecticut Health Center, Farmington, CT, 4Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA, 5Neuroscience, University of Connecticut Health Center, Farmington, CT

Hatching in anamniotes is a critical developmental event, but its timing is adaptively plastic, responding to environmental conditions. To elucidate the role of nutrient availability in this process, we took advantage of the well-defined phenotypes exhibited by zebrafish with genetic and nutritional deficits in the metabolism of copper, a trace element essential for development. Treatment of developing embryos with neocuproine, a membrane permeant copper chelator, resulted in a dose-dependent decrease in the rate and percent of hatching through 96 hours post fertilization. These data indicated that a copper-dependent pathway was involved in the hatching process. Peptidylglycine α-amidating monooxygenase (PAM), an evolutionarily conserved cuproenzyme, is essential for the biosynthesis of several peptides required in neuroendocrine physiology. Consistent with a direct role for this cuproenzyme in the copper-dependent hatching pathway, antisense (morpholino) abrogation of PAM expression resulted in a similar reduction in the rate and percent of hatching. Assays for PAM enzymatic activity revealed a marked decrease in PAM-morpholino injected embryos when compared to uninjected and control-morpholino injected embryos. In normal embryonic development the hatching gland, a developmentally regulated single sheet of cells, forms just over the yolk sac. As the embryo develops, hatching gland cells release a cysteine proteinase, cathepsin L, into the perivitelline fluid to degrade the chorion; hatching gland cells then undergo apoptosis. Although hatching gland morphology was normal in PAM-morpholino injected embryos, the expression and activity of cathepsin L were reduced in both PAM-morpholino injected and neocuproine-treated embryos, revealing a role for PAM in hatching gland function. To further understand the role of the hatching gland, transgenic fish expressing cytosolic EGFP under control of the cathepsin L promoter (Tg[ctslb:EGFP]) were generated. Transgenic embryos treated with neocuproine displayed more EGFP+ hatching gland cells at embryonic stages beyond when hatching should have taken place, indicating that these cells continued to express cathepsin L and failed to undergo apoptosis. Taken together, these studies reveal a critical role for copper availability in the adaptive plasticity of hatching and suggest a role for peptidergic signaling in this process. The effects of bisphenol A & alternatives, individually & in combination, on the development of *Xenopus laevis* (clawed frog).

L. Thottumari¹, L.G. Chukrallah¹, F.S. Raleigh¹, L.H. Twersky¹; ¹Biology, Saint Peter's University, Jersey City, NJ

Bisphenol A (BPA) is used as an intermediate in the production of polycarbonate plastics and epoxy resins, which can be found in adhesives, food and drink packaging, and paper coatings. We are comparing the effects of BPA, a known environmental endocrine disruptor, to its replacements, bisphenol S (BPS) and bisphenol F (BPF), individually and in combination, on the development of *Xenopus laevis* (clawed frog). BPA is known to stimulate cellular responses by binding to estrogen receptors as well as being a thyroid hormone antagonist. The effects of BPS and BPF are not yet understood, however they have been found in urine samples. The development of *X. laevis* has been used as a model system due to the large number of offspring produced, the relatively rapid rate of development, and the organism's dependence on thyroid hormones for metamorphosis. Two trials were completed: the first trial had 11 groups starting at stages 8-9 and the second trial had 9 groups starting at stage 16. Embryos were incubated in concentrations of 5 μg/mL and 10 μg/mL of BPA, BPS, and BPF and combinations of the three at concentrations of 5 μg/mL, 3 μg/mL, and 6 μg/mL. Survivorship, length and rate of development were measured and any changes in morphology were noted. We observed a bubble malformation in the following groups: 5 μg/mL BPF, 5 μg/mL BPA, 10 μg/mL BPS, 10 μg/mL BPF, 5 μg/mL BPA: 5 μg/mL BPF, and 6 μg/mL BPA: 3 μg/mL BPS. The bubble malformations were found in the head or body region of the tadpoles. Two malformations of the tail were also found in 10 μg/mL BPS and 5 μg/mL BPA: 5 μg/mL BPS groups. Several statistically significant differences in length were found. The 5 μg/mL BPA: 5 μg/mL BPF group averaged around 2 cm smaller than the control group. The 3 μg/mL BPA: 6 μg/mL BPS and the 6 μg/mL BPA: 3 μg/mL BPS groups were 1 cm larger than the control group. These differences in length were found only in combination groups. The highest rates of mortality were seen in 10 μg/mL BPF and 10 μg/mL BPA groups. Results indicate lower doses of BPS may have greater effects on mortality than the higher doses. There is a need for further investigation due to important environmental implications. Supported by a grant from the TriBeta Research Foundation.

Physical and molecular mechanisms of cell cycle synchronization in early Drosophila embryos.

V. Deneke¹, M. Vergassola², A. Puliafito³, S. Di Talia¹; ¹Cell Biology, Duke University, Durham, NC, ²Physics, University of California, San Diego, San Diego, CA, ³Oncology, IRCC, Turin, Italy

One of the most fascinating questions in biology is how spatiotemporal coordination is achieved in cells, tissues and populations. A remarkable example is the synchronized divisions that take place in the developing *Drosophila* embryo. The Drosophila embryo develops as a multinucleated syncytium (a common cytoplasm not divided by membranes), which undergoes 13 rapid and synchronous nuclear divisions. The synchrony of these early cell cycles is essential for proper embryonic development. In my talk, I will describe the recent work of my lab to dissect the molecular and physical mechanisms that ensure the spatiotemporal coordination of the cell cycle in early *Drosophila* embryos. I will show how
waves of Cdk1 activity synchronize the cell cycle, how such waves are controlled by an active mechanism during DNA replication, while mitotic waves are a passive, kinematic consequence of S-phase waves. Molecularly, the waves do not require the positive feedbacks that regulate mitosis, but are controlled by a double negative feedback between Cdk1 and Chk1. I will also present theoretical arguments, supported by experimental observations, which indicate that the observed waves are originated by a new physical mechanism, in which waves of chemical activity arise in time-dependent bistable systems. Finally, I will discuss how tissue-wide synchronization is established, presenting a new model integrating Cdk1 oscillations, actomyosin contractility and nuclear spreading. Our experiments argue for a new mechanism by which global synchronization can arise from a spreading of local synchrony.

Sperm Aster Growth and Dynamics during Pronuclear Migration.
J.L. Meaders¹, R. Sean¹, D.R. Burgess¹;
¹Biology, Boston College, Chestnut Hill, MA

The fertilizing sperm brings with it centrioles from which the sperm aster and mitotic spindle are formed. The role of the sperm aster is to capture the female pro-nucleus for pronuclear fusion and to centrally position the nucleus for the first cleavage division. Sperm aster migration was recently hypothesized to be due to microtubule (MT) length-dependent cytoplasmic pulling forces in which aster asymmetry and dynein are essential for male pronuclear centration (Tanimoto et al, 2016). We have re-examined the role of sperm astral MT growth and dynamics during pronuclear migration in the same higher invertebrate Lytechinus pictus. In contrast to the modeling of Tanimoto et al, we find that astral MTs are longer on the cortical facing side compared to those on the side facing the cell center. Furthermore, cortical facing MTs are anchored to the inner cell surface, which is also inconsistent with a MT length-dependent cytoplasmic pulling model. We next manipulated aster asymmetry in 1-cell zygotes by either increasing MT catastrophe or polymerization (Strickland et al, 2005). Neither compound affects fertilization or the length ratio of cortical vs cytoplasmic facing astral MTs. The result of suppressing sperm aster MT growth in L. pictus is arrested sperm-egg pronuclear migration, resulting in failure to center the nucleus and delayed cytokinesis despite having identical aster asymmetry when compared to controls. Conversely, increasing MT polymerization rates causes longer asters and faster sperm aster migration, without affecting female pronuclear migration. Finally, decreasing detyrosination of astral MTs prevents nuclear centration and causes defective aster morphology. Recent studies have indicated a tyrosinated tubulin preference for dynein (McKenney et al, 2016) and a detyrosinated preference for different kinesins (Sirajuddin, et al, 2014). Taken together, we predict a motor asymmetry in which the tyrosination profile of the sperm aster allows more dynein transport on the cytoplasmic astral MTs and more kinesin transport on the cortical-facing astral MTs, allowing the foce-balance required for male pronuclear centration. Such motor asymmetry coupled with potential cortical pushing forces by growing astral MTs may provide the forces necessary for sperm aster positioning.

Functional roles of hnRNPA2/B1 by RNA epigenetic modification in mammalian embryonic development.
J. Kwon1, Y. Jo1, S. Namgoong1; 1Animal science, Chungbuk national university, Cheongju, South Korea

Heterogeneous nuclear ribonucleoprotein A2/B1 (hnRNPA2/B1) plays an important role in influence of pre-messenger RNA (pre-mRNA) processing, mRNA metabolism and transportation in cells. Current research reveals that hnRNPA2/B1 can m6A modification on pre-mRNA or pre-miRNA and affect alternative splicing and miRNA processing. However, functional role and relationship between m6A and hnRNPA2/B1 in early embryo development are unclear. Here, we present evidence that hnRNPA2/B1 is crucial for the early embryo development by regulating of specific gene transcripts. hnRNPA2/B1 was localized in the nucleus during subsequent embryonic development since fertilization. Then, Knockdown of hnRNPA2/B1 induced by RNA interference (RNAi) was used to analyze the role of hnRNPA2/B1 during mouse preimplantation development. Knockdown of hnRNPA2/B1 delayed embryo development and blocked to further post-implantation development after 4-cell stage. Transcriptome analysis indicated that hnRNPA2/B1 KD blastocyst was changed of global gene expression patterns related with transcription, translation, cell cycle, ES cell differentiation, and RNA methylation. Interestingly, ICM marker OCT4 and Sox2 was significantly decreased in blastocyst stage. m6A RNA modification regulator methyltransferase like 3(METTL3) knock-down embryos mis-localize of hnRNPA2/B1 at the nucleus and decreased of m6A RNA methylation. On the other hand, hnRNPA2/B1 knock-down embryos increased m6A intensity. Together, our results suggested that hnRNPA2/B1 essential for early embryogenesis through the regulation of transcription related factors and the effect of cell fate transition through m6A RNA epigenetic modification.

The role of cadherin-based adhesions during trigeminal ganglia assembly.
C. Wu1, L.A. Taneyhill2; 1Animal and Avian Sciences, University of Maryland, College Park, MD

Cranial sensory ganglia play a vital role in the nervous system through their relay of sensory information from extrinsic and intrinsic sources to the brain. These ganglia are generated from the intermixing and coalescence of two distinct cell populations: neural crest cells (NCCs) and placode cell (PC)-derived neurons. Defects in NCC and PC development can lead to various congenital and hereditary malformations, disorders and diseases, including CHARGE and Branchio-Oto-Renal spectrum syndromes, heart-related anomalies, and cancers. Cranial ganglia assembly requires the formation of cadherin-based adherens junctions within the NCC and PC-derived neuron populations; however, the molecular composition of these adherens junctions is still unknown. To this end, we are using the assembly of the cranial trigeminal ganglia in the developing chick embryo as a model to define the molecules mediating these intercellular interactions. We hypothesize that NCCs and PCs intermingle and aggregate through the creation of specific cadherin-based adherens junctions, thereby permitting proper trigeminal gangliogenesis. Our prior work demonstrated that NCCs and PC-derived neurons express a distinct repertoire of cadherin proteins, with Cadherin-7 (Cad-7) and N-cadherin (N-cad) observed in migratory NCCs and PC-derived neurons, respectively. Using gene perturbation experiments, we now show that alterations in NCC Cad-7 influence trigeminal ganglia assembly, including the contribution of NCCs and
PC-derived neurons to the ganglion. Furthermore, in vivo biochemical studies point to a potential role for the formation of heterophilic cadherin-based adhesions between NCCs and PC-derived neurons. Taken together, our work will provide additional insight into the mechanisms that orchestrate the cellular movements essential for cranial gangliogenesis, and, collectively, will impact our understanding of the normal formation of, and diseases associated with, NCCs, PCs and the sensory nervous system. Importantly, our results may be directly translatable to other tissues generated from heterotypic cell types and will therefore have broad implications for human health.

Sonic hedgehog guides axons through release of a Dock-ELMO complex.
S. Makihara1,2, S. Morin1, J. Côte3,4,5, P.T. Yam1, F. Charron1,2,3,4,6,
1Molecular Biology of Neural Development, Institut de Recherches Cliniques de Montréal, Montreal, QC, 2Integrated Program in Neuroscience, McGill University, Montreal, QC, 3Department of Anatomy and Cell Biology, McGill University, Montreal, QC, 4Department of Medicine, University of Montreal, Montreal, QC, 5Department of Biochemistry, University of Montreal, Montreal, QC, 6Division of Experimental Medicine, McGill University, Montreal, QC

In the developing spinal cord, Sonic hedgehog (Shh) attracts commissural axons toward the floorplate. How Shh regulates the cytoskeletal remodelling that underlies growth cone turning is unknown. We found that Shh activation of the Rho GTPase Rac1 requires the activity of Docks, which are unconventional GEFs. Knockdown of Dock3 and 4, or their binding partner ELMO1 and 2, abolished commissural axon attraction by Shh in vitro. Dock and ELMO were also required for correct commissural axon guidance in vivo. Moreover, we found that polarised Dock activity was sufficient to induce axon turning, indicating that Docks are instructive for axon guidance. Mechanistically, we show that Dock and ELMO interact with Boc, the Shh receptor, and that this interaction is reduced upon Shh stimulation. Furthermore, Shh stimulation translocates ELMO to the growth cone periphery. Together, we propose a model where release of the Dock/ELMO complex from Boc by Shh leads to Rac activation and growth cone turning. This identifies Dock/ELMO as new effectors of non-canonical Shh signaling in axon guidance.

Characterizing cell size dependent transcription with Xenopus embryos and cytoplasmic extracts.
L.C. Einstein1, H. Chen1, M.C. Good1,2;
1Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, 2Bioengineering, University of Pennsylvania, Philadelphia, PA

Recent work has demonstrated that cell size plays a fundamental role during early embryogenesis. After fertilization, cells within the embryo divide without growing, which results in reduced cell size. Prior to gastrulation, these divisions are driven maternally by pre-loaded mRNAs and proteins while the zygotic genome lies dormant. Upon zygotic genome activation (ZGA), genes necessary for gastrulation and the formation of differentiated germ layers are expressed and maternal products are cleared from the embryo. However, the mechanisms by which ZGA occurs are poorly understood. Previous research has suggested that timer and sizer mechanisms may control the timing of ZGA. For example as cell size reduces, an increased DNA to cytoplasm ratio (D:C) has been proposed to trigger transcriptional
activation. Studies on the effect of D:C ratio on ZGA have shown that addition of exogenous DNA in vivo or in vitro is sufficient to trigger a global onset of transcription. However, these studies have not directly tested the contribution of cell size to ZGA. A limitation of studies in embryos is that it is difficult to manipulate cell size. In order to mimic the broad range of cell sizes present in an embryo and to do so without compromising the complex processes that drive cellular function, our lab has developed a synthetic cell like system with controllable dimensions. This system allows me to investigate the relationship between cell size and transcription. To fully characterize this relationship, we require an assay sensitive enough to detect early zygotic transcripts. Our lab has developed a method for detecting nascent transcripts with 5-ethyl-uridine (5-EU) metabolic labeling in Xenopus laevis embryos and extracts. Using this method, I measure global changes in nascent transcription in Xenopus embryos, size sorted dissociated blastomeres, and embryo extracts. Using RT-PCR on biotinylated 5-EU RNA conjugated to streptavidin beads, I detect a specific subset of early RNA polymerase II dependent transcripts associated with ZGA, confirming that 5-EU labels nascent zygotic transcripts. The results of my studies support a cell size dependent model for ZGA and provide a novel system in which to characterize the mechanisms that link cell size and gene expression.

\textsuperscript{1}Biology Department, Haverford College, Haverford, PA

During gastrulation prospective mesodermal cells must be brought onto the inside of the developing embryo. In the fruit fly \textit{Drosophila melanogaster} this requires precise spatial and temporal regulation of \textit{folded gastrulation (fog)} and \textit{T48} gene expression. The \textit{fog} and \textit{T48} gene products then act in parallel to activate Rho mediated cell signaling pathways. This in turn leads to constriction of the apical side of the cells, thereby initiating the internalization of the prospective mesoderm. This process of apical constriction and many of the molecular components involved are conserved in other morphogenetic events and in other species (including neural tube formation in vertebrates). However, direct homologs of \textit{fog} and \textit{T48} in vertebrates have not been identified. We are interested in understanding the evolution of this morphogenesis pathway and have begun by identifying \textit{fog} and \textit{T48} homologs in other dipterans. Sequence analysis of the identified \textit{fog} homologs shows \textit{fog} to be a rapidly evolving gene while \textit{T48} is evolving less rapidly. We are now analyzing the role of functional motifs in the Fog protein in fruit fly species. We have also identified homologs of \textit{fog}, the Fog receptor \textit{MIST}, and \textit{T48} in the mosquito \textit{Anopheles gambiae}. This insect has been reported to gastrulate differently to \textit{Drosophila melanogaster} and was previously thought to lack a \textit{fog} homolog. We are therefore examining the cell shape changes underlying gastrulation, and the expression of \textit{fog}, \textit{MIST} and \textit{T48} in \textit{A. gambiae} embryos. Ultimately we hope these studies will provide insight into the evolutionary processes that shape the developmental pathways of morphogenesis.

*Wolbachia* infection status, embryo-wide distribution and subcellular localization patterns during early embryonic development in a variety of *Drosophila* species.

M.A. Levine¹, M.L. Chien-Hale¹, M. Chenworth¹, R.M. Lewinsohn¹, J.J. Hofmann¹, J.T. Fingerut², S.P. McRobert², R.E. Hoang¹;
¹Biology Department, Haverford College, Haverford, PA, ²Department of Biology, Saint Joseph’s University, Philadelphia, PA

*Wolbachia* are intracellular endosymbionts found within the cells of many arthropods, including an estimated 40-60% of all insects. These endosymbiotic bacteria are known to be involved in the pathogenesis of a number of insect and filarial nematode mediated diseases in humans. In many cases *Wolbachia* also have an impact on the fertility and fecundity of the host insects in ways that maximize the maternal transmission of the bacteria from one generation to the next. These effects on the host have led to much interest in using *Wolbachia* as a biopesticide to reduce pest insect populations. However, little is known about how *Wolbachia* interact with their host at a cellular and molecular level. Fruit fly species provide a useful model system to explore such interactions. In our lab, and others, it has been shown that different fly-*Wolbachia* species combinations show varying patterns of *Wolbachia* distribution in the host embryo. In this study we have investigated the embryo-wide distribution patterns of different host-*Wolbachia* species combinations in a variety of lab cultured and locally caught fruit fly species. We have found that differences in distribution patterns persist during the period of incorporation of the *Wolbachia* into the developing germline of the host. However, our initial studies imply that on the level of individual cells the *Wolbachia* localize in a consistent sub-cellular pattern and show a likely interaction with microtubules. This is consistent with results from others that have demonstrated association between *Wolbachia* and microtubules in individual fly species during oogenesis and/or embryogenesis. Our ongoing work involves further investigation into shared aspects of *Wolbachia*-host interaction during early embryogenesis across species. We have also extended our study to include *Wolbachia* infection status and capability of locally caught *Drosophila suzukii*. This invasive fly species causes substantial damage to U.S. fruit crop production. There is therefore interest in whether *Wolbachia* could be used as an alternative population control technique. However, such approaches require a better understanding of *Wolbachia-host interactions in local fly populations.* Ultimately we hope that the discovery of conserved aspects of host-*Wolbachia* interaction will lead to a deeper understanding of the mechanisms whereby these important bacteria interact with a wide range of host species.

Spatiotemporal Regulation of Zygotic Genome Activation During Early Embryogenesis.

H. Chen¹, L.C. Einstein¹, M.C. Good¹²;
¹Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ²Bioengineering, University of Pennsylvania, Philadelphia, PA

Thousands of zygotic genes are activated during maternal-to-zygotic transition (MZT); however, how massive gene expression is spatially regulated within an embryo is still unknown. Using Xenopus as a model, we detected nascent transcripts by labeling RNA with 5-ethynyl uridine (5-EU). In combination with click chemistry and confocal imaging, we were able to track zygotic genome activation (ZGA) at the single-cell level in an embryo during the mid-blastula transition (MBT). As expected, we found that the
EU-RNA was not detected in embryos prior to cleavage 10 (C10), consistent with published gene profiling data derived using RNA extracted from whole embryos. Interestingly, ZGA is not uniform in space or time – high levels of zygotic transcription were evident in only a few cells at C10, approximately half the embryo at C13 and entire embryo at C16. This observation argues against a timer model, in which ZGA onset corresponds to a specific time post-fertilization. To validate our labeling approach, we co-microinjected 5EU and α-amanitin. We found that α-amanitin treatment eliminated nearly all nascent transcription, suggesting that the EU-labeled RNAs we image are predominantly RNA polymerase II dependent. The spatial patterns of ZGA prompted us characterize whether ZGA is cell size dependent. By quantifying the EU-RNA level in single cells at different stages, we found that the EU-RNA level was inversely correlated with cell size, supporting a cell-size sensing model for ZGA. To differentiate between the effects of cell size and number of cell divisions, we generated mini-embryos that are one eighth volume of the normal embryos. Large-scale transcription initiated as early as cleavage 8 in mini-embryos but was still off in wild-type embryos. These data suggest that by reducing cell size below a size threshold, genome activation is triggered. Finally, a higher percentage of cells in the presumptive ectoderm compared to the presumptive endoderm were transcriptionally active at the MBT, suggesting a potential link between spatial onset of ZGA and germ layer specification. Taken together, our results provide new insights into ZGA regulation and a spatial map of ZGA onset during early embryogenesis in vertebrates.

Characterization of epithelial cell rearrangements during lens placode invagination.
N.S. Houssin1, T.F. Plageman1;
1Optometry, Ohio State University, Columbus, OH

Development of the vertebrate eye serves as a valuable model for epithelial morphogenesis. At the onset of lens formation, the surface ectoderm thickens to form the lens placode, a structure positioned adjacent to the retinal primordium that undergoes a series of cell rearrangements and shape changes that drive invagination of the tissue to form the lens pit and subsequently the lens vesicle. Currently, the cellular mechanisms driving epithelial invagination of vertebrate structures such as the lens placode remain incompletely characterized. Although, the role of apical constriction (AC) and mechanically constrained tissue growth have previously been investigated, their contribution only partially explains this process. In order to better characterize lens placode invagination, cellular junctions of mouse and chick embryos were visualized using fluorescent live microscopy with either a transgenic fluorescent protein (E-cadherin(TG) or a fluorescent probe that binds to F-actin (SiR-F-actin). It was observed that the lens placode cells and those immediately surrounding them have distinct behaviors. The central lens placodal cells significantly reduce their apical area isotropically and maintain their cellular junctions with neighboring cells within the placode. However, the cells immediately peripheral to the lens placode are anisotropic in shape and dynamically rearrange themselves such that a net central/radial tissue movement is achieved. One of the dynamic cell behaviors observed is the formation and resolution of epithelial rosettes, a hallmark of intercalation movements that can elongate epithelial tissues. Because the Par-complex protein Par3 has previously been implicated to regulate invertebrate epithelial rosette resolution, its role during vertebrate placode invagination was determined. While Par3 protein appears to be isotropically localized in lens placode peripheral cells, it appears to be localized to the vertices of rosettes. Static analysis of fixed embryos lacking Par3 protein demonstrated that rosette structure and
anisotropic distribution depend on Par3. Further analysis of lens placode cell behavior in the absence of Par3 using live imaging and automated pattern recognition tools will shed light into the role of rosette resolution, radial cell movement, and Par3 function during vertebrate epithelial invagination.

Determining how cellular phase transitions partition the myotube cytoplasm.
J.A. Smith¹, S. Dundon², A.S. Gladfelter³;
¹Biology, The University of North Carolina at Chapel Hill, Chapel Hill, NC, ²Cellular Developmental Biology, Yale University, New Haven, CT

Syncytia, cells containing multiple nuclei, are found throughout the biosphere. These cells are essential for mammalian muscle and placenta development, and are a common state of fungal pathogens. Interestingly, nuclei in fungal, muscle, and placenta syncytia have different transcriptional programs despite sharing the same cytoplasmic environment. This independent nuclear behavior suggests that the cytosol is compartmentalized thereby insulating neighboring nuclei. We have found that mRNAs are non-randomly positioned near nuclei in fungal syncytia via incorporation into granule-like RNA/protein (RNP) structures. These structures are droplet-like and the core components can undergo liquid-liquid phase separation. In this system, liquid droplets act to spatially regulate mRNAs controlling the cell cycle. We hypothesize that cytosol compartmentalization via RNP droplets is a conserved mechanism for multinucleate cells to spatially organize the cytosol. To test this hypothesis, we are using mouse myotubes in which nuclei have autonomous transcriptional programs in a common cytoplasm and mRNAs appear spatially patterned. Transcripts encoding the acetylcholine receptor (AchR) show non-random subcellular localization, where AchR protein clusters also form, suggesting these transcripts are locally translated. Here, we identified FXR1, or Fragile X-Related protein, as a potential AchR binding protein through a bioinformatics screen. FXR1 is an intrinsically-disordered RNA-binding protein, and is essential for muscle development with knockout mice dying shortly after birth due to respiratory or cardiac failure. To study FXR1 in muscle syncytia we are using the C2C12 cell line, which can be easily differentiated in culture. We found that FXR1-GFP forms liquid-like droplets that fuse in the myotube cytosol. We have optimized smFISH for differentiated C2C12 myotubes to visualize AchR mRNA, and found that AchR transcripts are not homogenously distributed in the cytoplasm, consistent with previous findings. Additionally, FXR1 droplets partially colocalize with AchR mRNA. To identify regions of FXR1 required for droplet formation, we created mutations in predicted RNA binding domains and disordered regions. By imaging artificial syncytia created using U2OS human osteosarcoma fibroblasts transfected with these constructs, we identified mutations that alter the ability of FXR1 to form droplets as well as the morphology of the droplets formed. This work furthers our understanding of how cytoplasmic partitioning via phase transitions is conserved, by identifying and characterizing FXR1 RNP droplets in myotube syncytia.

Though cell cycle regulation plays a key role in numerous developmental processes, including morphogenesis and differentiation, the regulatory systems that control the cell cycle remain poorly understood due to the inability to visualize changes in cell cycle state in vivo. We have adapted a cell cycle state biosensor originally designed for cell culture for use in zebrafish. The sensor provides a visual readout of cell cycle state based on the nuclear and cytoplasmic localization of DNA Helicase B (DHB), which is determined by CDK2 levels, in addition to a nuclear mask and a membrane marker. To test DHB, we compared it to Fluorescence Ubiquitin Cell Cycle Indicator (FUCCI), a previously validated cell cycle sensor with limited resolution, and found that DHB accurately differentiates between G1 phase and S/G2 phases and is also able to distinguish between S/G2. Next, we induced cell cycle arrest in the zebrafish tailbud using pharmaceuticals to provide a baseline for quantifying the nuclear/cytoplasmic ratio of DHB in each phase of the cell cycle. Finally, using the newly calibrated biosensor, we explored the effects of cell cycle dysregulation on tailbud development. Through microinjection of a plasmid which ubiquitously expresses CDKN1A/p21, a cyclin-dependent kinase inhibitor associated primarily with inhibition of CDK2, we found that overexpression of CDKN1A/p21 induced G1 cell cycle arrest in tailbud cells and disrupted notochord development. Our sensor provides new insights into the relationship between cell cycle regulation and morphogenetic changes and allows for high-resolution live imaging of the zebrafish tailbud.

The role of polycomb group ring finger 5 (Pcgf5) in pressure overload hypertrophy.
J. Jang1, s. Seo1, C. Lim1, G. Oh1;
1Department of Life Sciences, Ewha Womans University, seoul, Korea, South

Pcgf5 is one of core components of polycomb repressive complex 1 (PRC1)-related complexes which catalyze monoubiquitination of histone H2A to repress gene expression. However, the biological function of Pcgf5 remains largely unknown. We generated Pcgf5 knockout mice with LacZ-reporter. Pcgf5 expression is restricted to the heart of embryos and adult mice. Mice homozygous for a Pcgf5 null allele survived to adulthood. To study the role of Pcgf5 in adult heart, we induced pressure overload cardiac hypertrophy in 10 - 12 week-old wild-type (WT) and Pcgf5-/- mice using surgically creating transverse aortic constriction (TAC). The cardiac functions of WT and Pcgf5-/- mice were assessed at 0 (before TAC), 1, 3, 6, 9, 12 and 15 weeks after TAC by echocardiography. Echocardiography revealed that Pcgf5-/- mice had significant increased heart weight to body weight ratio, increased left ventricular (LV) mass (1 week after TAC), increased LV anterior wall (1 week after TAC), increased diastolic LV internal diameter (12 weeks after TAC) and reduced ejection fraction (1 week after TAC), compared with WT mice. Taken together, Pcgf5-/- mice developed cardiac hypertrophy at an earlier time point after TAC, suggesting that Pcgf5 plays a role in development of cardiac hypertrophy.

A fluorescence based cell cycle state biosensor in C. elegans and its use in characterizing cell cycle state during vulval morphogenesis.
A.Q. Kohrmann¹, D.Q. Matus¹, W. Zhang¹;
¹Biochemistry and Cell Biology, Stony Brook University, Stony Brook University, NY

During organismal development, differential regulation of the cell cycle is critical to many cell biological processes, including differentiation and morphogenesis. While the complete cell division lineage of C. elegans is known, how the control of cell cycle is linked to fate specification and morphogenesis remains poorly understood, due to our inability to directly visualize cell cycle state. In order to visualize cell cycle state live, we have adapted a CDK2 biosensor for use in C. elegans. Our biosensor uses the dynamic nuclear/cytoplasmic localization of a portion of Human DNA Helicase B (DHB) linked to GFP to assess cell cycle state. The dynamic localization is the result of phosphorylation of the biosensor by CDKs. We have modified this sensor to allow for algorithmic assessment of cell cycle state. Similar to reported results from cell culture, we are using this biosensor to quantify lineage specific differences between cycling cells, quiescence and differentiation, provide new biological insights into the role of cell cycle during gastrulation and the control and timing of the cell cycle in specification of uterine cells and the morphogenesis of the C. elegans vulva.

Myocardial-specific functions of Jarid2 in the heart.
E. Cho¹, M.R. Mysliwiec¹, C.D. Carlson², A.Z. Ansari³, R.J. Schwartz⁴, Y. Lee⁵;
¹Cell and Regenerative Biology, University of Wisconsin-Madison, Madison, WI, ²Trinity Christian College, Palos Heights, IL, ³Biochemistry, University of Wisconsin-Madison, Madison, WI, ⁴Biology and Biochemistry, University of Houston, Houston, TX

Jarid2 (Jumonji A/T-rich interaction domain 2) is an essential factor for normal heart development. We have demonstrated that deletion of Jarid2 in mice results in cardiac malformations recapitulating human congenital cardiac disease, and dysregulation of gene expression during development. However, the cardiac-specific developmental function and the precise epigenetic regulation of gene expression by Jarid2 remain to be elucidated. Here we demonstrated that cardiac-specific deletion of Jarid2 in the developmental or postnatal myocardium causes cardiac malformations and functional defects. We employed three different cardiac-expressing Cre transgenic mice. Deletion of Jarid2 by Nkx2.5-Cre (Jarid2Nkx) caused cardiac malformations including ventricular septal defects, thin myocardium, hypertrabeculation, increased cardiac jelly and neonatal lethality. In contrast, later deletion of Jarid2 in mice with cTnt-Cre or aMHC-Cre transgenic lines did not cause gross abnormalities in development. By employing combinatorial genome-wide approaches and molecular analyses, we show that Jarid2 together with PRC2 regulates a subset of Jarid2 target gene expression and H3K27me3 enrichment during heart development. Specifically, Jarid2 is required for PRC2 occupancy and H3K27me3 on the Isl1 locus, leading to proper repression of the target gene expression during cardiac development. Jarid2 represses neural gene expression, cardiac jelly, and several important factors such as Isl1 and Bmp10, all of which are crucial for normal ventricular development. Thus, early deletion of Jarid2 in the myocardium results in dysregulation of gene expression and developmental defects later in development. Interestingly, deletion of Jarid2 by aMHC-Cre (Jarid2aMHC) resulted in complete lethality by 9 months of age with dilated cardiomyopathy. Jarid2aMHC mice showed an increase in fetal gene
expression, such as Tnni1 and Acta2, and a decrease in p27 levels at young ages. Therefore, Jarid2 is also required for myocardial maturation and maintaining cardiac function in adult stages. Our studies revealed epigenetic regulation of Jarid2 in association with PRC2 within the developing myocardium. We discovered that Jarid2 is necessary to establish correct epigenetics on the target genomic loci during a narrow developmental window, which is prior to differentiation of cardiac progenitors into cardiomyocytes and maturation of cardiomyocytes.

The Micropeptide Myomixer Controls Cell Fusion and Skeletal Muscle Formation.
P. Bi1, A. Ramirez-Martinez1, H. Li1, J. Cannavino1, J. McAnally1, J. Shelton1, E. Sanchez-ortiz1, R. Bassel-Duby1, E.N. Olson1;
1Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX

Skeletal muscle formation occurs through fusion of myoblasts to form multinucleated myofibers. From a genome-wide clustered regularly interspaced short palindromic repeats (CRISPR) loss-of-function screen for genes required for myoblast fusion and myogenesis, we discovered an 84-amino acid muscle-specific peptide that we call Myomixer. Myomixer expression coincides with myoblast differentiation and is essential for fusion and skeletal muscle formation during embryogenesis. Myomixer localizes to the plasma membrane, where it promotes myoblast fusion and associates with Myomaker, a fusogenic membrane protein. Myomixer together with Myomaker can also induce fibroblast-fibroblast fusion and fibroblast-myoblast fusion. We conclude that the Myomixer-Myomaker pair controls the critical step in myofiber formation during muscle development.

Tks5-Mediated Podosome Formation Governs Mammalian Myoblasts Fusion.
M. Chuang1, Y. Liu1;
1Institute of Molecular Medicine, College of Medicine, National Taiwan University, Taipei, Taiwan

The multi-nucleated skeletal muscle fibers arise from the fusion of myoblasts. While actin cytoskeleton has been known as the driving force to promote myoblast fusion, how exactly actin is reorganized in fusing myoblasts and by what means myoblast becomes fusion competent remain unclear. Here, we demonstrated that myoblast utilizes podosome, a protrusive actin-enriched structure, to propel cell-cell fusion. The ability of myoblast to form podosome is governed by the induction of a podosome scaffold protein, tyrosine kinase substrate with 5 SH3 domain (Tks5). Importantly, the expression of Tks5 is critical for myoblast fusion but not its differentiation. Furthermore, we found that Tks5 recruits another podosome component, dynamin-2, to the plasma membrane where myoblast fusion occurs. Dynamin-2 is a large GTPase functioning on membrane fission and actin reorganization. Tks5 regulates both the subcellular distribution of dynamin-2 in myoblast and its self-assembly around actin filaments. Specifically, the actin binding ability of dynamin-2, not the membrane fission activity, is required for myoblast fusion. Taken together, our results unveil that myoblast acquires fusion competency through Tks5 induction which controls the maturation of podosome thus impels myoblast fusion. Our findings also explain the paradoxical function of the membrane fission protein, dynamin-2, on intercellular membrane fusion.
Acquisition of myofibroblastic phenotype of stromal cells under pathological condition is critical process for the pathogenesis of fibrotic disease and cancer progression. Although the mechanical properties of extracellular matrices under the pathological condition is variable, most researches for the myofibroblast differentiation has been carried out under the conventional culture condition (e.g., plastic stiff culture dish). In this report, we show that the microtubule acetylation induced by TGF-β1 is a critical factor for initiation of fibroblast differentiation under the soft ECM condition resembling the early pathological condition. Inhibition of tubulin acetylation by knockout (KO) of αTAT1, a microtubule acetylation transferase 1, using CRISPR/Cas9 system in mouse embryonic fibroblast (MEF) resulted in the decrease of several myofibroblast marker genes expression and cellular contractility. Comparison of RNA-seq results obtained from WT and αTAT KO MEF under the soft ECM culture condition indicated that microtubule acetylation is responsible for bulk of gene expression corresponding to the myofibroblast differentiation. Moreover, overexpression of K40Q α-tubulin (acetyl-mimic mutant) not K40A α-tubulin (acetyl-null mutant) in αTAT KO MEFs recovered myofibroblast marker gene expression. Mechanistically, acetylated-α-tubulin is sufficient to dynein dependent nuclear translocation of YAP coactivator, via enforced acetylated-α-tubulin-dynein complex. Blockade of dynein activity with pharmacological inhibitor, EHNA and overexpression of dynamitin significantly reduced nuclear translocation of YAP and expression of myofibroblast marker genes on soft ECM condition. Collectively, these findings demonstrate that the signaling axis for TGF-β1/acetylated-MT/dynein-based nuclear translocation of YAP is critical progress for the acquisition of myofibroblastic phenotype on soft ECM environment and it rendered to advantage for development pathogenesis.

Regeneration of missing tissue requires both generation of new cells after wounding as well as information to correctly pattern the new tissue. However the sources and regulation of positional information during regeneration remain poorly understood. Planarians are flatworms with a robust ability to regenerate from nearly any injury. By one week after amputation of the head or tail, planarians regenerate all missing tissue in a newly formed outgrowth termed the blastema. Prior work has identified positional information in planarians using RNA interference phenotypes in which incorrect tissues are regenerated. For example, Wnt pathway inhibition leads to regeneration of ectopic heads instead of tails, and inhibition of the BMP pathway leads to formation of ectopic ventral tissue on the dorsal side. Remarkably, recent work has shown that members of these key developmental signaling pathways are expressed predominantly in planarian muscle cells, leading to the hypothesis that muscle cells maintain positional information during regeneration. The planarian body-wall musculature forms a
sub-epidermal network composed of three layers: circular fibers that are oriented along the medial-lateral (ML), diagonal fibers, and longitudinal fibers that are oriented along the anterior-posterior (AP) axis. We found that the planarian bHLH family transcription factor myoD, a homolog of the mammalian myogenic factor, controlled formation only of longitudinal fibers. Inhibition of myoD reduced the number of longitudinal fibers and led to regeneration failure despite normal homeostatic tissue turnover. This phenotype revealed that longitudinal fibers express key factors that are required to initiate regeneration. Conversely, the NK1 homeodomain transcription factor nkk1-1 is required only for circular fiber formation. Inhibition of nkk1-1 reduced the number of circular fibers and resulted in abnormal regeneration of a bifurcated AP axis where two fused heads form within a single anterior blastema. Planarian muscle is therefore more than a contractile and structural tissue with subsets of body-wall muscle playing distinct regulatory roles in wound signaling and patterning to enable regeneration.

1Cell Biology, Duke University Medical School, Durham, NC, 2Molecular Biology, Massachusetts General Hospital, Boston, MA

Unlike humans, vertebrate species like zebrafish activate cardiomyocyte division after cardiac tissue damage, regenerating lost muscle. Regulation of chromatin organization is a principal mechanism underlying animal development, it is unknown to what extent injury-induced structural changes in chromatin underlie heart regeneration. Here, we set-out to define nucleosome changes during heart regeneration. We generated a transgenic zebrafish strain expressing a biotinylatable H3.3 histone variant in cardiomyocytes and derived a cell type-specific profile of histone exchange in heart muscle. We identified thousands of inter- and intragenic regions that revise H3.3 occupancy during regeneration, many of which were undetectable by alternative chromatin scanning technology. In transgenic reporter lines, a subset of H3.3-enriched regions directed gene expression in subpopulations of ventricular cardiomyocytes, whereas other elements showed enhancer activity preferential to injury- or Neuregulin1-elicited cardiomyocyte proliferation. Many consensus binding motifs near regeneration-associated genes were enriched among predicted enhancer sequences, suggesting a regulatory network for heart regeneration. Our cardiomyocyte H3.3 profiles provide a fertile resource to understand and manipulate the genetic program of the heart to build new muscle.

Preterm birth compromises cerebellar development: evidence from a pig model.
I. Iskusnykh1, R. Buddington2, A. Zakharova1, L. Mukhametzyanova1, V. Chizhikov2;

1Department of Anatomy and Neurobiology, University of Tennessee Health Science Center, Memphis, TN, 2School of Health Studies, University of Memphis, Memphis, TN

A large fraction of preterm infants have compromised neurodevelopment. Motor dysfunction and cognitive impairment in preterm infants were associated with hypoplasia and cellular lesions in the cerebellum. However, the cellular and molecular mechanisms that mediate cerebellar abnormalities in preterm infants remain largely unknown. In this study we investigated the impact of preterm birth on
cerebellar development and identified specific molecular targets affected by preterm birth using the pig as a large animal model. Cerebella were collected from preterm piglets delivered at 91% term (day 105 out of 115 days of gestation) via c-section and raised for 10 days using milk replacer. Naturally born term pigs were used as controls. Specific cerebellar populations were identified by immunohistochemical staining. Cells were counted using unbiased stereological methods. For gene expression analysis, external granule cell layer was isolated by laser capture microdissection and analyzed by real-time RT-PCR. Based on Calbindin immunohistochemistry, we found that preterm birth does not affect either morphology or density of Purkinje cells at term equivalent age. Similarly, there was no difference in the number of Pax2+ molecular layer interneurons between preterm and term pigs. Ki67 and Tag1 immunohistochemical analysis revealed, however, that preterm birth specifically compromises proliferation, but not differentiation of cerebellar granule cells. Laser capture microdissection / quantitative-PCR analysis identified several key cerebellar developmental genes, including both secreted molecules and intrinsic factors, that were misregulated in preterm pigs, likely contributing to the granule cell abnormality. Thus, our analysis of a pig model argues that preterm birth compromises cerebellar development by primarily affecting proliferation of granule cells and suggests that disruption of this cellular population contributes to motor and cognitive impairment in preterm human infants.

Identification of novel transcription factor in the generation of mid-brain during embryo development: Application of alternative transcription factor binding site-prediction-method.
Y. Shin¹, J. Kang¹, Y. Lee¹, K. Kim², H. LEE²;
¹General Medical Research Institute, CHA Bundang Medical Center, Bundang, South Korea, ²Biomedical Research Institute, Seoul National University Hospital, Seoul, South Korea

Cell fate specification relies on the action of critical transcription factors (TF) that become available at distinct stages of embryonic development. Mid-brain dopamine neurons (mDA\textit{n}) play a central role in the modulation of several brain functions, including voluntary movements, emotion, and cognition. The progressive degeneration of substantia nigra mDA\textit{n} gives rise to some of the main motor features of Parkinson’s disease (PD). Current treatments for PD are symptomatic and how the phenotype of DA neurons is normally established and the ways in which pathology affects the maintenance of cell identity are, therefore, important considerations. A number of transcription factors regulate the development of this set of neurons and some remain constitutively expressed throughout life. These maintenance transcription factors are closely associated with essential neuro-physiological functions and are required ultimately for the long-term survival of the mid-brain dopamine neurons. The development of mDA\textit{n} is controlled by a combination of between cell extrinsic pathway (SHH-FGF8 or Wnt1) and intrinsic signals (FOXA2, LMX1A). Both Nurr1 and Pitx3 are required for mDA\textit{n} differentiation and survival. Here, human neural progenitor cells were more efficient differentiation into dopamine neurons in the treatment to the small chemical compound X than other conventional differentiating factors, confirmed by in vitro results. To understand the developmental patterns of gene expression in the dopamine differentiation of human neural progenitor cells, we performed transcription analysis of targeting neurons at different treatment time points by in vitro culture with or without small molecules or SHH or negative control condition using next-generation RNA sequencing (RNA-seq). We showed that distinct gene expressions shown by different factor-treated cells (negative, SHH and compound X) and most genes were down-regulated and four genes uniquely up-regulated by compound X and predicted to be related to neurogenesis by bioinformatics data analysis. Furthermore, that genes uniquely up-regulated by compound X, Nurr1 and TH act in a coordinated manner for dopamine differentiation and they have
motifs in its promoters which novel transcription factor X binds by alternative transcription factor binding site prediction method. We found that novel transcription factor X expressed mid- brain of E10 embryonic mouse but not mid-brain of over E12 embryonic mouse brain. The Transcription factor X protein merged with TH+ cells and bind to the promoter of TH gene. Our results suggest that a novel transcription factor X is one of the required factor for mDA specification during brain development

M.C. Jud, J. Lowry, T. Padilla, A. Miller, H. Shao, Z. Bao, B. Bowerman;
1Institutue of Molecular Biology, University of Oregon, Eugene, OR, 2Developmental Biology, Memorial Sloan Kettering Cancer Center, New York, NY

Embryonic morphogenesis is a developmental process that constructs organs and body plans by coordinating cell shape and cell migration to establish tissue organization. The roles that the cytoskeleton and cell adhesion have during morphogenesis for cell shape changes and movement have been well documented. However, many of the signaling and biochemical pathways that underlie these dynamics remain incompletely understood.

Genes that regulate morphogenesis are likely to also have requirements earlier in development, making their identification challenging. Thus temperature-sensitive, embryonic lethal (TS-EL) alleles in C. elegans provide an excellent tool for investigating genetic pathways necessary for morphogenesis. Our lab has isolated a collection of ~1,000 TS-EL mutants. We now seek to identify and clone all of the morphogenesis-defective mutants within our collection. To date, we have identified 68 mutants with penetrant and 29 mutants with variable terminal morphogenesis-defective phenotypes (respectively defined as ≥70% or 50<70% of mutants arresting at a single embryonic stage). The majority of the highly penetrant mutants arrest without elongation. We then identify the causative genes using a combined SNP mapping and whole genome sequencing approach, along with genetic complementation tests. In a collaboration, the mutants we identify are further analyzed for cell fate patterning defects using an automated cell lineage platform developed in Zhirong Bao’s lab. We reason that mutants exhibiting normal cell fate specification but abnormal cell shape or location represent true morphogenetic mutants. So far, we have identified 19 alleles representing 13 genes, including glp-1 (3 alleles), let-19 (3 alleles), emb-5 (3 alleles), mom-4, emb-4, chaf-1, rib-1, hlih-1, sart-3, cdc-25.2, and Irr-1.

One gene, Irr-1 (Leucine rich repeat), encodes a protein that functions as a substrate recognition subunit for Cullin 2-RING ubiquitin ligase complex (CRL2\textsuperscript{LRR})\textsuperscript{1}. Introduction of C. elegans CLR2\textsuperscript{LRR} in human cell culture prevents inhibition of the Rho/ROCK/LIMK pathway and activates cofilin, an actin depolymerizer (Starostina et al., 2010). Therefore, LRR-1's role in regulating the remodeling of the actin cytoskeleton makes it particularly interesting, as let-502/ROCK is known to be important for C. elegans embryonic morphogenesis. We are currently characterizing the Irr-1 morphogenesis defects using the cell lineage platform and by using CRISPR to make an endogenous GFP::LRR-1 transgenic line to characterize its expression. Our long term goal is to advance our understanding of embryonic morphogenesis in C. elegans by identifying previously unknown players that influence this fundamentally important biological process.

Cardiac transcriptome profiling during regeneration in zebrafish.
D.A. Zuppo1, M.A. Missinato1, R.A. DeMoya1, M. SaydMohammed1, M. Tsang1;
1Department of Molecular Genetics and Developmental Biology, University of Pittsburgh, Pittsburgh, PA

Myocardial infarctions (MIs) are a prevalent form of cardiovascular disease (CVD) and are a leading cause of global mortality. MI is characterized as an ischemic injury that induces cardiomyocyte (CM) necrosis and subsequent fibrosis of the damaged region. The post-MI scar leaves patients at risk for recurrent MI and heart failure, and one reason for the scar's permanence is the heart's inability to induce sufficient CM proliferation. Mammalian CMs proliferate rapidly during development, but become post-mitotic shortly after birth and fail to divide after injury in adults. Unlike mammals, adult zebrafish possess robust CM proliferation and undergo complete cardiac regeneration. Using ventricular amputation in adult zebrafish as our injury model, we sought to determine which genes play a significant role in CM proliferation after injury and which mechanisms they operate through. In this study, we performed RNA-seq on uninjured and 3 days post-amputation (3dpa) AB* ventricles and validated gene up-regulation with semi-quantitative PCR and RNAseq. cenpf and foxm1 were among those genes induced after amputation. Both genes are highly expressed during mammalian cardiac development but their expression is significantly down-regulated 7 days after birth suggesting they could be important regulators of CM proliferation. Cenpf is a kinetochore-binding protein that may also play roles in vesicle trafficking, DNA-binding, and cell migration, whereas Foxm1 is a transcription factor that regulates the expression of multiple pro-mitotic genes. We hypothesize that cenpf and foxm1 are critical for CM proliferation after injury and that their loss will disrupt the regenerative capacity in adult zebrafish. Currently we are expanding our preliminary findings that cenpf−/− mutant hearts possess large scars even at 30dpa when WT hearts have completed regeneration. Moreover, Cenpf is significantly expressed proximally to the injury zone at 3dpa, which hints at potential roles in CM proliferation. Our goal is to elucidate the exact mechanisms these genes in heart regeneration in hope of providing new therapeutic avenues for mammalian heart repair.

Understanding the molecular basis of human craniofacial disorders using Caenorhabditis elegans as a model organism.
A.A. Alsubait1, A.K. Corsi1;
1Department of Biology, The Catholic University of America, washington, DC

Craniosynostosis is a birth defect in which one or more of the fibrous sutures in an infant’s skull close prematurely resulting in an abnormal head shape. Craniosynostosis occurs in about one of every 2,000 births. Mutations in TWIST1, a basic helix-loop-helix transcription factor, has been found in patients with craniofacial disorders. In this study, we aim to understand the molecular basis of craniofacial disease using Caenorhabditis elegans as a model organism. C. elegans is an excellent model genetic system to study Twist because it has a single TWIST homolog known as HLH-8. Also, HLH-8, its partner HLH-2, and downstream target genes are well conserved with hTWIST proteins. Twist-containing dimers regulate the expression of target genes by binding an enhancer element called the E-box. We study the Notch ligand gene, arg-1, as an HLH-8 target gene. The 385 bp arg-1 promoter region contains three different E-boxes that could be bound by either HLH-8/HLH-8 homodimers or HLH-8/HLH-2 heterodimers. The three E-boxes are sufficient for maintaining the full expression pattern of arg-1 in a subset of
mesodermal tissues including the head-mesodermal cell (HMC), vulval muscles (VMs), and enteric muscles (EMs). In our previous work, we generated an allelic series of different glutamic acid substitutions (E29) at a conserved residue of the HLH-8 DNA binding domain, to mimic the mutations found in craniofacial patients. We discovered that not all of the E29 homozygous mutants were equal regarding phenotypes. E29G, A, and Q were ~100% Egg-laying defective but were mildly constipated. Additionally, 74%-100% of these mutants were able to drive expression of the HLH-8 target gene arg-1 in EMs but not in VMs indicating that these alleles retain the ability of DNA binding. We propose that E29 mutants favor binding a particular E-box DNA sequence over the other. To generate reagents to test our hypothesis, we swapped the different E boxes found in the 385 bp arg-1 promoter region and studied the resulting gene expression. We generated three arg-1 promoter constructs. The first construct was mimicking the WT pattern (E1-E2-E3). In the second one, we swapped E3 with E1, and in the third construct, we swapped E1 with E3. We found that the E1 box sequence is essential for arg-1 expression in HMC but not VMs. Also in animals with swapped constructs, we noticed a decrease in the VMs arg-1::gfp expression indicating that in VMs, arg-1::gfp expression requires having both E-boxes (E1 and E3) besides E2, for maximum VMs expression levels. Next, we will be crossing the HLH-8 E29G, A, and Q mutants in these reporters to evaluate the contribution of the E-box sequences and to see if in these mutants the expression is altered.

Breaking Hertwig’s Rule in the Drosophila Follicular Epithelium.
T.M. Finegan¹, D. Na², A.V. Skeeters³, N.S. Dawney⁴, P.W. Oakes³, A.G. Fletcher⁵, D.T. Bergstralh⁴; ¹Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom, ²Department of Biomedical Genetics, University of Rochester Medical Center, Rochester, NY, ³Department of Physics Astronomy, University of Rochester, Rochester, NY, ⁴Department of Biology, University of Rochester, Rochester, NY, ⁵School of Mathematics and Statistics, University of Sheffield, Sheffield, United Kingdom

We investigated proliferation and tissue regularity in a simple epithelium undergoing elongation. Through live imaging and semi-automated image analysis, we found that cell division drives the early Drosophila follicular epithelium towards optimal geometric packing. This increase in regularity demands that cells break Hertwig’s rule, a long-established principle of cell biology which holds that divisions orient along the cell shape long axis. We show that planar division orientation aligns with the elongating axis of the egg chamber, and not predicted by interphase cell shape. Planar division orientation relies on the actin scaffolding protein Canoe/Afadin, but in contrast to other systems, is not achieved through the asymmetric enrichment of the Pins/Mud spindle-orienting machinery. Spindle orientation in the apical-basal and planar axes are independent. This work highlights the diversity of division control in epithelial tissues, even within the same organism, and suggests a broad means of planar division orientation in epithelia.

Wnt Signaling in Migratory Neural Crest Cells In The Chick Spinal Cord.
S.M. Goodfellow\textsuperscript{1}, F.R. Santana\textsuperscript{1}, L.M. Galli\textsuperscript{2}, L.W. Burrus\textsuperscript{1};
\textsuperscript{1}Biology Dept, San Francisco State University, San Francisco, CA

Neural crest (NC) cells are a subset of migratory cells that generate a variety of different cell types during embryonic development. Neural crest cells have filopodia that have long been implicated in migration. Recently, it has been shown that neural crest cells provide important signals, such as Wnts, to tissues along the path of migration. Wnt producing cells, such as neural crest, require functional PORCN and WLS to generate and transport Wnts to target cells. PORCN, an ER transmembrane protein, adds a palmitate to Wnt that is essential for Wnt secretion and signaling. WLS regulates the sorting and transport of Wnts to the cell surface where it can then be transported out of the cell. Recent studies in Drosophila and zebrafish have shown that Wnts can be transported via actin-based filopodia. Thus, we hypothesized that filopodia in neural crest cells might also function in the delivery of signals such as Wnt. To test this hypothesis, we developed biologically active WNT1-GFP and WLS-mCherry fusion proteins. These constructs were introduced into premigratory neural crest cells via in ovo electroporation. Migratory neural crest cells were subjected to live-imaging using confocal microscopy. In the absence of exogenous WLS-mCherry, WNT1-GFP was primarily localized to the ER and Golgi. Upon co-expression of WLS-mCherry and WNT1-GFP, most WNT1-GFP was redistributed to the cell surface. In addition, we observed an apparent increase of filopodia containing both WLS-mCherry and WNT1-GFP in migratory neural crest cells. To test whether these projections were actin based, we tested for the co-localization of Utrophin-261-EGFP. We found that Utrophin-261 is indeed localized to these projections, thus indicating that the projections are actin-based. As Myosin-X (MyoX) is often found in actin-based projections, we then tested for the localization of a variant of MyoX, HmmMyoX, to these projections. HmmMyoX was found localizing at the tips of some of the projections. Thus, our results show that co-expression of WLS and WNT1 1) induced formation of new filopodia 2) promoted localization of WNT1 to these structures 3) the structures contain actin and 4) MyoX is localized to the tips of the filopodia.

Mask and Yorkie are required for cell adhesion in the Drosophila retina.
M.W. DeAngelis\textsuperscript{1}, R.I. Johnson\textsuperscript{1};
\textsuperscript{1}Biology, Wesleyan University, Middletown, CT

The conserved Hippo signaling pathway is critical for the regulation of tissue growth in both Drosophila and mammals. Transcription of Hippo pathway target genes is mediated by the transcriptional coactivator Yorkie (YAP/TAZ in mammals). Active Yorkie (Yki) translocates to the nucleus where it forms complexes with transcription factors to facilitate the transcription of growth-promoting genes. Recently, the protein Mask was discovered to be a cofactor of Yki and required for the transcription of several Yki target genes. Our results show that Mask is required during development of the Drosophila retina. When Mask levels are reduced, retina display a decrease in overall cell number along with severe patterning defects. Such mispatterning is likely attributed to junctional defects observed when Mask and Yki levels are reduced. This suggests that Mask and Yki are regulators of cell adhesion in the retina. Such a requirement would implicate the Hippo signaling pathway as a novel regulator of cell adhesion during organ morphogenesis.

Quantitative analysis of the contribution of apical constriction to neural tube closure.
A.T. Baldwin1, J.B. Wallingford2;
1Molecular Biosciences, University of Texas at Austin, Austin, TX

Neural tube closure is a complex morphogenetic process that requires several distinct cell behaviors to be successfully executed. Apical constriction (AC) of neural plate cells has long been known to contribute to neural plate folding, but the cell-biological mechanisms of AC in the neural plate are poorly understood. Additionally, recent studies of AC in Xenopus have shown that AC itself is a multifaceted process that may be comprised of both apical surface and apical junction constrictions. To better understand how AC contributes to neural plate morphogenesis, we are combining live imaging and quantitative analysis in the Xenopus neural plate in order to understand how various forms of AC contribute to neural tube closure. Additionally, we are utilizing modern genetic manipulations such as CRISPR/Cas9-mediated gene knockouts and AC effector proteins such as Shroom3 or SH3PXD2B to study the contribution of AC to apical constriction behaviors in the neural plate at both the whole-tissue and sub-cellular levels. Together, these techniques will allow for dynamic analysis of many aspects of AC during neural tube closure while simultaneously building workflows that can be used to study many aspects of neural tube closure in a live organism.

C-cadherin is required for localization of actomyosin contractility machinery during convergent extension.
R.J. Huebner1, J.B. Wallingford2;
1Molecular bioscience, University of Texas at Austin, Austin, TX

Convergent extension (CE) is a process of collective cell migration that drives anterior-posterior (AP) axis elongation in animals ranging from Drosophila to mammals. A key step during CE is polarized junction exchange in which AP cell-cell junctions shrink and are exchanged for mediolateral cell junctions. This requires polarized actomyosin contractility at the shrinking junctions, but it is unclear how the contractility machinery interacts with the cell adhesion molecules that hold these junctions together. Here, we use in vivo subcellular time-lapse imaging of Xenopus laevis mesoderm to investigate how the cell-cell adhesion protein C-cadherin interfaces with the actomyosin contractility machinery. Our initial prediction, based on study of E-cadherin during epithelial CE, was that junction shrinking required reduction of cell adhesion through active clearing of C-cadherin. However, during mesenchymal CE, we observed the opposite and C-cadherin was enriched at AP junctions. Also, we observed concurrent pulses of C-cadherin and actin specifically at shrinking junctions, suggesting cooperative function. To directly test if C-cadherin was required for junctional enrichment of the actomyosin contractility machinery, we knocked down C-cadherin. We found that contractile myosin was depleted from all cellular junctions after disruption of C-cadherin. Interestingly, actin was still present at cell junctions in the C-cadherin depleted tissue. This result lead us to conclude that C-cadherin is required to bring contractile myosin, but not actin to cell-cell junctions and suggests that C-cadherin has a role in constructing or maintaining the actomyosin machinery. Also, these results support a novel mechanism of cadherin function during mesenchymal CE as C-cadherin is not removed from shrinking cell junctions and instead actively contributes to junction remodeling.

Hedgehog signaling constrains cell movements during early eye development.
S. Lusk1, H.B. Gordon1, E.O. Wirick1, B. Froelich1, K.M. Kwan1;
1Human Genetics, University of Utah, Salt Lake City, UT

During development, cells and tissues must undergo dramatic movements to form 3-dimensional organs, the specific structure of which is critical for function. Precise tissue organization is required for the morphogenesis of the vertebrate eye as developmental defects in the eye structure commonly account for visual impairment. One such defect, uveal coloboma, is a significant cause of blindness worldwide and is characterized by a hole or cleft in the eye. Mutations in the Hedgehog (Hh) receptor Patched lead to hyperactive Hh signaling and have been shown to cause coloboma in both humans and zebrafish. Using a combination of 4-dimensional live imaging, computational methods, and molecular genetics, we have determined the morphogenetic events including cell movements, division and death underlying optic cup morphogenesis and how these are disrupted by hyperactive Hh signaling. At the cellular level, we used 4D cell tracking to pinpoint a population of cells whose origin and movements are disrupted when Hh signaling is overactivated. Further, at the single cell level, migration behaviors are disrupted: rather than a migratory bipolar morphology, these cells exhibit multipolar morphology and cease to move. To determine the molecular mechanism by which hyperactive Hh signaling disrupts cell movements and eye formation, we assayed both transgenic reporter and endogenous target gene expression to determine when and where hyperactive Hh signaling first alters development. Using transplantation experiments, we additionally determined that overactive Hh signaling acts non-cell autonomously to disrupt cell morphology and migration, through a Gli transcription-dependent mechanism. With these findings, we present a model in which a specific level of Hh signaling is critical to regulate cell behaviors: we hypothesize that overactive Hh signaling leads to increased production of a secreted molecule or cell-surface protein that in turn disrupts migration behaviors. We have thus identified the cellular mechanism by which overactive Hh signaling disrupts optic cup morphogenesis, and we are currently working to identify the critical Hh factor downstream of Hh signaling that directly regulates migration.

Fetal programming and induction of inflammatory response in the gerbil prostate caused by n-6 fatty-acid intake from corn oil.
M. Marcelio De Jesus1, A.C. Negrin1, R.M. Góes1,2;
1Department of Functional and Structural Biology, University of Campinas (IB/UNICAMP), Campinas, Brazil, 2Department of Biology, State University of São Paulo (IBILCE/UNESP), São José do Rio Preto, Brazil

The quality of dietary lipids in the maternal diet during gestation can negatively affect organogenesis and enhance susceptibility of the offspring to diseases in adult life, a process known as fetal programming. Excessive n-6 fatty acid (FA) intake can favor the development of some diseases, especially those related to inflammatory response. The capacity of these FA to induce fetal programming of prostate has not yet been investigated. The present study evaluated whether maternal intake of n-6 FA during gestation leads to fetal programming of the gerbil prostate. Pregnant Mongolian gerbils (Meriones unguiculatus) were randomly divided into Control (C) and Oil (O) groups. O females received, by gavage, 0.1mL of corn oil from gestational day 8 to 23. Adult male offspring (16 weeks old, n=10...
animals/group) were euthanized and the ventral prostatic lobe was analyzed using stereological, histopathological, immunohistochemical [androgen receptor (AR), phospho-histone H3 and cluster of differentiation 3 (CD3)] and Western blotting [AR, phosphorylated protein kinase B (pAkt), estrogen receptor α (ERα) and liver X receptor α (LXRα)] methods. Serum levels of testosterone (T) and 17β-estradiol (E2) were measured by ELISA. Maternal intake of n-6 FA during gestation decreased the prostatic weight of offspring at adulthood. Stereological analysis showed that this reduction was due to a decrease of 22.6 and 29.7% in the volume of the epithelial and luminal compartments, respectively. Although T levels did not differ between the groups, AR-positive stromal cells and prostatic AR protein expression were enhanced in O. E2 levels and ERα protein expression increased 46 and 61% in this group, respectively. According to histopathological analysis, maternal intake of n-6 FA caused an increase in the incidence and multiplicity of inflammatory-related disorders such as reactive hyperplasia, and also of prostatic intraepithelial neoplasia. These lesions exhibited a particular aspect with inflammatory cells, including CD3 lymphocytes, located predominantly in the subepithelial layer of the prostatic acini. The stromal proliferative index and pAkt protein expression were enhanced in O. LXRα protein expression also increased in this group. This may represent a tendency to down-modulate the accumulation of inflammatory molecules and to ameliorate the inflammatory effects caused by n-6 FA intake. Together, these data indicate that the maternal intake of n-6 FA during gestation affects prostatic organogenesis and leads to perturbations in the epithelial-stromal interaction, disrupting AR, ERα and LXRα and promoting inflammatory-related disorders in Mongolian gerbils at adulthood.

Mouse trophoblast lineage development requires Smad4-dependent signaling.
J. Guo1, Y. Chen2;
1Neuroscience Center, University of North Carolina-Chapel Hill, Chapel Hill, NC, 2Dept. Biological Sciences, Kent State University-Trumbull, Warren, OH

Mouse trophoblast stem (TS) cells established from the outgrowth of the polar trophectoderm of blastocysts or the extraembryonic ectoderm of post-implantation embryos are precursors of trophoblasts and can contribute to all trophoblast lineage derivatives in vivo, providing a powerful in vitro system for studying trophoblast stem cell self-renewal and differentiation. Although it is known that Transforming Growth Factor beta (TGF-β)/Nodal related signaling together with FGF4 signaling is critical for TS cell self-renewal, the intracellular signaling transduction of TGF-β related signaling and its crosstalks with other signaling pathways in trophoblast lineage development remain poorly understood. The function of Smad4, the central mediator of TGF-β related signaling, in trophoblast lineage development has not been fully investigated, partially due to the early lethality of Smad4 null embryos. Utilizing Smad4-deficient TS cells derived from preimplantation embryos, we find that Smad4 deficiency alters the kinetics and lineage distribution during trophoblast lineage differentiation in vitro. In particular, Smad4-deficient TS cells exhibit enhanced differentiation in the spongiotrophoblast and trophoblast giant cells lineages at the expense of the syncytiotrophoblast lineage. Moreover, our studies provide evidence linking the differentiation defects seen in the Smad4 null TS cells to alterations in TGF-β, MAPK signaling pathways, as well as Wnt signaling pathway. Pharmacological manipulation studies reveal that canonical Wnt signaling is involved in the regulation of TS cell self-renewal and differentiation. Our analyses provide insights into the molecular interplays of signaling pathways that regulate trophoblast lineage development.

A Trimeric Transmembrane Mechanism Underlying Enterobacter cloacae Resistance to Triclosan.
J. Marotta¹, K.J. Karnas¹;
¹Biological Sciences, Cedar Crest College, Allentown, PA

Multidrug resistant bacterial infections are rising worldwide, shifting from what once was a biological phenomenon to what is quickly becoming a global health crisis. The creation of antibiotic resistant strains has been facilitated by the overuse of antimicrobial compounds, such as triclosan. For the past several decades, triclosan was added to consumer products such as toothpaste, hand sanitizer, and plasticware. Its overuse has created an environmental crisis, as it has been found in water runoff, soil, sediment, and other substrates. Triclosan contamination provides a selective pressure that likely leads to novel strains that are resistant to this and other antimicrobial compounds. Despite these potential outcomes and limited FDA ban, triclosan continues to be included in some products (e.g. toothpaste) globally, worsening the environmental contamination that has been accumulating for over 40 years. We have previously demonstrated that repeated exposure of various bacterial species to triclosan, tetracycline, and chloramphenicol selects for strains with both resistance to that compound and cross-resistance to other antimicrobials. In addition, growth curve analysis has shown an inverse correlation between novel strain resistance and rate of growth. This study focuses on the transmembrane efflux pump of Enterobacter cloacae. This Gram-negative pathogen is prevalent in both the environment and clinical settings, and is one of the major underlying causes of severe antibiotic resistant intensive care unit infections. Previous studies have indicated that its AcrAB-ToIC efflux pump is associated with the removal of an array of antibiotics including tetracycline and chloramphenicol from the cell, thus increasing organismal resistance to these compounds; this study extends those findings to triclosan-resistant strains and further assesses the connection between efflux pump overexpression and antibiotic resistance. Study methods include real time qPCR analysis of associated genes and intracellular real-time dye efflux assays. Our expression studies show a significant increase in AcrAB transcription. Current studies are extending the scope of these findings by looking at ToIC and a number of activators and repressors involved in operon regulation (e.g. SoxS, MarA, EnvR). Future research includes an extensive study of the consequences of overexpression and repression of the AcrAB operon via cloning into a controlled expression plasmid in E. coli. Ultimately, data derived from this study could lead to a better understanding of the cellular mechanisms that underlie the multidrug resistance, provide a tool for assessing the impact of environmental triclosan on the creation of multidrug resistant species, and offer a potential target for bacterial inactivation.

An antibacterial mechanism of bac8c via apoptosis-like response on Escherichia coli.
H. Lee¹, D. Lee¹;
¹School of Life Sciences, Kyungpook National University, Daegu, South Korea

Bac8c (RIWVIWRR-NH₂), an 8-mer peptide modified from amino acids 4-11 of Bac2a, has been known to exert significant broad-spectrum antimicrobial activity. In the present study, the findings suggest a novel
mechanism for the antibacterial effect of bac8c on *Escherichia coli*, namely, the induction of a bacterial apoptosis-like response. We propose a possible mechanism for the bacterial apoptosis-like death that includes the following: accumulation of reactive oxygen species (ROS) (detected with H₂DCFDA staining), increased intracellular calcium levels (detected with Fura-2 AM), disruption of the membrane potential [detected with DiBAC₄(3)], activation of a bacterial caspase-like protein (detected by FITC-VAD-FMK staining) and DNA degradation (detected with TUNEL assay) which is the hallmarks of late apoptosis in bacterial cells treated with bac8c. We also performed RecA expression assay with western blotting and observed activation of SOS response to repair the damaged DNA using RecA and LexA mutant strains. To summarize, bac8c are involved in the apoptosis-like response in *E. coli* and the novel mechanisms which were identified in this study, suggest that bac8c may be an effective antimicrobial agent with far lower propensity for inducing microbial resistance than antibiotics.

**Understanding Role of VraT in Methicillin-Resistant *Staphylococcus aureus***.
C.E. Wilson¹, V.A. Segarra², A. Sarkar³;
¹Biology, High Point University, High Point, NC

*Staphylococcus aureus* is a major causative organism of infective endocarditis and may result in mortality rates as high as 35% in isolated breakouts. Resistance to frontline antibiotics such as oxacillin and vancomycin suggests novel antibiotics or prophylactic agents are required. Recent studies have shown that deleting a gene coding for the membrane protein called VraT re-sensitizes *S. aureus* to vancomycin via disruption of bacterial signaling pathways. This confirms VraT is a biologically validated drug target. We are currently attempting to understand the structure of VraT and how it promulgates antibiotic resistance. As a first step in our project, we are deleting the VraT gene from methicillin-resistant *S. aureus* using a Group II intron-disruption cassette to generate a re-sensitized mutant strain unable to make the VraT protein. We use this mutant as a tool to design prophylactics against drug resistance or adjuvants for combination therapy with oxacillin and vancomycin.

**Apple cider vinegar changes Escherichia-coli pathogenic protein expression profiles and curbs infected leucocyte cytokine secretion.**
D. Yagnik¹, V. Serafin¹, A. Shah³;
¹Natural sciences, Middlesex University, London, United Kingdom

Antimicrobial infections in the elderly and immunocompromised patients can often lead to complications and host resistance. The World Health Organisation predicts a global escalation in antimicrobial resistance in years to come. Extra-intestinal pathogenic *Eschericia-coli* (E-coli) are the most frequent cause of blood bourne, urinary tract and hospital acquired infections. They can be difficult to treat and can easily spread causing sepsis and even organ failure if not treated in time. Treatment options are still limited hence there is a real need for novel or alternative therapeutics which could combat these infections. Objective: The aim of this study was to investigate the antimicrobial activity of Apple cider vinegar (ACV) on E-coli growth and cellular interactions. Methods: We diluted the ACV at various concentrations and incubated these directly with E-coli at various concentrations using the microdilution technique. We also infected freshly isolated leucocytes from peripheral blood obtained by consensus from healthy human peripheral blood donors. Leucocytes were co-incubated with E-coli for
6, 12, 24 hour time periods and with ACV. Collected supernatants were analysed for cytokine content using ELISAs. We also looked at the impact of ACV directly on the structure of E-coli carrying out tandem mass spectral proteomic analysis. Results: We showed that ACV inhibited E-coli growth, the minimum inhibitory concentration was found to be 1/100 dilution of 5% concentrated ACV. We also saw a dose dependent down regulation of induced monocytes tumour necrosis factor alpha secretion from 2.3 +/- 0.3 ng/ml to 0.2 +/- 0.1 ng/ml (Mean +/- SD) with p<0.05. Proteins analyses of microbial cultures following ACV treatment for 24 hours compared to untreated showed there was an alteration in expression of key metabolic protein involved in E-coli growth cycles. Other proteins that were noticeably absent were those involved in pathogenesis, organelle structure, carbon, glucose metabolism and cellular oxidation or reduction reactions. Conclusion: This study demonstrates that ACV displays antimicrobial activity which can penetrate microbial membranes as well as organelles and destroys key metabolic proteins.

The effects of acetic acid on biofilm formation and wound healing using a zebrafish model.
A. Blake1, M. Belaunzaran1, B. Schoffstall1;
1Department of Biology, Barry University, Miami, FL

Biofilm is an accumulation of multi-species and multicellular microbial mass embedded in polysaccharide matrix with adhesive abilities. Complex biofilm has remarkable ability to impede normal immune responses and aggressive medical interventions, leading to difficulties in treating infections of wounds, heart valves, and bone tissue. We must utilize in vitro, in vivo, and ex vivo models to gain understanding of biofilm formation and eradication. We have previously established a wound model using Danio rerio (zebrafish), both in vivo, and as a novel ex-vivo tissue explant culture, to analyze the formation, growth, and treatment of biofilm. We have compared formation of biofilm within zebrafish penetrating burn wounds using three specific strains of Staphylococcus epidermidis. S. epidermidis RP62A (WT) is a robust biofilm-former, 1457 (WT) is a moderate biofilm-former, and 1457 aapΔ/icaΔ does not form detectable biofilm. Using zebrafish tissue explant cultures, we previously found evidence of bacterial growth in all three strains; however, only the RP62A strain formed robust, macroscopic biofilm and demonstrated microscopic Gram stain evidence of cell clusters held together with polysaccharide matrix. Here, we demonstrate our efforts to begin assessment of the effectiveness of acetic acid treatments on disrupting biofilm formation, both in vitro and using our zebrafish in vivo and ex vivo explant culture models. We hope to gain understanding of the role that acetic acid treatment could play in the treatment of bacterial biofilm infections of chronic wounds.

FzlA, an essential regulator of FtsZ filament curvature, controls constriction during Caulobacter division.
P.J. Lariviere1, P. Szwedziak2,3, J. Löwe2, E.D. Goley1;
1Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD, 2Structural Studies Division, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, 3Institute of Molecular Biology and Biophysics, ETH Zürich, Zürich, Switzerland

During bacterial division, polymers of the conserved tubulin-like GTPase FtsZ assemble at midcell to form the cytokinetic Z-ring, which is postulated to coordinate peptidoglycan (PG) remodeling and
envelope constriction. Determining precisely how Z-ring structure and dynamics are mechanistically coupled to PG metabolism and, more broadly, to division are major goals in the field. Curvature of FtsZ filaments was previously found to promote membrane deformation in vitro, though the role that curved filaments play in facilitating division in vivo remains undefined. Our lab studies FzlA, a bacterial division protein that stabilizes highly curved FtsZ filaments, as a tool for assessing the contribution of FtsZ filament curvature to cell constriction.

Using X-ray crystallography, we determined the structure of FzlA to inform a structure-function analysis of FzlA’s interaction with FtsZ. We phenotypically characterized a panel of mutant FzlA strains, then biochemically assayed activity of the corresponding mutant proteins toward FtsZ. We found that in Caulobacter crescentus, FzlA must bind to FtsZ for division to occur and that FzlA-mediated FtsZ curvature is critical for efficient division. Using single-cell microscopy, we subsequently observed that mutation of FzlA affects cell constriction rate, which we propose corresponds with its ability to bind and curve FtsZ polymers. Further, we found that a slowly constricting fzlA mutant develops “pointy” poles, suggesting that FzlA influences the relative contributions of radial versus longitudinal PG insertion at the septum. These findings implicate FzlA as a critical coordinator of envelope constriction through its interaction with FtsZ and demonstrate a functional link between FtsZ curvature and efficient constriction in C. crescentus.

Spatial-temporal regulation of bacterial cell division machinery by FtsZ treadmilling dynamics.
X. Yang
Z. Lyu
R.J. McQuillen
J. McCausland
J. Xiao
1Department of Biophysics  Biophysical Chemistry, Johns Hopkins University, School of Medicine, Baltimore, MD

Bacteria cells recruit more than twenty proteins to assemble the cell division machinery or ‘divisome’. How these proteins are regulated and coordinated in the future division site is still not completely clear. In Escherichia coli, a tubulin homolog FtsZ could polymerize and form a ring-like structure (Z-ring) at the middle cell where the cell divides. Z-ring formation initiates the recruitment of downstream proteins of a ‘matured’ divisome. Previous studies have shown FtsZs in the ring turnover dynamically both in vivo and in vitro. By using total internal reflection microscopy (TIRF) and 3D structural illumination microscope (3D-SIM), we demonstrated the FtsZ filaments in the ring constantly treadmill around the cell circumference. The dynamic treadmilling behaviour is not caused or related to the known FtsZ regulators, such as ZapAB, MinCDE, and SlmA, but coupled with its intrinsic GTPase activity. The treadmilling speed reduces significantly in FtsZ GTPase-deficient mutant strains, and the septal morphology becomes abnormal and asymmetric. The asymmetric or incomplete septal morphology highly indicates that treadmilling dynamic could modulate the distribution and/or activity of other proteins in divisome, which are responsible for cell wall synthesis. We monitored the localization and mobility of the essential transpeptidase FtsI by 3D-single molecule tracking. These molecules showed directional movement around the future septum with the speed highly correlated with the treadmilling speed of FtsZ. In wild type cells, both FtsI treadmilling and FtsI movement could complete the whole ring circumference in ~100 second time scale which is 1/10-1/20 of the total cell division time under our experiment condition. This indicated that FtsZ ring dynamically redistribute the cell division machinery to build the septal cell wall piece by piece until a uniform septum completed. However, the defected FtsZ with slow treadmilling speed (similar to the division time) can only sample part of the division site and lead to an incomplete septum.

Dual labeling of bacterial peptidoglycan and tubulin FtsZ to study bacterial cell division.
H. Liang1, X. Yang2, J. Xiao3, C.L. Grimes4;
1Chemistry and Biochemistry, University of Delaware, Newark, DE, 2School of Medicine, Johns Hopkins University, Baltimore, MD

Peptidoglycan (PG), an essential component of bacterial cell wall, protects bacterial cells from changes in osmotic pressure and helps to maintain cell shape. PG is constructed from short peptide chains and two carbohydrates, N-acetyl-glucosamine (GlcNAc) and N-acetyl-muramic acid (MurNAc). We recently developed a method combined organic synthesis, biochemistry, and genetic engineering approaches to label Escherichia coli bacterial PG on its MurNAc sugar backbone. Unnatural PG intermediates with bioorthogonal functionalization were synthesized and incorporated into PG via a specific cell wall recycling pathway. Remodeled cells were then labeled with a bioorthogonal click reaction to link a fluorescent molecule onto the cell wall. Using this method, the bacterial cell wall including the dividing PG-ring was successfully visualized and analyzed by Structured Illumination Microscopy (SIM) and Stochastic Optical Reconstruction Microscopy (STORM). To achieve a better understanding of the dynamics and three-dimensional architecture of bacterial cell wall during cell division, we engineered the E. coli cell strain to label on the bacterial tubulin FtsZ, a protein serves as the scaffold of divisome assembly. Dual labeling on the bacterial PG and FtsZ protein provides a new approach to study the interaction between PG carbohydrate and cell divisome, and the forming of Z-ring during cell division. This study would also help to reveal new details about the assembly order during cell wall dividing and determine that whether the PG biosynthesis or FtsZ polymer constriction provides the force for cell division.

1School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, 2Max Bergmann Center of Biomaterials, Leibniz Institute of Polymer Research, Dresden, Germany, 3Department of Biochemistry, University of Wisconsin-Madison, Madison, WI, 4Department of Microbiology, Institut Pasteur, Paris, France, 5Departments of Physics and Integrative Biology, University of California, Berkeley, Berkeley, CA, 6Department of Biomedical Engineering, University of Wisconsin-Madison, Madison, WI

The shapes of most bacteria are imparted by the structures of their peptidoglycan cell walls, which are determined by many dynamic processes that can be described on various length scales ranging from short-range glycan insertions to cellular-scale elasticity. Understanding the mechanisms that maintain stable, rod-like morphologies in certain bacteria has proved to be challenging due to an incomplete understanding of the feedback between growth and the elastic and geometric properties of the cell wall. Here, we probe the effects of mechanical strain on cell shape by modelling the mechanical strains caused by bending and differential growth of the cell wall. We show that the spatial coupling of growth to regions of high mechanical strain can explain the plastic response of cells to bending and quantitatively predict the rate at which bent cells straighten. By growing filamentous Escherichia coli cells in doughnut-shaped microchambers, we find that the cells recovered their straight, native rod-
shaped morphologies when released from captivity at a rate consistent with the theoretical prediction. We then measure the localization of MreB, an actin homologue crucial to cell wall synthesis, inside confinement and during the straightening process, and find that it cannot explain the plastic response to bending or the observed straightening rate. Our results implicate mechanical strain sensing, implemented by components of the elongosome yet to be fully characterized, as an important component of robust shape regulation in E. coli.

Brownian ratchet mechanism for faithful segregation of low-copy-number plasmids.
L. Hu1, A.G. Vecchiarelli2, K. Mizuuchi3, K.C. Neuman1, J. Liu1;
1National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, MD; 2Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI; 3National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD

Bacterial plasmids are extrachromosomal DNA that provides selective advantages for bacterial survival. Plasmid partitioning can be remarkably robust. For high-copy-number plasmids, diffusion ensures that both daughter cells inherit plasmids after cell division. In contrast, most low-copy-number plasmids need to be actively partitioned by a conserved tripartite ParA-type system. ParA is an ATPase that binds to chromosomal DNA; ParB is the stimulator of the ParA ATPase and specifically binds to the plasmid at a centromere-like site, parS. ParB stimulation of the ParA ATPase releases ParA from the chromosome, after which it takes a long time to reset its DNA-binding affinity. We introduce a Brownian ratchet model that recapitulates the full range of actively segregated plasmid motilities observed in vivo. We demonstrate that plasmid motility is tuned as the replenishment rate of the ParA-depletion zone progressively increases relative to the cargo speed, evolving from diffusion to pole-to-pole oscillation, local excursions, and, finally, immobility. When the plasmid replicates, the daughters largely display motilities similar to that of their mother, except that when the single-focus progenitor is locally excursive, the daughter foci undergo directed segregation. We show that directed segregation maximizes the fidelity of plasmid partition.

16s RNA gene Restriction Fragment Length Polymorphism of Guánica Salterns Halobacteria.
A.G. Méndez Pérez1, J.M. Planas-Rivera1;
1Natural Science Department, University of Puerto Rico at Aguadilla, Aguadilla, Puerto Rico

One of the most intriguing things in science are extremophiles, it is fascinating the different physiological characteristics that this organism poses to survive on those extreme environments. How they manage to support harsh environmental conditions, how the fight high osmotic pressures and other situations is really fascinating. Guánica salterns halobacteria is an extremophile organism that live in a saline in Guánica Puerto Rico, we have isolated this extremophiles and performing a full characterization of the halobacteria and we are pursuing to develop the full phylogenetic tree for this archaean. We have gather data to believe that we found a new species of halobacteria,. We are cloning the gene by PCR cloning using primers develop in our lab. DNA sequencing of the amplified fragments and restriction fragment length polymorphism analysis of the 16s RNA gene of the Guánica Saltern Halobacteria, a highly conservative gene in species, will be done. To further characterize it, the DNA sequencing data will be use on a homology Blast analysis to compare it with other known halobacteria.
We are doing clonal expansion of the halobacteria, DNA extractions, PCR cloning, restriction enzymes (RFLP), agarose electrophoresis, and bioinformatics tools. The knowledge of this halobacteria can enrich the scientific community, not only by the founding of a new species but the new characteristics that this organism can have hidden in their genome. Halobacteria are of great interest, not only for being extreme and have information in their physiology to survive in an extreme environment but we have data that shows that this organism produce pigments that can be used as food coloring, it has proteins that are functional in high salt environments that can be used in process of fermentation by big companies. Guánica Saltern Halobacteria can have the protein for the future great technique in biotechnology, or the future in the fermentation process to produce molecules that can impact the medical field.

Isolation and Characterization of Surface Bacteria Associated with the Sea Urchin Lytechinus variegatus.
H.J. Molina\textsuperscript{1}, J.F. Gaige\textsuperscript{1}, L. Jayant\textsuperscript{1};
\textsuperscript{1}Science, Borough of Manhattan Community College, York New, NY

This study focusses on identifying and characterizing bacterial flora that coexist on the surface and test of the sea urchin Lytechinus variegatus. Several bacterial strains were isolated from different batches of wild type sea urchins by gently swabbing their test, mouth and gonadopores with a sterile tip and plating them onto marine agar plates. More than 60 different bacteria were re-streaked till single colonies were obtained. Results indicated that all isolated bacteria were gram negative rods. They also tested positive for the enzyme oxidase and did not ferment lactose. One of them showed agarolytic properties. A few of them harbor endogenous cryptic plasmids ranging in size from 5Kb to 20Kb. A total of 13 strains were selected to be investigated phylogenetically by 16S rDNA gene amplification and sequence analysis. The sequences obtained will be compared with 16S rDNA gene sequences from databases. Bacteria will be tested for antimicrobial properties and the presence of bioactive compounds.

Calcium plays a role in the survival of protist co-isolated from the eggs of sea urchin Lytechinus variegatus and Lyechinus willamsi.
J.F. Gaige\textsuperscript{1}, H.J. Molina\textsuperscript{1}, L. Jayant\textsuperscript{1};
\textsuperscript{1}Biology, Borough of Manhattan Community College, New York, NY

Without treatment, harvested sea urchin eggs disintegrate within 24 hours and become heavily infested with a certain species of protists. It is not clear if the protists disintegrate the eggs or simply consume the degrading eggs. Freshly spawned eggs of sea urchin Lytechinus variegatus were incubated in regular sea water at a normal calcium concentration and in calcium free sea water for four days. Calcium free sea water with natural salinity and low salinity sea water with calcium were used as controls. Results indicated that protists did not proliferate or survive in both calcium free waters. However, eggs disintegrated even in the absence of protists though at a slower rate. There is clear indication that protists are not responsible for disintegration of the eggs. Furthermore, it appears that calcium is very essential for the survival of this protist. Classification and the symbiotic role of this protist with sea urchins needs to be investigated.

Analysis of damaging effect of Betadine combined with the enzyme nuclease toward bacteria Serratia marcescens.
E.F. Zainutdinova¹, A. Rizvanov¹, M.N. Filimonova¹;
¹Institute of Fundamental Medicine and Biology, Kazan Federal University, Kazan, Russia

Gram negative bacteria Serratia marcescens is recognized as important pathogen. We displayed the culture growth caused by addition into the broth of the filter papers that 14 years ago were soaked with various strains of bacteria S. marcescens, and then were dried, and after that were stored at 4C. As S. marcescens also demonstrates an incredible resistance to the action of antibiotics we decided to work out a combined preparation that includes Betadine, making pore in cells’ membranes, and the enzyme, nuclease, potently degrading both RNA and DNA.
We found a complete loss of viability of S. marcescens culture after 3 min incubation in the presence of 10-fold water diluted Betadine (povidone iodine - topical antiseptic). The further dilution of Betadine diminished its suppression of S. marcescens growth. Electronic microscopic examination of S. marcescens cells after 15 sec incubation with 5000-fold diluted Betadine showed both the damage of the boundary layers of the cells, and changes in chromatin, as well as migration of cytoplasmic membrane into the cytosol, which probably connected with the diminishing turgor. The Betadine effectiveness depended on both the culture density and the growth phase. The culture of the stationary phase was most sensitive to the action of the diluted Betadine and, vice versa, least sensitive, at the lag phase. The purified as had previously published [1] nuclease was found to maintain 30-40% of the residual activity after 20 min incubation with 2000-fold diluted Betadine. Combining the diluted Betadine, with the nuclease enhanced the damage to S. marcescens cells. The electronic microscopic examination of the cells after 15 sec incubation with a mixture of the diluted Betadine and the nuclease showed that the microbial material in the vast majority contained the cells with a distorted shape: curved, rounded, and also structures resembling fragments of cells. Quite often we observed structures resembling cells with a “trail” that suggested the outflow of the protoplast. In most cases, almost complete loss of the boundaries between periplasm, cytoplasm, cell wall, cytoplasmic membrane and nucleoid region was observed. As a result, the cells resembled a mixture of haphazardly located fragments of different electron density.
This study was conducted according to the Russian Government Program of Competitive Growth of Kazan Federal University. Albert A. Rizvanov was supported by state assignment 20.5175.2017/6.7 of the Ministry of Education and Science of Russian Federation.

Multidrug Resistance in Disparate Bacterial Species Following Triclosan Exposure.
J. Marotta¹, N.M. Raimondi¹, L.R. Koseki¹, A. Connell², L.S. Feldman¹, L.P. Exton², K.J. Karnas³;
¹Biological Sciences, Cedar Crest College, Allentown, PA, ²Emmaus High School, Emmaus, PA

The Food and Drug Administration (FDA) considers the increased resistance of bacteria to antimicrobials to be a major public health threat. Initiatives to ensure proper use of these agents are countered by the
public demand for substances that can regularly be used to impede the growth of bacteria that cause human disease. One such agent, triclosan, has been used as a supplement in common personal hygiene products such as toothpaste, shampoo, and hand sanitizer for several decades as a way to discourage bacterial growth. Its effectiveness was first questioned by the FDA in 1974, but its use has continued. Noting a lack of evidence regarding efficacy, the FDA banned triclosan and 18 other antimicrobial ingredients from most commercially available products beginning in January 2017; however, this merely limited its use as this chemical continues to be included in such products as plastics and toothpastes. In addition, there has already been a significant ecological accumulation of triclosan in soil, sewage, water runoff, and natural bodies of water. The Florence Statement on Triclosan and Triclocarban that was introduced at the 36th International Symposium on Halogenated Persistent Organic Pollutants in 2016 summarized concerns raised by a multitude of studies demonstrating a negative impact on the environment, concerns for the health of humans and aquatic organisms, and the potential for increased microbial resistance. The study presented here directly links triclosan to derived microbial resistance in a variety of bacterial species (e.g. Alcaligenes faecalis, Enterobacter aerogenes, Enterobacter cloacae, Escherichia coli, Micrococcus luteus, and Staphylococcus aureus), and further affirms that this resistance impacts the susceptibility of those species to other antibiotics. Strains repeatedly exposed to triclosan quickly became partially- or fully-resistant to that chemical, as demonstrated by Kirby-Bauer antibiotic testing and growth curve analysis of cultures grown in the presence and absence of triclosan. Furthermore, these derived strains showed altered response to other antimicrobial drugs, such as chloramphenicol and tetracycline. Given that triclosan will likely persist in the environment, this study raises concerns regarding long-term alterations to naturally occurring bacteria and their resistance to antibiotics. Further research seeks to characterize the underlying molecular changes that lead to this cross-drug resistance, identifying commonalities among the strains, and further assessing the types of compounds rendered ineffective in these novel bacterial strains with the hope of identifying potential targets for combating multidrug resistance.

**Comparison of virulence factors in clinical and environmental strains of actinobacterium* Tsukamurella tyrosinosolvens* based on whole-genome sequencing.**

V.A. Romanova¹, E.A. Boulygina¹, T.V. Grigoryeva¹, A.V. Laikov¹;¹Institute of Fundamental Medicine and Biology, Kazan Federal University, Kazan, Russia

Actinobacteria are an extensive phylum of microorganisms, including both pathogenic and biotechnologically beneficial bacteria. One of such representatives is *Tsukamurella tyrosinosolvens*. Therefore, the question of the safety of using opportunistic actinobacteria in biotechnological processes and, in particular, in the processing of industrial wastes remains open. Currently three whole genome sequences for T. *tyrosinosolvens* strains are presented in the NCBI database: PS2 (test strain), CCUG 38499 (clinical strain) and JCM 15482 (soil strain). The first strain was isolated by us as an alkane-oxidising bacteria from the industrial wastewater sludge repository. *T. tyrosinosolvens* PS2, which showed no specific activity on blood agar and salt egg yolk agar, was considered as a potential non-pathogenic strain for comparative analysis. Hemolytic and lecithinase activity for another two strains is unknown. The identification of genetic determinants of pathogenicity in the bacterial genomes among the factors that determine the adhesion, invasion, secretion and resistance of microorganisms was performed using the MP3 program (“Prediction of Pathogenic/Virulent Proteins”). A total of 533 genes were found, 516 of which were shared by all strains, 7 genes were unique for the *T. tyrosinosolvens* PS2 strain, and 10 genes appeared to be specific for the clinical and soil isolates. In the genome sequence of
the hydrocarbon oxidizing strain *T. tyrosinosolvens* PS2 no invasion factors participating in the primary attack of cells and tissues of the host organism, such as trypsin, and endopeptidase enzymes genes, that cleave peptides and proteins, were detected. In addition, a lack of genes for the pseudaminic acid synthesis, which is necessary for the bacterial cell movement, colonization of mucous membranes and host tissue invasion, was demonstrated. Key genes of the type IV secretion system, which carries out the virulence proteins secretion into the eukaryotic cell, were not found. Among the unique *T. tyrosinosolvens* PS2 strain genes, bacteriophage were found, which could be considered as indirect pathogenic factors. Thus, the differences revealed by the *T. tyrosinosolvens* strains genome comparison are of interest for studying host-pathogen interactions. Lack of genes for the primary attack of host organism cells and tissues probably reduces the level of PS2 strains’ virulence. The identical profile of virulence factors in both soil and clinical strains indicates potential danger of soil bacteria as a source of opportunistic infection.

The research was performed using the equipment of the Interdisciplinary Center for Shared Use of Kazan Federal University according to the Russian Government Program of Competitive Growth of Kazan Federal University.

**Assaying the Relative Effectiveness of Biofilm Disruption by Natural Oils.**

L.R. Vega¹, K. Livingston³, C.J. Hengartner¹;

¹Biology, Barry University, Miami Shores, FL

Biofilm formation is a survival mechanism some bacteria have evolved to adapt to host defense systems and harsh environmental conditions. Biofilms exhibit characteristics that are distinct from those expected for planktonic microorganisms including: increased antibiotic resistance, increased resistance to environmental stresses, and the expression of virulence factors. As such, biofilms contribute to bacterial pathogenicity. A crucial component of biofilms is the polysaccharide matrix, which allows adherence of bacteria to surfaces. We developed qualitative and quantitative methods to analyze biofilms formed in static cultures of *Staphylococcus aureus* and *Staphylococcus epidermidis*, two clinically important pathogens and aim to use these methods to examine the biofilm inhibiting properties of various chemicals. Under our laboratory conditions, *Staphylococci* produce a polysaccharide rich biofilm matrix that can be disrupted by diastase. In these new studies we examine the qualitative and quantitative effects of natural, easy to find oils including: olive oil, coconut oil rapeseed oil and peanut oil to disrupt biofilms. The ability to disrupt existing biofilms using oils may inform novel topical therapies. The results of our latest findings will be presented. Grant Support: NIH-NIGMS MBRS RISE: R25 GM059244-15

**Essential roles for sterols in bacterial cell biology.**

S. Stettner¹, M. Helling², F. Basile¹, N. Ward¹;

¹Molecular Biology, University of Wyoming, Laramie, WY, ²Chemistry, University of Wyoming, Laramie, WY

Sterols are necessary membrane components in eukaryotic cells, and regulate membrane structure, function, and dynamics. Bacteria generally lack sterols, and contain hopanoids as functionally analogous surrogates. The planctomycete bacterium Gemmata obscuriglobus produces membrane sterols, but
their function remains enigmatic. It belongs to the greater Planctomycete-Verrucomicrobia-Chlamydiae (PVC) bacterial superphylum, where many members contain unique membrane morphological features plausibly connected to sterols. We are pursuing two aims related to sterols. Firstly, we are investigating the function of sterols in G. obscuriglobus. As genetics have only recently been developed in this bacterium, we pursued this question using a chemical depletion approach. We found G. obscuriglobus membrane sterols to be essential for survival, the first reported instance in a bacterial species. Using time-lapse light microscopy, we observed a profound defect in cellular replication associated with sterol depletion, suggesting G. obscuriglobus membrane sterols are essential for proper cell division. Secondly, we have begun to determine the prevalence and function of sterol biosynthesis across the PVC superphylum using complementary microscopy and gas chromatography mass spectrometry approaches. We found three candidate sterol-producing species within the Verrucomicrobia, though further quantitative analysis is needed. One of these bacteria exhibits a similar sterol depletion phenotype to that observed in G. obscuriglobus. Our results support novel roles for sterols in prokaryotic cell biology, particularly in regard to cell division.

Strong Antimicrobial Activity Displayed By Newly Synthesized Hydroxamic Acids And Their Derivatives.
S. Dosanjh¹, J. Klinkerth¹, C. Ellameh¹, R. Aslanian¹, M. Bendaoud¹;
¹Biology, New Jersey City University, Jersey City , NJ

The increasing antibiotic resistance of pathogenic bacteria and decreasing availability of naturally produced antibiotics have made it crucial for researchers to design and synthesize new therapeutic agents with antimicrobial properties. Several chemical compounds including hydroxamic acids, and their derivatives were newly synthesized by the chemistry department and tested in our lab for antibacterial activity against eight different ATCC strains of pathogenic bacteria. The antimicrobial activity of each compound was evaluated using the disk-diffusion assay, liquid broth assay, and data derived from microtiter plate absorbance reading. While some compounds displayed a wide spectrum of antibacterial activity others did not have any effect on bacterial growth. These results enabled us to narrow down the potential active site or functional group in the molecules responsible for the activity. Future work will focus on designing and testing new derivatives with a broader spectrum of activity.

Discovery of a Marine Bacteria with a Wide Spectrum Anti-Bacterial Activity.
J. Klinkerth¹, S. Dosanjh¹, C. Ellameh¹, M. Bendaoud¹;
¹Biology, New Jersey City University, Jersey City , NJ

Biofilms forming and antibiotic resistant bacteria are responsible for most infectious diseases and hospital related bacterial infections. The need for new antimicrobial and antibiofilm compounds is becoming vital as the incidence of these types of infection is dramatically increasing. The focus of our research is the identification and characterization of new anti-biofilm and anti-microbial substances. An unknown marine bacterium found in the Newark Bay coastal water was isolated and tested for possible anti-biofilm and anti-microbial activity. Cell free extracts of the unknown marine bacteria were made and tested against various strains of Staphylococcus aureus, Staphylococcus epidermidis, Klebsiella pneumoniae, Pseudomonas aeruginosa, Erwinia carotovora, and Escherichia coli. The unknown extract
consistently exhibited strong antimicrobial activity against a wide range of gram negative and gram positive bacteria. The active compound appears to be greater than 100 kDa in size and heat sensitive. Proteinase K, DNase and RNAse treatment had no effect on the activity of the extract. Further studies will be conducted to characterize and identify the unknown bacteria and the active fraction of the extract.

*Plasmodium falciparum* GPCR-like receptor SR25 mediates extracellular K+ sensing coupled to Ca2+ signaling and stress survival.

M.S. Moraes\(^1\), A. Budu\(^1\), M.K. Singh\(^1\), L. Borges Pereira\(^1\), J.C. Levano Garcia\(^1\), T. Pozzan\(^2\), C.R. Garcia\(^3\);  
\(^1\)Physiology, University of Sao Paulo, Sao Paulo, Brazil, \(^2\)Scienze Biomediche, Università di Padova, Padova, Italy

During its development, *Plasmodium falciparum* is exposed to changes in ionic content in their surrounding environment. We have found that the *P. falciparum* serpentine-like receptor PfSR25 is involved in KCl-evoked Ca2+. In accord, switching of isolated parasites from a high KCl solution (140 mM) to a low KCl solution (5.4 mM) triggered increases [Ca2+]cyt. The KCl-elicited Ca2+ response was blocked by a phospholipase C (PLC) inhibitor, U73122 or by internal Ca2+ store depletion. This response was never observed when NaCl was used as the KCl substitute. In contrast, the calcium response in the parasite were suppressed by the knockout of the gene for the PfSR25 receptor (PfSR25-). Our results also demonstrate that PfSR25 plays important roles in adaptive response to stress: a) hyperosmotic stress resulted in a significant decrease in wild type parasites (WT) volume, but not in PfSR25- parasites; b) sodium nitropusside (SNP) exposure decreased parasitemia and upregulated metacaspase expression in PfSR25- parasites; c) wt parasites showed a significantly greater survival than PfSR25- parasites during albumax starvation; and d) PfSR25- exhibited a smaller hemozoin formation than that of WT after treatment with piperaquine (PQ). The present data showed a critical role for PfSR25 receptor in *P. falciparum* development and a better understanding of this pathway may help to clarify their role into these different functions.

*Isolation of Apicomplexan Blood Parasites from Caribbean Stegastes Damselfishes.*

D.E. Walters\(^1\), K. Liburd\(^1\), N. Blake\(^1\), A.G. Campbell\(^2\), P.C. Sikkel\(^3\), J.B. Robinson\(^1\);  
\(^1\)Biology, University of the Virgin Islands, St. Thomas, VI, \(^2\)BioMed, Brown University, Providence, RI, \(^3\)Biology, Arkansas State University, Jonesboro, AR

Apicomplexa are intracellular protozoan parasites that infect a wide array of host animals including humans, other mammals, birds, reptiles, fish and invertebrates. Apicomplexa are responsible for severe human disease such as malaria, but little is known about other natural apicomplexan infections. Fish infections can be used as alternate model systems to study these parasites. In the Caribbean, some of the most abundant coral reef fish, Stegastes damselfishes, are infected with Apicomplexa parasites in their red blood cells. To characterize the lifecycle, host range, and transmission route of these parasites, our goal is to develop methods to isolate and detect them in infected fish samples. **We hypothesize that we can isolate parasites from fish blood using Percoll density step gradients to fractionate cells.** To
test our hypothesis, we captured damselfish from their natural reef habitat, collect blood, and release them. Next, patterns of fractionated cells were compared from blood samples with varying degrees of infection. We also optimized various techniques for detecting parasites, including microscopy, PCR and western blot. We identified parasites in Giemsa-stained whole blood smears from 40% (4 of 10) Stegastes adustus, dusky damselfish, captured and released in Brewers Bay, St. Thomas in June 2017. We also were able to detect parasites in some fractionated blood cells using microscopy. PCR and western blot analysis will be used to confirm that some blood cell fractions are enriched with parasite DNA and proteins. PCR analysis followed by DNA purification and sequencing tested primer specificity for the parasite 18S rDNA. Sequences amplified from damselfish blood matched to other Caribbean fish apicomplexan isolates in the NCBI nucleotide database using BLAST. Our results suggest that we can fractionate fish blood, detect parasite DNA and visualize infected cells using microscopy. These techniques can be used for future experiments to identify the range of tissues and hosts infected, towards mapping the lifecycle and transmission routes of these apicomplexan parasites. The positive impact of our research will be significant, as our findings will facilitate the application of this naturally occurring infection to the study of human disease.

Unconventional trafficking of a DNA replication protein through secretory pathway in apicomplexan Plasmodium falciparum.
B. Sharma¹, R. Sharma¹, S.K. Dhar¹;
¹Special Centre for Molecular Medicine, Jawaharlal Nehru University, New Delhi, India

Malaria, caused by Plasmodium sp., continues to be a major factor contributing to the disease burden of many countries. Amongst the various species of Plasmodium, P. falciparum is known to induce the deadliest form of malaria. It replicates at least four times during its life cycle in human and Anopheles mosquito. Additionally, it has evolved an intricate secretory system within itself as well as in the host cells for its survival. P. falciparum owes its successful survival to the efficient replication machinery as well as the ability to manoeuvre the host system according to its requirements. This study is an attempt to unravel the unusual trafficking of a Plasmodium origin recognition complex subunit homolog, PfOrC2, possibly involved in DNA replication through the endoplasmic reticulum (ER) en route to the nucleus. Some proteins follow this path from ER to nucleus under special circumstances, but such a pathway has not been reported in a pathogenic organism like P. falciparum. Based on experiments employing specific antibodies against the N-terminus and C-terminus of PfOrC2 and a series of inhibitors acting on the anterograde transport from ER (Brefeldin A) & intra-membrane proteolysis (Z-LL)₂, we found that the full-length protein is following the ER-Golgi secretory pathway and getting processed by a signal peptide peptidase. Subcellular localisation of the full-length protein and the processed fragment was established through GFP fusion parasite line, immunofluorescence assays and fractionation. The processed form is targeted to the nucleus in an-importin dependent manner (impeded by ivermectin) constitutively and might function in DNA replication and other auxiliary function. This is the first report on the ER-association and processing of a nuclear protein implicated in DNA replication in a parasite, similar to trafficking of transcription factors in higher eukaryotes.

A cdc2 homolog is required for completion of oral development during regeneration and cell division in the giant ciliate *Stentor coerules*.  
S.B. Reiff¹, W.F. Marshall II;  
¹Biochemistry Biophysics, UCSF, San Francisco, CA

The giant unicellular ciliate *Stentor coerules* has the ability to fully regenerate after being cut into pieces, in a way that perfectly preserves the original polarity and structure. This regeneration ability is particularly remarkable because *Stentor* has a complex cortical architecture, with longitudinal ciliary rows running between an oral apparatus at the anterior end and a holdfast at the posterior end. The molecular details behind this incredible phenomenon have remained largely unstudied, and we wish to understand how the regeneration process is coordinated at the molecular level. To identify candidates for RNAi knockdown we analyzed the kinome of *Stentor*. *Stentor* was found to encode over 2000 kinases, making up 6% of the total protein coding genes. Many of these consist of expansions in mitotic kinase families such as CDKs, PLks, Auroras, NDRs, and NEks. As some of the details of the regeneration process parallel the events of cell division, we wish to understand whether the cell co-opts cell division signaling pathways to initiate and control regeneration. To begin to investigate the role of the cell cycle in regeneration, we performed RNAi knockdown of CDK1/cdc2 homologs in *Stentor*. For some of the cdc2 genes, knockdown resulted in slowed division with daughter cells of strikingly unequal size. For other homologs, however, knockdown results in cells unable to complete division. In these cases, the cells are still able to initiate oral development but ultimately exhibit aberrant oral morphology, both prior to division and during regeneration. We conclude that the oral regeneration process employs CDK signaling pathways. In future work we aim to understand the full extent to which *Stentor* uses cell cycle signaling pathways to coordinate and control regeneration.

The localization and functional analysis of a novel centrin (TgCentrin2) in human pathogen *Toxoplasma gondii*.  
J. Liu¹, J.M. Leung¹, L.A. Wetzel², Y. Zhang³, J.M. Murray¹, L. Florens ³, K. Hu¹;  
¹Biology, Indiana University Bloomington, Bloomington, IN, ²Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, ³Stowers Research Institute, Kansas City, MO

Centrins are EF-hand containing proteins ubiquitously found in eukaryotes and are key components of centrioles/basal bodies as well as certain contractile fibers. We previously identified several centrins in the human parasite *T. gondii*, all of which are localized to the centrioles. However, one of them, TgCentrin2, is additionally targeted to ring-like structures at the apical and basal ends of the parasite, as well as a set of 5-6 annuli about ~1/4 body length from the parasite apex. Using TgCentrin2 as the probe, we seek to elucidate the composition and function of these novel centrin-containing structures, which will provide new insights into centrin biology. Because TgCentrin2 appears to be an essential gene, we designed a dual regulation method that combines transcriptional and protein stability control to achieve tight, conditional regulation of TgCentrin2 level in the cell. We discovered that the knockdown of TgCentrin2 results in severe defects in multiple aspects of *T. gondii* lytic cycle, including cell replication, cytokinesis, and cell motility. Our data also indicate that there is differential turn-over or incorporation kinetics of TgCentrin2 in its different locations. Lastly, using proteomic methods, we
have identified and are currently characterizing a group of novel TgCentrin2 interacting proteins, which may help to design new anti-parasitic measures.

Board Number: B847  
The activity and function of TgDCX, a component of non-tubular tubulin polymers in the human parasite, Toxoplasma gondii. 
^1Department of Infectious Diseases, University of Miyazaki, Miyazaki, Japan, ^2Nikon Instruments Inc, Melville, NY, ^3Biology, Indiana University, Bloomington, IN, ^4Seattle Structural Genomics Center for Infectious Disease, Seattle, WA, ^5Beryllium Discovery, Seattle, United States

Purified tubulin subunits spontaneously form microtubules in vitro, and thus tube formation is an intrinsic property of the tubulin subunits. However, in the human parasite, Toxoplasma gondii, these same tubulin subunits are assembled into 14 non-tubular fibers spirally arranged in a truncated cone-shaped complex (the conoid) as well as at least 5 other structures formed of canonical (tubular) microtubules. Identifying the structural determinants of the conoid and characterizing their activity in catalyzing the formation of the ribbon-like conoid fibers will therefore provide insight into how the intrinsic tendency of tubulin subunits to form a tube can be overridden by associated proteins. One candidate for this role is TgDCX, a protein bound to the conoid fiber in Toxoplasma that has a doublecortin (DCX) domain and a TPPP/P25-alpha domain, both of which are known modulators of tubulin polymer structure. Using an icosahedral virus particle containing exactly 240 copies of fluorescent proteins as the calibration standard, we estimated that approximately every 2 tubulin subunits is decorated with one TgDCX molecule in the conoid fibers. We previously showed that loss of TgDCX radically disrupts the structure of the conoid, severely impairs host-cell invasion, and slows growth. We recently found that recombinant TgDCX bundles tubulin polymers in vitro and in vivo. Furthermore, by cross-species complementation, we are able to generate "conoids" in which the TgDCX molecules are partially or fully replaced with a homolog from a photosynthetic, free-living relative of T. gondii that has a drastically different conoid structure. This makes it possible to examine the molecular basis for the evolution of this fascinating cytoskeletal complex over hundreds of millions of years. The non-tubular polymeric form of tubulin found in the conoid is not found in the host cell, suggesting that TgDCX may be an attractive target for new parasite-specific chemotherapeutic agents. To facilitate that effort, a C-terminal fragment of TgDCX that contains the DCX domain has been crystallized by the Seattle Structural Genomics Center for Infectious Disease.

Deciphering the role of proteasomal machinery in phagocytosis in Entamoeba histolytica.  
R. KUMARI^1, S. TIWARI^1;  
^1SCHOOL OF BIOTECHNOLOGY, JAWAHARLAL NEHRU UNIVERSITY, NEW DELHI, India

Current phagosomal maturation models have mostly been derived from the endosomal maturation models in which ubiquitination/proteasomes machinery functions at multiple steps from early to late stages, including optimal ligand based internalization and endosomal maturation via the ESCRT pathway. The role of ubiquitination/proteasomes in phagosome maturation is, however, controversial due to reductionist approaches using one phagocytic receptor [1] and opsonized latex beads [2] or due to suspected contamination with non-specific proteins in purified phagosomes [3].
We have used the protozoan parasite, E. histolytica, along with red blood cells (RBCs) to understand the molecular mechanism of phagocytosis in this organism. E. histolytica is a professional phagocytic cell. This system is likely to represent the entire complexity of the phagocytic process due to use of unmodified cells and a natural ligand for phagocytosis. Biochemical assay of phagocytosis showed a significant inhibition by proteasome inhibitors. Confocal imaging after incubation with RBCs for 5 min showed 27.3% and 18% cells with phagocytic cups and 6.2% and 2% cells with phagosomes in control and proteasome inhibitor treated cells, respectively. EhCaBP1 is an early protein to be recruited to the phagocytic cups but falls-off after the cup closure and detachment from the plasma membrane. Relative fluorescence intensity of EhCaBP1 was significantly higher at the phagocytic cups in proteasome inhibitor treated cells. This could be due to a stabilization of EhCaBP1 protein by proteasome inhibitors as was observed by western blotting. Phalloidin staining of the actin polymerization at the phagocytic cup did not show any significant difference upon inhibition of proteasome activity. Live cell imaging showed a sustained interaction of RBCs with treated cells without internalization. These results suggest a slower kinetics of phagocytic cup and phagosome formation upon inhibition of proteasome activity and will be discussed in relation to the current models of phagosome maturation in E. histolytica. These studies may also have implications of ubiquitination/proteasomal involvement in phagosomal maturation process in high eukaryotes.

J. Limonta¹, N. Dolce¹, M. Ng¹, G. Mayer¹;
¹Biology, Manhattan College, Riverdale, NY

Giardia lamblia, a flagellated protozoan parasite, if ingested, infects the lumen of the small intestines in humans. This parasite is found in various animals, such as dogs, cats, and birds. G. lamblia is most commonly transmitted to humans via ingestion of contaminated food and water. Its presence in aquatic environment is relatively unorthodox and its presence in public waterways is a public health concern. The goal of this study is to determine the prevalence of G. lamblia in Atlantic oysters (Crassostrea virginica), ribbed mussels (Geukensia demissa), and steamers (Mya arenaria) collected from Orchard Beach and Soundview Park, Bronx, NY. The mussels were collected on September 15, 2016 at low tide. Tissues were dissected followed by DNA extraction and PCR analysis. Thus far, we found a prevalence of 77% (21/28) and a prevalence of 65% (11/17) of G. lamblia in Soundview Park and Orchard beach, respectively. Additional experiments will be conducted to determine whether there is a difference in the prevalence and genotype of G. lamblia between the two sites. Furthermore, we will be able to assess the temporal variation in G. lamblia prevalence at Orchard beach from 2014-2016. In conclusion, Atlantic oysters and ribbed mussels can be used as a biological sentinel to detect G. lamblia in public waterways and reservoirs.

Parasites as an Alternative Model for Lipid Metabolism: Gene Expression Analysis of an Oyster Parasite Perkinsus marinus during Lipid Starvation.
K.M. Noell1, J.S. Pitula2;
1Department of Natural Science, University of Maryland Eastern Shore, Princess Anne, MD

Our laboratory is interested in understanding the response of Perkinsus marinus, a protozoan parasite of oysters, to lipid starvation as a means of understanding its underlying metabolic pathways. Previous work has shown that this parasite is capable of synthesizing its own fatty acids, and as well as acquiring them from their host. As citrate can serve as a source of Acetyl CoA, we are also investigating the role of cytosolic aconitase as a potential regulator in this process, as there is evidence for phosphorylation of this enzyme to favor citrate production. No one, to our knowledge, has delineated the role of cytosolic aconitase in fatty acid biosynthesis. We have performed differential mRNA gene expression in P. marinus, in which cells were starved of lipids for 11 days, as compared to lipid replete cells. There was not a noticeable upregulation of FAII-pathway enzymes for saturated fatty acid synthesis, although citrate synthase was upregulated approximately 3-fold, consistent with allostery activation of acetyl CoA carboxylase-1. Polyketide polyunsaturated fatty acid synthase and delta 5/ delta 6 fatty acid desaturase were upregulated by approximately 2-fold. Surprisingly, a number of enzymes involved in beta-oxidation were upregulated, which contrasted with the expectation that free fatty acids from triglycerides would be directed towards salvage pathways for membrane synthesis. Consistent with this, ACC-2 was down regulated 2-fold. Interestingly, maltose acetyl transferase was also upregulated 2-fold, implying that acetyl units from beta-oxidation may be re-directed to sugar acetylation. The implications of this complex interplay will be discussed, along with future experiments to address lipid and sugar metabolites present in this parasite under lipid starvation conditions. Finally, the activity and phosphorylation status of aconitase-1 will be assessed under these conditions.

Farnesol inhibits both translation initiation and morphological differentiation in the human fungal pathogen, Candida albicans.
N.E. Egbe1, M.P. Ashe2;
1Biological Sciences, Nigerian Defence Academy, Kaduna, Nigeria, 2Faculty of Biology, Medicine and Health, The University of Manchester, Manchester, United Kingdom

Candida albicans is a polymorphic yeast that can cause life threatening systemic infections in immunocompromised individuals. One key attribute of C. albicans that enhances its pathogenicity is the ability to switch morphologies between filamentous and vegetative modes in response to specific environmental conditions. Stressful changes in such cellular conditions commonly cause a rapid inhibition of global protein synthesis leading to altered programmes of gene expression. In Saccharomyces cerevisiae, fusel alcohols signal nitrogen scarcity and induce pseudohyphal growth enabling yeast colonies to spread towards nutrient replete areas away from toxins. These alcohols also inhibit protein synthesis by targeting the translation initiation factor, eIF2B. eIF2B is the guanine nucleotide exchange factor for eIF2, which supports eIF2.GTP production and represents a key regulated step in translation initiation. In this study, a variety of cell biological and genetic assays suggest that in C. albicans, fusel alcohols and ethanol inhibit protein synthesis by targeting the translation initiation factor, eIF2B. These alcohols also lead to a morphology switch from yeast to hyphal or pseudohyphal growth.
The capacity to switch morphology is linked to pathogenesis for C. albicans. Farnesol, a quorum sensing alcohol secreted by C. albicans in its growth medium also inhibits translation initiation but does not appear to impact upon eIF2B activity. Rather, biochemical and mass spectrometric analysis suggest farnesol affects some aspect of mRNA interaction with the small ribosomal subunit during translation initiation. Intriguingly, farnesol has the opposite effect on morphological switching to hyphal-like forms, in that it prevents such transitions. These results highlight the possibility that regulation at different stages of the translation process can result in highly diverged phenotypic outputs, presumably as a consequence of differential regulation of the translation of specific mRNAs. Overall the integration of these responses may have implications in pathogenicity.

Unraveling calcium programmed hunting biodynamics of the swan-necked predatory ciliate Lacrymaria.
S.M. Coyle¹, M. Prakash¹;
¹Bioengineering, Stanford University, Stanford, CA

Cells are remarkable machines capable of using molecular activities to perform extraordinary mechanical feats. To achieve this, signaling mechanisms must coordinate multiple active systems within the cell and regulate their actuation, but our understanding of how such complex behaviors are programmed is poorly understood for all but a handful of systems. Here, we investigate how calcium signaling controls the mechanical systems biology and biodynamics of a hunting behavior in a swan-necked ciliate Lacrymaria olor. Lacrymaria is a single-celled predator that attaches its large body to a substrate and hunts for food through repeated cycles of extension and contraction of its highly agile head and neck that can span more than seven body lengths. By tracking and quantifying the geometric features of the head and neck over time, we observe complex oscillatory dynamics indicative of stretching, relaxation, and contraction of an elastic torsional system. Analysis of the fluidic flow-fields generated around the organism implies that stretching events arise from a strong pulling force generated by the head. In contrast, the magnitude of the restoring force and contraction events appear to be under calcium control, as dramatic changes to head and neck dynamics were observed upon perturbation of calcium signaling. Live cell imaging of calcium signaling dynamics suggests mechanisms by which the organism uses both global and localized calcium signals to sculpt the physical and material properties of this elastic system. Our ongoing work aims to identify molecular mechanisms through which calcium acts and the cues that regulate its global and local release. Together, this work clarifies the important role that signaling can play in organizing the activities in complex mechanical cellular machines to perform specific complex behaviors.

Role of PLC-IP$_3$ Pathway in Intraerythrocytic Development of *Plasmodium falciparum*.
M. Fila Pecenin$^1$, L. Borges Pereira$^1$, K. Mikoshiba$^2$, A. Thomas$^3$, C. Garcia$^4$;  
$^1$Parasitologia, Instituto de Ciências Biomédicas, Universidade de São Paulo, São Paulo, Brazil,  
$^2$Developmental Neurobiology, RIKEN Brain Science Institute, Saitama, Japan, $^3$The State University of New Jersey, New Jersey Medical School Rutgers, New Jersey, NJ, $^4$Fisiologia, Instituto de Biociências, 
Universidade de São Paulo, São Paulo, Brazil

The apicomplexan parasite *Plasmodium falciparum* is responsible for the most severe form of malaria, a disease that affects mainly affects underdeveloped and developing countries. Previous studies from our laboratory showed that Ca$^{2+}$ mobilization within the parasite is activated by a signaling pathway initiated by melatonin and this culminates in the synchronization of parasites during the intraerythrocytic phase of the life cycle. Although no (inositol 1,4,5-trisphosphate) (IP$_3$) receptor has been identified in *P. falciparum*, melatonin signal transduction pathways in the parasite seems to be in part due to phospholipase C (PLC) activation and IP$_3$ production. 2-aminoethyl diphenylborinate (2-APB) is a well-known IP$_{3}$R inhibitor in mammalian cells. In *P. falciparum* we demonstrated that 2-APB is able to inhibit melatonin-induced Ca$^{2+}$ rise. Thus, our goal in this work was to evaluate the effect of two 2-APB analogues, DPB162-AE and DPB163-AE, in melatonin-induced Ca$^{2+}$ release and parasite development. Using the fluorescent Ca$^{2+}$ indicator Fluo-4/AM, we analyzed Ca$^{2+}$ fluctuations in *P. falciparum* 3D7 strain in the presence of 2-APB, DPB162-AE and DPB163-AE. Additionally, we investigated the effect of these compounds in intraerythrocytic development by flow cytometry. Our results demonstrate that both 2-APB analogues block melatonin-generated Ca$^{2+}$ rise in the parasite and impair SOCE. The same concentration compounds were able to reduce parasitemia after 24 and 48 hours of treatment. Interestingly, melatonin did not stimulate SOCE in *P. falciparum*, but probably may be linked to depletion of Ca$^{2+}$ from intracellular stores as previously demonstrated. Finally, efforts to find new strategies to combat *Plasmodium* development are fundamental due to arising of resistant strains to the current antimalarial drugs. Therefore, melatonin signaling pathway seems to be a potential target for the development of antimalarial drugs.

Discovery of a lineage-specific mitosomal membrane protein possibly involved in vacuole-mitosome contact in *Entamoeba histolytica*.
H.J. Santos$^{1,2}$, Y. Hanadate$^{2,3}$, K. Imai$^4$, T. Nozaki$^{1,2,3}$;  
$^1$Department of Biomedical Chemistry, Graduate School of Medicine, The University of Tokyo, Tokyo, Japan, $^2$Department of Parasitology, National Institute of Infectious Diseases, Tokyo, Japan, $^3$Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan, $^4$Biotechnology Research Institute for Drug Discovery, National Institute of Advanced Industrial Science and Technology, Tokyo, Japan

Entamoeba histolytica, an anaerobic intestinal parasite causing dysentery and extra-intestinal abscesses in humans, possesses a highly reduced and divergent mitochondrion-related organelle (MRO) called mitosome. The Entamoeba mitosome has been found to have a compartmentalized sulfate activation pathway, which was recently implicated to have a role in amoebic stage conversion. Mitochondria and MROs are bound by a double-membrane barrier, lined with various proteins that allow for protein and metabolite transport, lipid transfer, dynamics and organelle-organelle interaction. However, the outer
and inner membranes of the E. histolytica mitosome possess only a few homologs involved in protein or substrate transport, suggesting that the mitosomal membranes are equipped with components that may have been modified by unique and possibly lineage-specific elements. Using a specialized prediction pipeline, we collaborated to screen and discover lineage-specific mitosomal membrane proteins. We confirmed three novel Entamoeba-specific transmembrane mitosomal proteins (ETMPs). ETMP1 was predicted to have one transmembrane domain and two coiled-coil regions by in silico analyses. It was demonstrated to be integrated to the mitosomal membranes based on carbonate fractionation and immunoelectron microscopy analysis. ETMP1 forms a 180 kDa complex and immunoprecipitation analysis detected a candidate interacting partner that is localized to vacuolar and vesicular membranes. We expressed this ETMP1-binding partner and the subsequent immunofluorescence and immunoelectron microscopy data demonstrated an unprecedented vacuole-mitosome contact.

A prospective lipid import mechanism of Plasmodium falciparum in erythrocytes stages.
E.H. Hayakawa1, H. kato1, H. Matsuoka1, M. Mori2;
1Division of Med. Zoology, Dept. of Infection and Immunity, Jichi Medical University, Shimotsuke, Japan, 2Div. of Therapeutic Pharmacology Cell Biological Pathology, Chiba Institute of Science, Choshi, Japan

Plasmodium falciparum (P. falciparum) infection is known to cause decreases in low density-lipoprotein (LDL), high density lipoprotein (HDL) and cholesterol level in blood. P. falciparum does not have de novo cholesterol synthesis pathway and it must import cholesterol from surrounding environment. However, it is not completely known how cholesterol molecules enter infected erythrocytes by crossing multiple membranes to reach parasite. To answer these questions, we used different drugs, cholesterol synthesis inhibition (statin), transport inhibitor (ezetimibe), and activating ligand of peroxisome proliferator-activated receptorsα; PPARα(fibrate), and investigated the effects of those reagents on P. falciparum growth in erythrocyte stages. We observed growth rate of P. falciparum was inhibited at the presence of ezetimibe, and other regents did not influence the parasites growth. Reported data of the reductions in LDL and HDL in malaria patients suggested us a possibility that lipoproteins were taken up as a carrier for cholesterol transport. To answer this question, we investigated an effect of hepatic cells on P. falciparum growth by setting up a co-culture system with/without drugs. Ezetimibe was not effective for P. falciparum growth in the co-culture system, but statin strongly facilitated a better parasite growth in the presence of hepatic cells. Statin is known to enhance the Niemen-Pick C (NPC1L1) expression in small intestine as mRNA level. Our data suggest a possibility that P. falciparum imported cholesterol via NPC1L1 protein in erythrocytes, or parasite protein homologous to NPC1L1.

MicroRNA dynamics in oligodendrocytes in the context of autoimmune demyelination.
A. Didonna1, J.R. Oksenberg1;
1Department of Neurology, University of California San Francisco, San Francisco, CA

MicroRNAs (miRNAs) belong to a class of evolutionary conserved, non-coding small RNAs which negatively affect the expression of target genes by promoting either RNA degradation or translational inhibition. In recent years, converging studies have identified miRNAs as key regulators of
oligodendrocyte (OL) functions. OLs are the cells responsible for the formation and maintenance of myelin in the central nervous system (CNS) and represent a principal target of the autoimmune injury in multiple sclerosis (MS). Thus, clarifying the possible contribution of miRNA dysregulation to OL degeneration in MS could represent a crucial strategy for the identification of still unveiled pathogenic processes as well as novel therapeutic targets. However, due to the extreme complexity of the cyto-architecture and cell heterogeneity of the CNS, the study of miRNA dynamics in specific cellular populations of the brain has been challenging. MiRAP is a novel cell-specific miRNA affinity-purification technique which relies on genetically tagging Argonaut 2 (Ago2), an enzyme involved in the physiological processing of miRNAs. In this work, we have exploited miRAP potentiality to isolate and characterize the miRNA repertoire from OLs upon induction of experimental autoimmune encephalomyelitis (EAE), a murine disease model that recapitulates several features of MS. To this extent, the first conditional mouse model expressing an epitope-tagged version of Ago2 (GFP-Myc-Ago2) was generated by means of the Cre-Lox binary system, using an Olig1-Cre driver line. Detailed immunoprecipitation experiments and confocal microscopy imaging confirmed that transgene expression in the CNS is restricted to OLs and persists in demyelinated EAE lesions. Subsequently, Taqman assays measuring the levels of miR-219, a miRNA particularly enriched in mature OLs, confirmed miRAP efficacy in isolating OL-specific miRNAs. Finally, after this thorough biochemical characterization, Next-Generation Sequencing (NGS) was employed to characterize the full repertoire of OL-specific miRNAs at different stages of the disease. Using this approach, miR-3102-5p was found significantly down-regulated at pre-symptomatic stages of EAE (5 and 10 dpi) while miR-5107-3p was up-regulated after disease symptoms manifested (15 and 20 dpi). If confirmed, these two miRNAs hold the potential to become promising candidates for future in vivo functional studies. In summary, the overarching goal of this project consists in providing the most comprehensive portray of global miRNA dynamics in the healthy and diseased CNS in a relevant model of MS. In the long term, this knowledge will serve to explore neuroprotective gene therapy approaches based on the delivery to the CNS of miRNA mimics and inhibitors, to prevent OL loss.

TRPV2 participates in T-independent B cell responses through the modulation of membrane potential.

M. ZHAO1, Y. FANG1, Z. SHEN1, J. HWANG1, Y. XIE1, M.J. CATERINA2, W. LIU1;

1School of life science, Tsinghua University, Beijing, China, 2School of Medicine, Johns Hopkins University, Baltimore, MD

The ligation of B cell receptor (BCR) triggers B cell activation through the network of complexes in the immunological synapse (IS) between cell-cell interactions. As a big family of nonselective ion channel, transient receptor potential (TRP) channels show diverse and versatile biological roles, including nociception, mechanosensation, membrane potential and thermosensation. Transient receptor potential vanilloid type 2 (TRPV2) is highly expressed in B lymphocyte. However, whether TRPV2 participates in the B cell activation and modulates the humoral response is barely addressed. Here, our recent study showed that TRPV2 is of vital importance in the initiation of B cell signaling. B cells isolated from the TRPV2 deficient mice exhibited dramatically impaired capability of B cell IS formation, signaling transduction, cytoskeleton mobilization and cell proliferation in response to cognate antigens. We evaluated membrane potential through the potentiometric fluorescent dye, FLIPR Blue. After the activation, TRPV2 deficient B cell showed a much smaller depolarization peak. The capsular polysaccharides can elicit antibody responses through BCR crosslinking in a T cell independent (TI) manner. These antigens with a large polysaccharide backbone are clinically important because they exist...
in the capsules *Streptococcus pneumonia* which is a leading worldwide cause of death for children. We immunized the mice with the *Streptococcus pneumoniae* PS1 and PS3. The TRPV2 deficient mice produced diminished amounts of PS1 and PS3 specific IgM. These findings confirmed the requirement for TRPV2 in response to the clinical human pathogen. TRPV2 modulates the B cell activation through the depolarization of the plasma membrane and the orchestration of signaling transduction.

**A novel IgG1 variant associates with autoimmune disease and modulates autoreactive B cell fate decision.**  
X. Chen¹, B. Yang¹, S. Chen¹, L. He¹, X. Sun², W. Yang¹, W. LIU¹;  
¹School of Life Sciences, Tsinghua University, Beijing, China, ²Department of Rheumatology and Immunology, Peking University People's Hospital, Beijing, China

The maintenance of autoreactive B cells in an anergic state is crucial for preventing autoimmunity. Autoreactivity is generated from somatic hyper-mutation in germinal center (GC) reaction and is substantially enriched in IgG+ memory B cells, but efficiently eliminated in the plasma cell compartment in healthy individuals. However, this immune tolerance checkpoint fails in autoimmune patients. The mechanisms that regulate the differentiation and selection of autoreactive B cells to plasma cells are still elusive. Here we reveal how illegitimate IgG-BCR signaling regulates the cell fate decision of autoreactive B cells in autoimmune disease. We found that patients harboring a novel variant of human membrane bound IgG1 (hlgG1-G396R) have more severe disease-related clinical manifestations. Using inducible autoimmune mouse models, we validate the pathogenic role of this variant in vivo in newly constructed G390R knock-in mice. Due to biased differentiation from autoreactive IgG1+ GC B cells and memory B cells, the G390R variant mice generate more plasma cells with dominant autoreactive repertoires, leading to a burst of broad spectrum autoantibodies. Mechanistically, the G390R variant lowers the threshold for BCR clustering, and drastically enhances the recruitment of Grb2 and Btk signaling molecules into the immunological synapses (IS) by potentiating phosphorylation of its immunoglobulin tail via the Lyn kinase. This triggers significantly longer dwell times of Grb2 in the IS, leading to hyper-activation of the phospho-ITT-Grb2-Btk signaling module upon antigen stimulation. Thus, our studies identify a novel risk locus for SLE and shed new light on a novel regulatory mechanism of IgG-BCR signaling and its roles in autoimmune disease pathogenesis, which may provide a target for therapies of autoimmune diseases.

**Hepatokine induction mediates anti-inflammatory actions of Colchicine.**  
J. Weng¹, R. Jiang¹, H. Tu², T.J. Mitchison¹;  
¹Department of Systems Biology, Harvard Medical School, Boston, MA, ²Alnylam Pharmaceuticals, Inc, Cambridge, MA

Inflammation recognizes and eliminates danger causing by invading pathogens or endogenous signals. However, uncontrolled inflammation also damages tissues. Colchicine, an anti-inflammatory medication that binds to tubulin and blocks microtubule polymerization, is frequently prescribed for gout, Familial Mediterranean Fever, pericarditis, and is being clinically tested for a wide spectrum of diseases. Understanding how an anti-microtubule drug blocks inflammation would help us design safer future drugs. Colchicine inhibits extravasation of neutrophils to inflamed tissues in man. In culture, it directly
inhibits neutrophil chemotaxis and maturation of the pro-inflammatory cytokine, IL-1β, but the required concentrations are 30-300x higher than plasma therapeutic concentrations, which calls into question the textbook model of direct action on leukocytes. Colchicine shows rapid clearance from blood (t1/2 ~ 0.3 hour), followed by selective accumulation in the liver, and slow elimination via bile (t1/2 ~ 1 day). This pharmacology leads us to propose an alternative “Liver Selective Action” model. By measuring biomarkers of microtubule perturbation and using hepatocyte-specific siRNAs, we identified hepatocytes as the main target of colchicine at low doses. Colchicine induced secretion of a divergent member of the TGF-β family, GDF15, from hepatocytes in mice. Conditioned serum from colchicine-dosed mice contained GDF15, blocked leukocyte adhesion, and inhibited IL-1β maturation. By comparing wild-type vs GDF15/- mice, we found that GDF15 was required for colchicine treatment of crystal-induced peritonitis (a gout model). Our results identify GDF15 as a colchicine-induced hepatokine and show that colchicine treats inflammation by selectively accumulating in hepatocytes, triggering GDF15 expression, which globally inhibits neutrophil extravasation.

Haploid genetic screens identify novel regulators of cell interaction and degranulation during cytotoxic lymphocyte-mediated cell death.
B.L. Menasche1, E.M. Davis1, J. Shen1;
1Molecular, Cellular, and Developmental Biology, University of Colorado Boulder, Boulder, CO

Cytotoxic Lymphocytes (CLs), which include NK cells and CD8+ T-cells, detect and eliminate transformed and pathogen-infected cells. While the physiological roles of CL-mediated apoptosis are well established, many regulators of these apoptotic pathways in target cells remain poorly understood. Using haploid genetic screens, we identified novel target cell genes that regulate cell death after treatment with TALL-104 cells, a model CL cell line. These novel genes include the glycophasphatidylinositol (GPI)-anchor synthesis pathway, chromatin structure regulators, and actin cytoskeleton components. In order to narrow down which step in CL-mediated apoptosis is regulated by each of these genes, we studied two strong hits in more detail. PIGP, which encodes an enzyme required for GPI-anchor synthesis, regulates target cell interaction with CLs. PBRM1, a member of the PBAF SWI/SNF chromatin remodeling complex, regulates the signaling between target cells and CLs required for CL degranulation and release of the toxic proteins perforin and granzymes.

Characterization of human immune cell survival and functionality in Danio rerio.
C.D. Paul1, K. Tanner1;
1Laboratory of Cell Biology, National Cancer Institute, Bethesda, MD

The inflammatory response is modulated both by tissue resident macrophages and recruited monocytes from peripheral blood. It is increasingly evident that chronic inflammation plays a critical role in human diseases such as atherosclerosis, obesity, diabetes, cancer, and neurodegenerative disorders. Here we sought a model system to interrogate human immune responses in vivo with single cell resolution in multiple tissues. Elutriated monocytes from de-identified healthy human donors were introduced directly into the circulation and into the brain of 2 day old zebrafish (Danio rerio). We determined that both monocytes and macrophages (differentiated in culture) survive in innate immune competent zebrafish for up to two weeks post-injection in the non-embryonic environment despite the lower
physiological temperature of the zebrafish (28.5°C). On average, 50% of the human cells survive after 3 days in vivo. Similar results were obtained in vitro, where flow cytometry analysis revealed that human monocytes cultured at the physiological temperature of the zebrafish survive, differentiate, and show M1 and M2 polarization phenotypes in response to cytokines comparably to cohorts cultured at human physiological temperature. To assay the functionality of human immune cells in the zebrafish microenvironment, real time, high resolution imaging allowed us to quantify cell migration for each cell type. The human cells show motility throughout multiple tissues comparable to host macrophages but slower than host neutrophils. Gene expression comparisons of in vivo educated human macrophages to in vitro cytokine treated human macrophages revealed gene expression profiles associated with the M1 and M2 phenotypes. In summary, these results characterized the function of human immune cells in the in vivo environment and physiological temperature of Danio rerio. These results suggest that we will be able to define human tumor-human immune cell interactions during the establishment of a metastatic lesion in Danio rerio at single-cell resolution and in real time.

Triclosan alters the secretion of Tumor Necrosis Factor alpha from human immune cells.
S.Z. Jamal1, W.J. Wilburn2, M.M. Whalen1;
1Chemistry, Tennessee State University , Nashville, TN, 2Biology, Tennessee State University, Nashville, TN

Triclosan (TCS) is an environmental contaminant added as an antibacterial agent to many products including mouthwashes, soaps, toothpastes, deodorants, and beauty products. TCS can be absorbed through skin and mouth and it has been found in human blood plasma, urine, amniotic fluid of pregnant women, and breast milk. Tumor Necrosis Factor Alpha (TNFα) is an essential pro-inflammatory cytokine that is produced by monocytes, macrophages, lymphocytes and neutrophils. TNF acts as a systemic inflammatory mediator in response to sepsis and infectious disease. Increased levels of TNFα can cause the stimulation of macrophages and helper T cells to produce additional inflammatory cytokines contributing to inflammation. While a normal inflammatory response is critical to health, high levels of inflammatory proteins such as TNFα can lead to chronic inflammation which contributes to a number of disease states including cancer. Alternatively, if immune cells are unable to secrete adequate amounts of TNFα this would leave the organism susceptible to infections. Previously, we have shown man-made environmental contaminants that gain access to the human system are able to alter the secretion of TNFα from human immune cells and we hypothesize that TCS also has the capacity to alter TNFα secretion. In the current study, peripheral blood mononuclear cells (PBMCs) were treated with TCS at concentration of 0.05-5µM for 24 h, 48h, and 6 days. TNFα level was measured by using enzyme-linked immunosorbent assay (ELISA). The result showed that 24 h exposure to TCS caused a significant increase in TNFα secretion at 5µM in cells from 4 separate donors. This increase maintained at 48 h and 6 days of exposure. Other concentrations of TCS, including the lowest of 0.05 µM, also caused significant increases in TNFα, but the specific concentrations at which the increases were seen varied among donors. These data show that exposure of (PBMCs) to TCS alters the secretion of TNFα. TCS has the capacity to increase this important master regulator of inflammation, which would have the potential to lead to development or exacerbation of several disease states. Supported by NIH grant 2U54CA163066

Board Number: B864
Exposure of human immune cells to triclosan alters the secretion of Interferon gamma.
F.A. Ismail1, W.J. Wilburn2, M.M. Whalen1; 1Chemistry, Tennessee State University, Nashville, TN, 2Biology, Tennessee State University, Nashville, TN

Triclosan (TCS) is a synthetic chemical with antibacterial function that inhibits the growth of microorganisms. TCS is used as an antifungal and antibacterial agent in many products such as: toothpaste, soaps, detergents, toys, surgical cleaning treatments, cosmetics, kitchenware, clothes, and office and school products. It is found in human blood and tissue samples. Interferon gamma (IFNg) is a cytokine that is specialized for innate and adaptive immunity against viral infections. IFNg is important for immunity against intracellular pathogens and for tumor control. As a pro-inflammatory cytokine, inappropriately elevated levels of IFNg can cause chronic inflammation, which has been shown to enhance the development and progression of certain cancers as well as other diseases. Accurate regulation of IFNg levels is important to avoid the loss of immune capability or the occurrence of chronic inflammation. The aim of this study is to investigate whether TCS alters the secretion of IFNg from human immune cells. Human peripheral blood mononuclear cells (PBMCs) were treated with 0 -5 μM TCS for 24 h, 48 h, and 6 days. IFNg levels were measured by enzyme linked immunosorbent assay (ELISA). After a 24 h exposure to TCS there were significant increases in IFNg seen at several concentrations in all donors tested (total of 4 distinct donors). The specific concentration at which increases occurred varied among cells from different donors. Increases in IFNg secretion were also seen after 48 h and 6 day exposure to TCS at certain concentrations. Thus, it appears that TCS is capable of disrupting secretion of this important immune system regulating cytokine which could have the potential to increase the potential for chronic inflammation. Supported by NIH grant 2U54CA163066

Sodium bicarbonate is the factor in culture media that potentially regulates nitric oxide production in a mouse macrophage-like cell line, J774.1 cells, treated with LPS and IFNg.
T. Kawakami1, A. Koike2, F. Amano1; 1Laboratory of Biodefense and Regulation, Osaka University of Pharmaceutical Sciences, Osaka, Japan

Macrophages are known to play pivotal roles in host-defense including inflammation, the both innate and acquired immune systems, and so on. Many of these macrophage functions are exerted through macrophage activation induced by a series of PAMPs (pathogen-associated molecular patterns) like lipopolysaccharide (LPS) as well as by cytokines like interferon γ (IFNg). We showed that the activated macrophage phenotypes induced by LPS and IFNg, such as production of nitric oxide (NO), pro-inflammatory cytokines like TNFα and IL-1β, as well as induction of superoxide-generating activity in J774.1/JA-4 cells were influenced by the culture media (Dulbecco's Modified Eagle's medium (DMEM) and Ham’s F-12 Nutrient Mixture). Among these phenotypes, inducible NO synthase (iNOS) expression was shown to be of great difference between the cells cultured in DMEM and F-12. After extensive studies on the components in these media, sodium bicarbonate (NaHCO₃) concentration was critical to exert the differences in the induction of the activated macrophage phenotypes. When the concentration of NaHCO₃ in F-12 (14 mM) was adjusted to 44 mM, which is the concentration in DMEM, iNOS expression and NO production in the activated macrophages became close to that in DMEM. The same was true vice versa. Besides, change of pH by its concentrations did not result in remarkable differences
in iNOS expression or NO production. These results suggest that NaHCO₃ could be a regulatory factor of iNOS expression and NO production in macrophages, and that the its concentration has a crucial role in macrophage activation.

**Mild electrical stimulation with heat shock ameliorates inflammation in imiquimod-induced psoriasis model.**  
Y. Tsurekawa¹, Y. Nakano¹, M. Morita¹, M. Moriuchi¹, M. Piruzyan¹, M. Takada¹, M. Suico¹, T. Shuto¹, H. Kai¹;  
¹Molecular medicine, Kumamoto University, Kumamoto, Japan

Psoriasis is a chronic refractory disease with skin inflammation. Antibody agents or steroids have strong anti-inflammatory effects, but long-term use of these drugs is unsuitable due to their severe side effects and inter-individual differences in therapeutic responses. Therefore, development of less invasive but highly effective treatments for psoriasis is anticipated. Previously, we have comprehensively studied the effectiveness of optimized combination treatment of mild electrical stimulation (MES) and heat shock (HS). MES+HS treatment had therapeutic effects on the inflammatory symptom in mouse models of diabetes and chronic kidney disease. Furthermore, MES+HS had beneficial effect and were tolerable in the patients with type 2 diabetes or metabolic syndrome in clinical trials. To determine the effect of MES+HS on psoriasis, we used imiquimod-induced psoriasis mouse model. Imiquimod was used as an agonist of Toll-like receptor 7, which accelerates the development of psoriasis. Daily application of imiquimod on mouse ear induced skin hyperplasia by increasing cell proliferation. Moreover, the expression of inflammatory markers such as cytokines and antimicrobial proteins was increased in imiquimod-treated skin. Importantly, MES+HS (10 min, daily) significantly suppressed skin hyperplasia as well as mRNA expression of keratinocyte proliferation marker, keratin 6A. Furthermore, MES+HS also inhibited expression of both inflammatory cytokines, such as IL-17A and IL-22, and antimicrobial proteins in keratinocytes. Together, our study shows that MES+HS is an effective treatment to suppress the inflammation in imiquimod-induced psoriasis model.

**IMPDH filament formation in human T cell activation.**  
S.J. Calise¹, E.K. Chan¹,²;  
¹Oral Biology, University of Florida, Gainesville, FL, ²Anatomy and Cell Biology, University of Florida, Gainesville, FL

**Objectives:** Inosine monophosphate dehydrogenase (IMPDH) catalyzes the conversion of IMP to xanthosine monophosphate (XMP), the rate-limiting step in de novo guanosine monophosphate (GMP) synthesis. In cultured cells, IMPDH polymerizes into rod- and ring-shaped structures (filaments) when IMP or GMP synthesis is inhibited by substrate depletion, like glutamine or serine deprivation, or by various drugs, including ribavirin, mycophenolic acid, and methotrexate. This suggests that IMPDH filaments assemble during stress related to nucleotide metabolism, although their function is still unknown. Assembly of IMPDH filaments in untreated, undifferentiated mouse embryonic stem cells hints they might function in highly proliferative cell types. Here, we investigate IMPDH polymerization in primary human T cells, which rely heavily on de novo pyrimidine synthesis to proliferate rapidly in response to antigenic challenge.
**Methods:** Peripheral blood mononuclear cells were activated ex vivo with classical T cell mitogens anti-CD3/anti-CD28, phytohemagglutinin (PHA), or concanavalin A (ConA), or with lipopolysaccharides (LPS) as a non-T cell activator control. Spleens were harvested from healthy C57BL/6 mice to measure basal IMPDH filament formation in vivo. IMPDH filaments were detected by immunofluorescence using affinity purified anti-IMPDH antibody.

**Results:** In two independent experiments, both rod- and ring-shaped IMPDH filaments were observed in ~30% of T cells after 24-hour treatment with anti-CD3/anti-CD28, PHA, or ConA, and in ~50% of cells after 72 hours. IMPDH filaments did not form in T cells left untreated or treated with LPS. Percentage of cells with filaments was consistent among anti-CD3/anti-CD28, PHA, and ConA treatments. Rods were more commonly observed than rings under all conditions (~90% rods vs. ~10% rings), and were similar in size to structures previously reported in cancer cell lines. IMPDH filaments formed in T cells did not disassemble after addition of fresh medium. Filament formation detected by anti-IMPDH antibody was correlated with positive staining of T cell marker anti-CD3. IMPDH filaments were also detected in a low percentage of cells in both the white pulp and red pulp of healthy mouse spleen.

**Conclusions:** Our data suggest that IMPDH filament formation is functionally relevant in T cell activation, and that filaments might be useful as morphological markers for T cell activation. Considering the lack of conclusive data on the function of these structures, establishing new ex vivo and in vivo models will be critical to uncovering how IMPDH polymerization affects cell function. We are currently investigating the role of IMPDH filaments in disease conditions related to T cell function.

HIV-1 gp120_{IIIB}/HIV-1 gp120_{RFL} -mediated human α7-nAChR’s up-regulation in macrophages and its implications in the cholinergic anti-inflammatory response (CAR).

S. Cotto-Ríos¹, M. Delgado-Vélez², J.O. Colón-Sáez³, O. Quesada⁴, J.A. Lasalde-Dominicci¹,²;
¹Department of Chemistry, University of Puerto Rico-Rio Piedras Campus, San Juan, PR, ²Department of Biology, University of Puerto Rico-Rio Piedras Campus, San Juan, PR, ³Department of Pharmaceutical Sciences, University of Puerto Rico Medical Science Campus, School of Pharmacy, San Juan, PR, ⁴Department of Physical Sciences, University of Puerto Rico-Rio Piedras Campus, San Juan, PR

Despite the successful reduction of the development of HIV/AIDS in patients receiving therapy, this population is at a higher risk to develop non-AIDS related diseases, which are often associated with inflammatory processes. It has been shown that acetylcholine (ACh), the main parasympathetic neurotransmitter, effectively deactivates peripheral macrophages inhibiting the release of pro-inflammatory mediators, including the cytokines TNF-α, IL-6, and IL-β. The ACh-dependent macrophage deactivation is mediated by the α7-nAChR which is expressed in peripheral macrophages and has been described as essential for the so-called cholinergic anti-inflammatory response (CAR). It is known that HIV-1 gp120 proteins can cause increased cytokines released that generate sustained immune activation in macrophages, which are the principal target for HIV-1 derived R5-tropism strains. We recently demonstrated that, in human macrophages, gp120_{IIIB} (X4-tropic strains) protein induces the up-regulation of the α7 nicotinic acetylcholine receptor (α7-nAChR), a key regulator of systemic inflammation that inhibits the production of pro-inflammatory cytokines. In that study, results indicate that gp120_{IIIB} disrupts the CAR in macrophages in vitro because the activation of α7-nAChR does not inhibit the production of pro-inflammatory cytokines (interleukins and chemokines). Here, we show that M-tropic gp120_{RFL}, induces higher level of α7-nAChRs in human derived macrophages. Our results demonstrated that HIV gp120_{RFL}/CD4-CCR5 receptor complex promotes α7-nAChRs up-regulation via a mechanism that is associated with the activation of p38-MAPK signaling that has been shown to up-
regulates an early gene (Egr1), a transcription factor known to drive the expression of α7-nAChRs. These findings suggest that HIV-1 glycoproteins can alter the expression of α7-nAChRs, resulting in changes in macrophages phenotype that influence the cholinergic anti-inflammatory response. Of biological significance, the present results suggest that HIV gp120\(_{JRFL}\) interfering with the CAR could contribute to a crucial, unresolved problem of HIV infection: chronic inflammation.

T cells only recognize antigens that appear on cell surfaces in the context of Class I and Class II Major Histocompatibility Complex (MHC) molecules. The two classes of MHC molecules are differentially expressed in cells. Activated human T lymphocytes express Class II molecules in addition professional antigen presenting cells (APCs). LPS stimulation can induce the expression of HLA-DR molecules (MHC Class II) and our aim was to observe their expression in polymorphonuclear neutrophils (PMNs) in cellular interactions in culture in blood samples for positive Chagas serology. From healthy human blood samples (n = 10) and samples with positive serology for Chagas (n = 6), anticoagulated with Heparin (in anonymity, with serology data) with ethical consent according to procedures approved by ethical committee of National Hospital Clinicas R169/13, autologous leukocyte cultures were performed in TC199 medium (SIGMA , St. Louis, MO) and in vitro stimulation with LPS (Sigma-Aldrich) 25 ng / ml at 37 ° C in a gaseous stove, 30 minutes and other controls without stimulation. Samples at 30 min and 24 hours were performed with HLA-DR Immunofluorescence (FITC; Santa Cruz Biotechnology) technique at 4 ° C overnight. Nuclear staining with DAPI (4,6'-diamidino-2-phenylindole) (Sigma, St. Louis, MO). Some samples were processed for ultrastructural study of cell interactions in culture with MET: Zeiss LEO-906E. Results: LPS stimulation induced expression of HLA-DR (MHC Class II) molecules in PMNs and samples for positive Chagas serology showed a higher number of HLA-DR + lymphocytes (p <0.001, t-test for paired samples). Interactions between PMNs and lymphocytes were observed and the latter showed abundant cytoplasm, and polarization of mitochondria. Conclusions: The ultrastructural aspects reveal signs of cellular activation in chagasic samples and interactions between PMNs and lymphocytes. Expression of HLA-DR in PMNs could involve antigen presentation via Class II

**Fas (CD95) signaling pathway is involved along with BAG-1M in the regulation of Hsp70-mediated chaperoning of aPKC under pro-inflammatory conditions.**  
A. Mashukova\(^1\), R. Forteza\(^2\), P.J. Salas\(^2\);  
\(^1\)College of Medical Sciences, Nova Southeastern University, Fort Lauderdale, FL, \(^2\)Dept. of Cell Biology, Univ. of Miami Miller School of Medicine, Miami, FL

Atypical PKC (aPKC) is a highly conserved key regulator of asymmetry in various tissues. A conditional (epithelium-specific) knockout mouse recently revealed that aPKC also has an essential anti-
inflammatory function as NF-κB inhibitor in intestinal epithelia. In addition, aPKC controls epithelial (anti-inflammatory) IL-10 secretion. Therefore the profound loss of aPKC observed in intestinal epithelium in a mouse model of DSS-induced colitis and in biopsy samples obtained from the patients diagnosed with inflammatory bowel disease (IBD) is likely an important pathophysiological mechanism of inflammation in organs with an epithelial parenchyma. We have established that in intestinal epithelial cells aPKC is post-translationally regulated through Hsp70-mediated refolding specifically localized to keratin intermediate filaments. Activation of inflammatory signaling pathways such as TLR4 activation, results in inhibition of Hsp70 chaperoning activity leading to aPKC ubiquitination and degradation. Two cofactors which can act as inhibitors of Hsp70 chaperoning activity have been described: FAF1 (FAS-Associated Factor 1) and BAG-1, both of which bind to ATPase domain of Hsp70. We have investigated the involvement of BAG-1 previously and were able to demonstrate that under pro-inflammatory conditions there is an upregulation of medium isoform of BAG-1 (BAG-1M). In the present study we aimed to elucidate the possible role of FAF1 and the Fas (CD95) signaling pathway. Fas (CD95) is a member of the tumor necrosis factor receptor family expressed on the basolateral membrane of intestinal epithelial cells. Fas and the cognate ligand FasL have been shown to be upregulated by inflammatory signals in intestinal epithelium. We found that administration of blocking anti-FasL antibody rescued aPKC from degradation in TNF-alpha treated Caco-2 cells. In addition, an in vitro rephosphorylation assay for Hsp70 refolding of aPKC demonstrated that anti-FasL antibody incubation restored Hsp70-dependent pT555 aPKC rephosphorylation. Likewise inhibition of Fas pathway rescued chaperoning activity of Hsp70 in luciferase refolding assays. When injected intraperitoneally in mice, anti-FasL antibody delayed the progression of disease activity index (DAI) in DSS-induced colitis. Importantly, anti-FasL antibody significantly rescued 50% of the steady-state levels of pT555 aPKC signal from the effects of DSS-induced inflammation. Altogether, these results indicate that Fas-mediated signaling similar to Bag-1M affects the chaperoning function of Hsp70 and mediates the effects of pro-inflammatory signals on the stability of aPKC.

Exploring the Role of Macrophages in Pregnancy Using a Rat Model System.
G. Mishra1, A. Nguyen2, N. Nawaz3, B. Hussain4, E. Lee5, V. Yau6, S.J. Bacon2,6;
1Department of Biochemistry, Mount Holyoke College, South Hadley, MA, 2Department of Biological Sciences, Mount Holyoke College, South Hadley, MA, 3Department of Sleep Medicine, Brigham and Women's Hospital, Boston, MA, 4Rollins School of Public Health, Emory University, Atlanta, GA, 5College of Medicine, University of Arizona, Tucson, AZ, 6Department of Neuroscience and Behavior, Mount Holyoke College, South Hadley, MA

Macrophages are professional phagocytes that survey the body for pathogens and secrete biomolecules that are relevant to cellular processes involving inflammation, development, and immunogenic tolerance. Past studies to elucidate the role of macrophages during pregnancy have utilized mouse models or human clinical samples. In rats, it is still not clear whether macrophages might have a role to play in processes necessary for gestation such as arterial remodeling, clearance of apoptotic cells, or uterine tissue repair during postpartum involution. Our lab is interested in understanding the putative roles of macrophages during pregnancy in the rat uterus. Using immunohistochemistry, we identified the presence of macrophages around the uterine lumen and within the metrial gland during mid-pregnancy and postpartum (unpublished). This led us to hypothesize that macrophages might be involved in the clearance of apoptotic cells as part of their greater role in remodeling. Using quantitative PCR (qPCR), we measured the expression levels of the genes T-cell immunoglobulin and mucin domain containing-3 (TIM-3) and Mer Tyrosine Kinase (MerTK) that are expressed by macrophages and are
involved in the binding and engulfment of apoptotic cells. While continuing to assay for TIM-3 and MerTK, we also measured the expression levels of anti-inflammatory molecules such as Transforming growth factor (TGF-1) and Interleukin-10 (IL10) in order to characterize the immunomodulatory phenotype of macrophages during mid-pregnancy and postpartum. Preliminary results suggested varying spatiotemporal patterns of expression for these genes. Of note, MerTK and TGF-1 appeared to display similar expression patterns across various time points in pregnancy such as day 12, 14, and 16 and postpartum day 3. Further, the expression of these genes in the rat metrial gland tissue did not always correlate linearly with the expression of CD68, a pan-macrophage marker in rats. This suggests that immune cell populations involved in uterine remodeling during pregnancy may be heterogeneous. Proper maternal immune function is essential to a successful pregnancy. Misregulation of key immune processes can lead to pregnancy-related disorders such as preterm labor and preeclampsia. The relevance of the macrophage to both the innate and adaptive arms of the immune system make it an important player during gestation and beyond. Our research suggests an important role for these immune cells in pregnancy-associated tissue remodeling as well. Future studies focusing on the rat uterine environment will increase our understanding of how macrophages affect pregnancy in rats and whether this may have relevant implications to humans.

Expansion of His48+CD11b/c+ myeloid cells in rats after vanadium and chromium salts administration.
M.K. Balabekova1, A.N. Tokusheva1, Y. Ostapchuk1, N. Abdolla2, R. Tukhvatshin3;
1Department of Pathophysiology, Asfendiyarov Kazakh National Medical University, Almaty, Kazakhstan,
2Laboratory of Molecular Immunology and Immunobiotechnology, M.A.Aitkhozhin’s Institute of Molecular Biology and Biochemistry, Almaty, Kazakhstan, 3Department of Pathophysiology, Kyrgyz State Medical Academy named after I.K. Akhunbaev, Bishkek, Kyrgyzstan

Exposure to various environmental pollutants is known to induce inflammatory changes, characterized by a release of cytokines and other soluble mediators. Moreover, toxic effect of various xenobiotics, including vanadium and chromium, may cause dysregulation of the immune response leading to chronic inflammation, which induces autoimmune diseases, diabetes, and malignant transformation of cells. The purpose of this research was to study the effect of intoxication with salts of heavy metals on immunosuppressive cells - MDSCs, which is shown to accelerate chronic diseases. In our study, sexually mature rats were administered ammonium vanadate (AV) and potassium dichromate (PD) at a dose of 5 mg/kg of BW for two weeks (AV/PD), after that lymphatic organs were studied on day 1, 7, and 14 after the end of AV and PD injections. Administration of AV and PD resulted in the decrease of spleen and thymus weight, also the cellularity of the thymus during the observation periods in the AV/PD group. Phenotypical analysis demonstrated that on day 1 after the beginning of the experiment freshly obtained splenocytes of AV/PD rats contained increased percentage of CD3+CD4+ T-lymphocytes comparing to control animals. Interestingly, during the next period of the experiment, a decreasing trend of CD3+CD4+ T-lymphocytes percent and significantly lower induced expression of IFNγ by these cells accompanied by increasing trend of His48+CD11b/c+ cells was noticed. Moreover, on day 14 we observed a progressive extension of His48+CD11b/c+ and His48highCD11b/c+ cells and concurrent decrease of CD3+CD4+ T-lymphocytes and their induced expression of IFNγ and IL-4 in the AV/PD group comparing to intact rats. Thus, it is possible that a reduced number of effector T cells observed in rats exposed to vanadium and chromium salts could be a result of abundant accumulation of
His48+CD11b/c+ and His48highCD11b/c+ cells that have phenotype similar to tumor-related total subset MDSC and G-MDSC, respectively, with immunosuppressive properties, in the periphery, and, in turn, it could participate in the maintaining of the immunosuppressive environment that supports persistence of chronic inflammatory conditions.

NT-07-16 reduces NF-κB signaling in RAW264.7 macrophages.
A. Gonye1, S.P. Gilmore2, S. Espinosa de Los Reyes2, E.C. Li3, M.M. Brown1, J.T. Gupton2, O.A. Quintero1, K. Fischer-Stenger1;
1Biology, University of Richmond, Richmond, VA, 2Chemistry, University of Richmond, Richmond, VA

The NF-κB pathway is vital for immune system regulation and pro-inflammatory signaling. Many inflammatory disorders and diseases, including cancer, are linked to dysregulation of NF-κB signaling. When macrophages recognize the presence of a pathogen, the signaling pathway is activated resulting in the nuclear translocation of the transcription factor, NF-κB, to turn on pro-inflammatory genes. Here we are investigating the effects of a novel microtubule-depolymerizing compound, NT-07-16, on this process. Since microtubules play a critical role in cell physiology compounds that target the microtubule network have been studied for their potential use as chemotherapeutic agents. However, some of these compounds, such as colchicine, are too toxic to be used in a clinical setting. Polysubstituted pyroles, JG-03-14 (3,5-dibromo-4-(3,4-dimethoxyphenyl)-1H-pyrrole-2-carboxylic acid ethyl ester) and its refined analog, NT-07-16, which possesses an additional methoxy group at the 2-position of the phenyl ring, also bind microtubules at the “colchicine site”. These compounds have been shown to be less toxic while still inhibiting the proliferation of many cancer cell lines. Previous studies from our laboratory also found that exposure to JG-03-14 decreased pro-inflammatory signaling in activated RAW264.7 mouse macrophages. Treatment with JG-03-14 resulted in the depolymerization of microtubules and decreased the production of nitric oxide and the pro-inflammatory cytokine, tumor necrosis factor-α in the macrophages. Our present work demonstrates that exposure to NT-07-16 also decreases the production of pro-inflammatory cytokines in lipopolysaccharide (LPS)-activated RAW264.7 macrophages, and it appears that the reduction in pro-inflammatory mediators may be due, at least in part, to a decrease in the translocation of NF-κB into the nucleus. These results suggest that upon activation of RAW264.7 macrophages, NF-κB translocation into the nucleus involves the microtubule network and that disruption of this network by NT-07-16 results in less NF-κB entering the nucleus reducing the inflammatory activity of the macrophages. In addition, since the NF-κB pathway is also known to trigger the production of Bcl-2 proteins which offer protection against apoptosis and increase the survival of cancer cells, we analyzed the effect of NT-07-16 on the production of the Bcl-2 protein in RAW264.7 macrophages. Our data suggest that exposure to NT-07-16 prior to LPS activation of the macrophages reduces the upregulation of Bcl-2 triggered by NF-κB signaling. Therefore, NT-07-16, which has already shown activity as an anti-proliferative agent towards cancer cells, may also be effective as an inhibitor of the NF-κB signaling pathway further enhancing its chemotherapeutic potential.

**Induction of M2 regulatory macrophages through β-adrenergic receptor signaling in the RAW264.7 macrophage cell line.**  
A.H. Pham¹, E.C. Gonye¹, L. Ward-Kavanagh¹, J.K. Stewart², K. Fischer-Stenger¹;  
¹Biology, University of Richmond, Richmond, VA; ²Biology, Virginia Commonwealth University, Richmond, VA

Catecholamines alter macrophage function by binding to adrenergic receptors on the cell membrane. Stimulation through β₂-adrenergic receptors is known to down regulate the activity of classically activated M1 macrophages while stimulation through α-adrenergic receptors typically enhances their function. Our studies with the RAW264.7 murine macrophage cell line as a model for macrophage function support these findings. Macrophages were pre-treated with the selective β₂-adrenergic receptor agonist formoterol or the non-selective α-adrenergic receptor agonist clonidine prior to lipopolysaccharide (LPS) activation and analyzed for production of the pro-inflammatory cytokines tumor necrosis factor α (TNFα) and interleukin-6 (IL-6) by ELISA. These studies showed that formoterol decreased and clonidine increased macrophage cytokine production. Furthermore, quantitative PCR (qPCR) demonstrated that LPS activation decreased the expression of β₂-adrenergic receptor mRNA and increased the expression of α₁A - and α₂-adrenergic receptor mRNA in the macrophages. Further analyses suggested that stimulation of the adrenergic receptors by norepinephrine (NE) may alter the phenotype of the macrophages. Classically activated M1 macrophages initiate the pro-inflammatory response to eliminate infection. Macrophages activated with LPS produce, along with pro-inflammatory cytokines, the enzyme inducible nitric oxide synthase (iNOS) which catalyzes the production of nitric oxide (NO) which has anti-microbial properties. The presence of the iNOS enzyme is indicative of the M1 macrophage phenotype. Alternatively activated M2 macrophages down regulate the immune response and promote tissue repair. These M2 macrophages express higher levels of the enzyme arginase-1 (Arg-1) which catalyzes the reaction of arginine to ornithine, a precursor to molecules participating in wound healing. Our qPCR results showed that expression of iNOS mRNA was reduced while expression of Arg-1 mRNA increased in macrophages pretreated with NE prior to LPS activation. Taken together these results suggest that exposure to NE may not only reduce the pro-inflammatory activity of macrophages but also induce development of the alternatively activated M2 phenotype in RAW264.7 macrophages.

**Asaronic acid ameliorates atherosclerotic inflammation by polarizing M1 macrophages to M2-like macrophages.**  
H. Oh¹, Y. Kang¹;  
¹Food science and Nutrition, HALLYM UNIVERSITY, Chuncheon, Kangwon-do, South Korea

Atherosclerosis is a chronic inflammatory disease and lipid metabolism disorder, and macrophage accumulation within the vascular wall is a hallmark of atherosclerosis. In atherosclerotic lesions, macrophages respond to various environmental stimuli that can modify their functional phenotypic subsets of pro-inflammatory M1 and anti-inflammatory M2 macrophages. The current study examined whether asaronic acid induced classical M1 to M2 activation of macrophage. Asaronic acid (2,4,5-Trimethoxybenzoic acid) identified as one of purple perilla constituents has been reported to exhibit antioxidant and cytostatic activity, as well as to exert anti-allergic effects. J774A1 murine macrophages
were incubated with lipopolysaccharide (LPS) or interleukin (IL)-4 in the absence and presence of 1-20μM asaronic acid. This study found that non-toxic asaronic acid at ≤20 μM dampened the secretion of the M1 cytokine IL-6 in macrophages exposed to 2 μg/ml LPS for 48 h. Moreover, asaronic acid suppressed macrophage induction of toll-like receptor 4, CD68 and CD36 enhanced by LPS. When J774A1 macrophages were treated for 48 h with 40 ng/ml IL-4, ≤20 μM asaronic acid enhanced the secretion of the M2 cytokine IL-10, evidenced by ELISA. These results demonstrated that asaronic acid inhibited M1 phenotype following exposure to TLR ligands of LPS, whereas this compound induced M2 genes by treating macrophages with IL-4 that increase IL-10 level. Therefore, asaronic acid is a therapeutic agent capable of switching M1 phenotypic macrophages to M2 phenotypes in atherosclerotic plaques.

Cell signaling involved in acute glycolytic response to immune cell activation.
Y. Kam¹, P.M. Swain¹, B.P. Dranka¹;
¹Cell Analysis, Agilent Technologies, Lexington, MA

Immune cell activation is precisely regulated to respond toward a specific stimulus only and turn on a series of cellular processes required. The cellular metabolism is one of the emerging factors required for the proper immune cell activation and differentiation. Several recent reports suggested that there is an immediate glycolytic response upon activation of T cells or macrophages not only as an indicative event but also as an essential component of activation. In the real-time monitoring of glycolysis and OXPHOS using a Seahorse XF analyzer, both CD4+ and CD8+ T cells as well as JurKat immortalized T cell lines showed a rapid increase in the basal glycolytic activity within 6 min by in situ administration of anti-CD4+ and CD8+ antibody-conjugated beads. Similarly, macrophages derived from human peripheral blood monocyte as well as RAW264.7 immortalized murine macrophage cell lines showed a significant escalation in glycolytic activity within an hour by lipopolysaccharide with or without interferon γ. The increase in glycolysis was well correspond to the key cytokine production in both cell types. The further real-time cell metabolism analysis using various inhibitors for cell signaling showed that Akt activation is an essential factor for both T cell and macrophage activation. Interestingly, T cell activation also requires actin cytoskeletal polymerization which is recently suggested to support PI3K-mediated glycolysis increase through aldolase. In contrast, macrophage activation-related glycolytic response was not affected by actin polymerization inhibitors. These results suggest that Akt activation can be a core player mediating the early glycolytic response. They also imply the glycolytic response upon immune cell activation is mediated by diverse signaling pathways depending on cell types and the real-time analysis of cellular metabolism can provide useful kinetic information to understand the cell signaling of immune cell metabolism.

**Apoptotic- and Necrotic-like Ultrastructural Phenotypes of Human Monocytes in Systemic Lupus Erythematosus.**  
I.A. Andrianova1, A.A. Ponomareva1, R.I. Litvinov2;  
1Institute of Fundamental Medicine and Biology, Kazan Federal University, Kazan, Russia, 2Department of Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Systemic lupus erythematosus (SLE) is an autoimmune disease characterized by multi-organ inflammation often associated with a high titer of anti-DNA antibodies. Monocytes are involved in the pathogenesis of SLE as a source of immune modulators for T- and B-lymphocytes and a pro-thrombotic factor due to exposure of tissue factor on the cell surface. The aim of this work was to investigate the structural changes of monocytes in SLE patients in correlation with the levels of anti-DNA autoantibodies. Monocytes of six SLE patients and three healthy donors were isolated by a density gradient centrifugation of citrated blood followed by negative immune separation and analyzed using transmission electron microscopy. The purity (>96%) of the CD14-positive monocytes was confirmed using flow cytometry and cell viability (>95%) was assessed by exclusion of trypan blue. Total individual 154 monocytes from SLE patients were analyzed and compared with 22 monocytes from healthy donors. Monocytes with normal ultrastructure (ruffled cell surface, formation of filopodia, an indented nucleus, and uniform chromatin distribution) comprised 64% in the SLE patients and 95% in healthy donors. Unlike monocytes from healthy subjects, 19% of monocytes from the SLE patients had morphological apoptotic-like features: smooth cell surface, retraction of pseudopods, electron-dense cytoplasm, mitochondrial swelling, and a spherical nucleus with perinuclear accumulation of condensed chromatin or condensation of chromatin into dense spherical particles. About 17% of monocytes from the SLE patients and 5% from the healthy donors had morphological necrotic-like features: rounding-up of the cell, retraction of pseudopods, low electron-density cytoplasm, small electron-dense mitochondria, and spherical pyknotic nucleus with more diffuse euchromatin. The SLE patients with a high titer of anti-dsDNA antibodies (>200 IU/ml) had significantly more monocytes with morphological apoptotic-like (25% vs. 6%, p<0.01, χ²-test) and necrotic-like (20% vs. 10%, p<0.05, χ²-test) phenotypes compared to the SLE patients with a normal titer of anti-dsDNA antibodies (<25 IU/ml). This study affirm that a substantial fraction of monocytes in SLE undergo morphological alternations that are more pronounced in patients with an increased level of anti-dsDNA autoantibodies. The results suggest the involvement of monocytes in the pathogenesis of SLE with adverse structural alterations associated with increased production of autoantibodies. The work was supported by the Program for Competitive Growth at Kazan Federal University.

**Parasitic wasp-derived multi-strategy extracellular vesicles specifically interact with cells of the Drosophila host’s cardiovascular/hematopoietic systems.**  
M.E. Heavner1,2, J. Ramroop2,3, Z. Razak2, B. Wey2,3, S. Govind1,2,3;  
1Biochemistry, The Graduate Center of CUNY, New York, NY, 2Biology, The City College of New York, New York, NY, 3Biology, The Graduate Center of CUNY, New York, NY

Spiked, 300-nm multi-strategy extracellular vesicles (MSEVs, previously virus-like particles) are produced by the parasitic wasp species Leptopilina heterotoma (Lh) in the venom glands of females. Along with wasp eggs and venom, MSEVs are delivered into the larval bodies of the wasps’ drosophilid hosts.
MSEVs cause apoptosis of circulating macrophages, lysis of circulating lamellocytes, and TUNEL-positive death of immature blood cells in the host larval lymph gland. This highly successful infection strategy destroys cellular immunity and thus protects developing wasp eggs that would otherwise be encapsulated by blood cells.

MSEVs possess (a) a signature of eukaryotic vesicular/transport proteins, (b) a pharmacopoeia of infection-related proteins, and (c) a wealth of novel proteins, some of which have domains similar to those found exclusively in prokaryotic proteins. A 40-kDa protein belongs to this latter class of novel proteins. Localized to MSEV spikes and surface, it is structurally similar to Type 3 secretion system tip proteins of the IpAD/SipD superfamily.

While the protein composition of MSEVs is now understood, the mechanisms by which they recognize, enter, and destroy host blood cells are not known. To begin to address these questions, we tracked the association of MSEVs in the larval hosts’ dorsal vessel and lobes of the lymph gland. We will present data that demonstrate that MSEVs enter the cardiac cells that line the dorsal vessel and interact with the extracellular matrix proteins associated with the dorsal vessel and cells of the anterior and posterior lobes. Furthermore, blood cells of the lymph gland lobes (that are targeted for destruction), as well as circulating phagocytes, phagocytose MSEVs, demonstrated by the co-localization of MSEV and endocytic pathway proteins.

MSEVs are not internalized by the normally tightly-grouped cells of the posterior signaling center (PSC) of the anterior lymph gland lobes, but instead are found in high densities in interstitial spaces between PSC cells. Additionally, PSC cells of infected lymph glands disperse into the bodies of the lobes, either singly or in smaller groups. Genetic ablation of the PSC conferred protection to the organ: PSC-less lobes exhibit low MSEV signal and reduced cellular destruction. RNAi-mediated knockdown of specific genes coding signals for hematopoietic quiescence or differentiation in the PSC did not similarly block the destructive effects of MSEVs suggesting PSC roles in parasite-activated hematopoiesis and parasite (MSEV)-mediated immune suppression.

Thus, MSEVs utilize the cardiovascular system to penetrate the host’s hematopoietic system, disintegrate the PSC, and utilize the cell’s endocytic machinery for uptake to unleash their apoptotic effects on fly macrophages.

ARTHITIS IMMUNE REPONSE MODULATION BY LOW-INTENSITY INFRARED LASER.
L.M. dos Anjos¹, P. Salvador², A.C. de Souza¹, A.S. da Fonseca³, F. De Paoli¹, J. Gameiro²;
¹Morphology, Federal University of Juiz de Fora, Juiz de Fora, Brazil, ²Immunology, Federal University of Juiz de Fora, Juiz de Fora, Brazil, ³Biophysics, Rio de Janeiro State University, Rio de Janeiro, Brazil

Low-level light therapy (LLLT) is a phototherapy treatment that promotes cell changes by biostimulation, modulating inflammatory processes and immunological responses. The aim of this work was to investigate the effects of LLLT arthritis treatment in immune cells of near lymph node. Inflammatory process was induced in region near talocrural and subtalar joints using zymosan solution. Eighteen C57BL/6 mice were divided into three groups according to laser (830 nm, 10mW) treatment: (I) zymosan-induced, (II) zymosan-induced + laser 3 J/cm² and (III) zymosan-induced + laser 30 J/cm². Twenty-four hours after last irradiation, the flow cytometry were performed to quantify dendritic cells CD80/CD86+, macrophage CD80/CD86+, lymphocyte TCD4+, lymphocyte TCD8+ and lymphocyte Treg population in the popliteo limph nodes. The group II showed a decrease in dendritic cells population (p<0,01), while dendritic cells CD80/CD86+ (p<0,02) (potent antigen presenter) increased. More, this group showed an increase in macrophages population (p<0,01) and a decrease of macrophage CD80/CD86+ (p<0,002), when compared to untreated group. The group III showed an increase in

Sunday-543
dendritic cells CD80/CD86+ (p<0.02), macrophage (p<0.001), lymphocytes TCD8+ (p<0.01) and lymphocytes Treg (p<0.05) populations, if compared to untreated group. Our results suggest that LLLT in both fluences tested were able to modulate the immune response through alteration in the number of antigens presentation cells. The group III (treated with LLLT at 30 J/cm²) also demonstrated the elevation of effector cells, tending to an anti-inflammatory profile by elevation of Treg cells. The modulation of immune response could be a novel anti-inflammatory pathway of LLLT and opens many possibilities for new uses for the therapy.

Myeloid cells ablation attenuates Concanavalin A-induced hepatitis by suppressing immune responses.

S. Dai¹, F. Liu¹, D. Feng², A. Kearns¹, X. Peng¹, B. Gao², X. Qin¹;
¹Department of Neuroscience, Temple University School of Medicine, Philadelphia, PA, ²Laboratory of Liver Diseases, National Institutes of Health, Bethesda, MD

Both of bone marrow (BM)-derived monocytes and tissue-resident macrophages play vital role in the maintenance of tissue homeostasis. Recently, we used our intermedilysin (ILY)-human CD59 (hCD59) mediated cell ablation method (Hu, et al, Nat Med 14, 98-) and documented that the specific elimination of myeloid cells protected against Concanavalin A (ConA)-induced acute hepatitis (Feng D., et al. JCI 126, 2321-1). ILY, a toxin secreted by Streptococcus intermedius, binds exclusively to the human-specific cell membrane protein, CD59 (hCD59). Once bound, ILY rapidly lyses the cells through necrosis by forming toxin pores. We established a floxed STOP-hCD59 knock-in mouse (ihCD59) in which hCD59 expression only occurs following Cre-mediated recombination. By crossing Cre-inducible floxed STOP-hCD59 transgenic mouse line (ihCD59+) mice with myeloid cell-specific Cre transgenic line, LysmCre+ mice, we generated a double transgene positive mouse (LysMCre+ihCD59+) in which Cre expression drives expression of hCD59 in myeloid cells. The rapid and specific ablation of myeloid cells by the injection of ILY to LysMCre+ihCD59+ mice completely blocked the development of ConA-induced hepatitis. The activation of NKT and T cells have been implicated to be necessary events in ConA-induced hepatitis. To further define the pathogenic role of myeloid cells and its interaction with other immune cells, we investigated the dynamic changes of immune cells and the relevant cytokines in the ConA-induced hepatitis with or without the myeloid cell ablation. We documented that the myeloid cell ablation suppressed infiltration of T and B cells, inhibited the activation of NKT cells without affecting the total numbers of NK and NKT cells, and decreased the serum level of IFN-gamma, a cytokine mainly secreted by NKT cells in the hepatitis. These results indicate that myeloid cells play a critical role in the maintenance of T and NKT activation, which contribute to ConA-induced hepatitis.

SALTS OF HEAVY METALS CAUSE PHENOTYPIC CHANGES OF IMMUNE COMPETENT CELLS - PARTICIPANTS AND REGULATORS OF ASEPHTIC INFLAMMATION.

M.K. Balabekova¹, A.N. Tokusheva¹, V.V. Trubachev¹;
¹Department of Pathophysiology, Asfendiyarov Kazkh National Medical University, Almaty, Kazakhstan

Changes in the structure and functions of various components of adaptive and genetically determined immunity in the result of the development of a secondary immunodeficiency state, can be not only due to diseases but also due to the adverse effects of chemical ecotoxicants. The course of the inflammatory
process against the background of the immune system disregulation, caused by intoxication with metal compounds, can serve as a model. Rapid development of research in the field of immunology has led to many scientific breakthroughs, and however, some aspects of immune-associate diseases remain under-explored. The goal of research was studying the functioning of individual immunity units in rats with aseptic inflammation and preliminary seeded with metal compounds. The research was carried out on not pedigree male rats weighting 180-220 grams. Animals were randomly divided into 4 groups of 30 animals each: control animals; the animals with aseptic inflammation; the animals, which had been orally fed on ammonium vanadate and potassium dichromate in a dose of 5 mg / kg bwt within two weeks; the animals in which, at the end of seeding with metal compounds, aseptic inflammation was modeled. In 1, 7 and 14 days after the modeling of aseptic inflammation in animals of all groups (10 individuals for each research period), blood was sampled under chloroform anesthesia, then euthanasia was followed by extraction of thymus, bone marrow, spleen and mesenteric lymph nodes. A two-week monitoring of the immune status of the rats under inflammation, after being preliminary seeded with ammonium vanadate and potassium dichromate, displayed prolonged course of inflammation and impaired wound healing. Haematologic state displayed a sharp inhibition of immune competent cells and the development of anemia, which is inherent in immune depression. The course of inflammation was aggravated by the intervention of anti-inflammatory activity of IL-10 in the first term, and TGF-β in the research remaining periods, which significantly influenced the development and outcome of the inflammatory process in experimental rats. Expressed structural changes in lymphatic organs throughout the experiment were represented by a decrease in the cortical-medullary index, dystrophically altered cells and their scarcity. Quite the opposite, evolving increase in cellularity was observed in the spleen, an increase in the cell populations with the MDSC phenotype having expansion toward G-MDSC, a significant reduction in the Th2 immune response, and a reduction in the cytotoxic CD3 + CD8 + T-lymphocyte content by the end of the experiment.

Effect of p53 activation on target gene expression and cytokine release in peripheral blood mononuclear cells.
A. Valiullina¹, M. Gomzikova¹, T. Khaibullin³, E. Garanina¹, E. Zmeievskaya¹, A. Rizvanov¹, E. Bulatov¹;
¹Institute of Fundamental Medicine and Biology, Kazan Federal University, Kazan, Russia

Multiple sclerosis (MS) represents a common chronic autoimmune diseases with largely unknown etiology that is characterized by demyelination of axons in brain and spinal cord tissues. In the recent years it has become apparent that p53, a well-known tumor suppressor, has a primary role in regulation of innate immune responses. Data includes increased p53 expression in MS lesions, predisposition of p53-deficient animals to autoimmune diseases and high levels of inflammatory demyelination. Here we report the effect of Nutlin-3a-induced p53 activation on expression of various p53-dependent genes and release of proinflammatory cytokines. The results indicate that treatment with gradually increasing Nutlin-3a concentrations (5 - 40 uM) leads to correspondent gradual increase in expression levels of p21, Mdm2 and Puma target genes in peripheral blood mononuclear cells. In addition, upon treatment of cells with 10 uM Nutlin-3a we observed rise in IL-6, IL-10 and TNF-alpha levels. Gene expression data was obtained by TaqMan real-time PCR using CFX96 Touch Detection System (Bio-Rad). Quantitative cytokine detection and measurements were performed using Luminex 200 multiplexing system (EMD Millipore) and ELISA assay (Vector-Best). Our results could assist better understanding the p53-dependent regulation of immune cells and aid the development of novel immunotherapies. The study
was funded by research grant 16-34-60213 mol-a-dk from the Russian Foundation for Basic Research (RFBR).

Cellular events mediating extracellular trap formation in HL60-derived and mouse neutrophils.

H.R. Thiam¹, S.L. Wong²,³, D.D. Wagner²,³,⁴, C.M. Waterman¹;
¹National Heart, Lung, and Blood Institute, National Institute of Health, Bethesda, MD, ²Program in Cellular and Molecular Medicine, Boston Children’s Hospital, Boston, MA, ³Department of Pediatrics, Harvard Medical School, Boston, MA, ⁴Division of Hematology/Oncology, Boston Children’s Hospital, Boston, MA

Extracellular trap (ET) release is a line of host defence during which activated immune cells such as granulocytes decondense and release their chromatin to the extracellular environment, leading to the formation of web-like DNA structures decorated with histones and cytotoxic proteins. This DNA “trap” participates in innate immunity by capturing and neutralizing bacteria, fungi and viruses. However, ETs also form in sterile inflammation. While a considerable amount of knowledge regarding the in vivo relevance of ET release has been cumulating, little is known about the cellular and biophysical mechanisms leading to ET formation. To determine the cellular events occurring during ET release, we performed high resolution live cell imaging of HL60-derived neutrophils stimulated to release NETs with ionomycin as well as mouse blood neutrophils (MBN) stimulated with ionomycin or LPS (bacteria component). MBN actin, microtubule and endoplasmic reticulum (ER) networks were visualized using vital dyes. HL60 cells stably expressing F-tractin-mApple were co-transfected with mEmerald-tagged ensconsin, lamin A/C, B1 and calreticulin-KDEL for visualizing respectively microtubules, the nuclear lamina and the ER. Cellular DNA was visualized with far-red Hoechst. Spinning disk confocal and DIC microscopy revealed that both ionomycin- and LPS-stimulated MBN as well as ionomycin-stimulated HL60-derived neutrophils undergo a stereotypical series of changes in cell morphology and cytoskeleton/endomembrane dynamics prior to NET release. Within minutes after stimulation, the actin cytoskeleton disassembles followed by drastic plasma membrane vesiculation and shedding coincident with ER vesiculation, but leaving the nuclear envelope (NE) intact. Subsequently, chromatin decondenses, the nucleus rounds up, and microtubules depolymerise. The NE ruptures, leading to rapid expulsion of decondensed chromatin into the cytosol. Finally, most cells rupture their cell membrane resulting in NET release. Peptidylarginine deiminase 4 (PADI4) has been shown to be required for NETs release. To determine its requirement for the cellular events leading to NETosis, we stimulated MBN from PADI4 deficient mice with ionomycin and visualized the cytoskeleton and endomembrane using vital dyes. We found that while actin and microtubule disassembly as well as ER vesiculation occur independently of PADI4, nuclear envelope rupture requires PAID4. Our data revealed that NET release proceeds via a well conserved succession of events that mediates the systematic disassembly of cytoskeletal and membranous components prior to chromatin release into the extracellular environment. The mechanism by which PADI4 mediates nuclear envelope rupture will be further studied in HL60-derived neutrophils.
Salmonella Typhimurium of macrophages leads to the production of exosomes that activate the immune response in naive cells.

W.W. Hui1, M.J. Edelmann1, B. Clapp2;
1Microbiology and Cell Science, University of Florida, Gainesville, FL, 2Department of Infectious Diseases and Pathology, University of Florida, GAINESVILLE, FL

Salmonella enterica serovar Typhimurium (S. Typhimurium) is a Gram-negative bacterium responsible for infections resulting in 1.2 million illnesses annually, therefore constituting a significant economic burden. Macrophages infected with S. Typhimurium react to this pathogen by stimulation of the receptor-mediated inflammatory pathways and by the presentation of pathogen-derived antigens to other immune cells. We hypothesized that pathogen-associated molecular patterns (PAMPs) are released via exosomes, which are formed in macrophages during S. Typhimurium infection. Exocytosis relies on multi-vesicular bodies (MVB) to invaginate creating intraluminal vesicles (ILVs), thereafter MVB will fuse with the host plasma membrane and released the ILVs to the extracellular space in which the vesicles are termed exosomes. Exosomes can carry various cargoes, including proteins, metabolites, and microRNAs, which are unique to different cell types, subpopulations of exosomes and physiological conditions present. There is a precedence for using exosomes derived from the acid-fast bacterium M. tuberculosis to provide immune protection. We demonstrate that exosomes carry PAMPs from S. Typhimurium-infected macrophages, stimulating naïve macrophages to produce chemokines such as RANTES, TNF-α, IL-1ra, MIP-2, CXCL1, MCP-1, sICAM-1, GM-CSF, and G-CSF. Moreover, we show that these exosomes stimulate primary bone marrow-derived MΦ (BMDMs) and DCs to produce some of these cytokines. LPS has been previously suggested to be transported via the secretory pathway of macrophages upon S. Typhimurium infection, and we show that this exosome-triggered stimulation of proinflammatory chemokines is TLR4-dependent. Exosomes derived from macrophages infected with S. Typhimurium producing 1-monophosphorylated lipopolysaccharides (LPS) triggered significantly less TNF-α in naïve cells in comparison to exosomes derived from macrophages infected with wild-type S. Typhimurium, suggesting the involvement of LPS. We also show that the LPS or other unknown molecule stimulating naïve cells is enclosed within exosomes. However, our data suggest that apart from LPS there might be additional PAMPs contributing to the function of exosomes, which is consistent with the fact that proteomic analysis led to the identification of bacterial antigens within these host vesicles. Finally, we show that intranasal administration of exosomes from infected MΦs leads to an anti-S. Typhimurium antibody production, and to stimulation of CD4+ and CD8+ T cells. In summary, our data support the hypothesis that bacterial antigens are carried in exosomes derived from S. Typhimurium-infected antigen-presenting cells (APCs), which contribute to the stimulation of naïve immune cells.

Science Communication: A new writing exercise to highlight STEM literacy.
M.T. Juarez;
1Biomedical Education, City College of New York, New York, NY

An important impact of our research depends on effectively communicating our discoveries. Scientific writing is a primary tool for the dissemination of research and an important skill to develop for our trainees. For many STEM trainees scientific writing represents a style of communication that is not taught during their early education. One strategy to learn scientific writing is through reading primary research literature. Often times we assign scientific articles as a reading exercise and then the trainee leads a journal club style discussion. However, this activity can result in a passive learning experience and not help the trainee develop their scientific writing skills. In an effort to promote trainee communication skills, I tested a writing exercise as a pilot project to develop a revised version of my previously published research article. Following the writing guidelines organized by the Frontiers for Young Minds journal, I worked for several months with two high school students on drawing the results and figures in an animated style. In particular, we created a novel scale to illustrate the qualitative analyses made in the research paper (“The Ouch Scale”). We also defined key concepts of the research article and wrote basic explanations of the experimental methods. Upon completion of the revised manuscript, the students gained an in-depth understanding of the research concepts. In addition, the writing of the text and illustration of the figures promotes an engaged sense of ownership for the students with the research. The final product of our writing exercise serves as a resource to share with new students as they join the lab. As a derivative of the creative writing project, we continue to develop new illustrations of our methods and results. Current work is being done to translate this writing exercise into an undergraduate level classroom environment through using small groups and discussions with invited speakers. Another application of this writing exercise is being incorporated into a graduate level seminar series in which a final report can include a section written in a Frontiers for Young Minds style. Upon reflection of this writing exercise, I encourage all research scientists to expand the impact of their discoveries and share their knowledge with society. Improving science communication will not only benefit scientific training but also promote scientific literacy within communities with limited access to STEM fields.

How Instructors Can Enhance Biology Students’ Motivation, Learning, and Grades Through Brief Relevance Writing and Worked Examples Interventions.
K. Mara¹, A. Kaplan², M.A. Balsai³, J.G. Cromley⁴, T. Perez⁵, T. Dai⁶, Y. Davidson⁷;
¹Biology, University of Southern Indiana, Evansville, IN, ²Psychological Studies in Education, Temple University, Philadelphia, PA, ³Biology, Temple University, Philadelphia, PA, ⁴Educational Psychology, University of Illinois Urbana-Champaign, Champaign, IL, ⁵Educational Foundations Leadership, Old Dominion University, Norfolk, VA, ⁶Educational Psychology, University of Illinois at Chicago, Chicago, IL

The high failure rates of students in “gateway” STEM courses has been a persistent problem for biology programs nationwide. Common wisdom contends that addressing this problem requires major curricular overhauls. As large systematic changes are often impractical, we propose an alternative approach: supplementing the regular instruction with brief online modules targeting specific motivational and cognitive (learning) mechanisms. We conducted an intervention study to test the effects of different combinations of cognitive and motivational modules on undergraduate Introductory Biology students’ motivation, biology reasoning, course achievement, and intentions to remain in science. Introductory Biology students at a large urban university were randomly assigned to a no-treatment control condition or one of eight combinations of cognition-motivation modules. Overall, six out of the eight interventions led to higher course grades ($p \leq 0.05$) compared to control group participants. In this poster, we report on a subset of these data: the cognitive module of Worked Examples (brief video demonstrations of biology problem solving) and the motivation module of Relevance Writing (brief open-ended writing assignments about connections of biology concepts to one’s life). The combination of worked examples (cognitive) and relevance writing (motivational) resulted in a 6.35% improvement in course grades ($p = 0.05$). Increased student engagement in these combined modules also led to higher motivation, biology reasoning, and course grades. While research on these modules requires collaboration between biology instructors and educational science researchers, the implementation of the Worked Examples and Relevance Writing interventions is easy and integrates with existing course content. These findings support the effectiveness of delivering brief supplemental cognition-motivation modules online to promote students’ success in introductory biology courses. This easily implemented intervention can utilize online tools such as Blackboard, Canvas, or Moodle, and takes the burden off faculty to radically change their instruction when such change is not practical.

Board Number: B3
Integration of Student-Led Independent Research Experiences in a Senior-Level Biotechnology Laboratory Course.
J.A. Jordan⁸, Q.N. Robinson¹, R.E. McFarlane³;
¹Department of Biology, Clayton State University, Morrow, GA

An opportunity of student-led independent research was incorporated as a requirement of the Biotechnology Laboratory course. This course is a combination of skills learned throughout their undergraduate studies at the university. Students use their scientific knowledge along with math and chemistry skills to prepare laboratory solutions. While in the class, they learn basic molecular biology skills that include the isolation of DNA and protein, principles of gel electrophoresis, PCR, Southern, and Western blotting. As part of the independent research activity, the students were required to prepare a detailed research proposal summarizing how they would use at least three of the techniques learned in
the class to research a scientific topic. The areas of research were optional and could be related to any area of science but approved by the instructor. Working in groups of two or three, the students researched a topic of interest and developed a hypothesis to evaluate. The students collected scientific data on their proposed laboratory experiments to support or not support their stated hypothesis. Final research proposals included background information on topic, hypothesis stated, data collection and analysis, and a discussion/conclusion of their results. Groups also suggested additional experiments in the future to address their scientific topics. At the end of the semester, all of the students completed a Qualtrics survey to evaluate the overall success of this experience. About 87% of the students strongly agreed/agreed that their knowledge about research increased by this experience and the activity stimulated more interest in doing scientific research. In summary, this opportunity allowed students to use their knowledge of science and medicine to explore a future in scientific research.

Cellular Construction Workshop – Modeling Cells as Biological Machines.
J. Allen, V. Srivastava, R. Smith;
1Science Health Education Partnership, University of California San Francisco, San Francisco, CA,
2Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA

Cellular engineering is an emerging discipline that harnesses the power of cells to solve medical and environmental problems. By focusing on the application of biological systems for problem-solving, rather than memorizing facts and details, we aimed to excite students about a career in cellular engineering. To this end, we developed a two-week workshop for high school students and teachers. The goal of this workshop was to reframe how students think about cells - as biological machines - to illustrate their complexity and their potential to solve real-world problems. We constantly used direct analogies between various biological systems and engineering models to reinforce the concept of cells as programmable systems for accomplishing various tasks.

The course was structured such that on a daily basis the learners were introduced to different biological systems, and were immediately challenged to model an observed biological behavior using Lego Mindstorms. This structure helped develop a strong understanding of DNA as a programming interface and cells as a dynamic substrate for engineering solutions. The students and teachers worked in teams as co-learners to accomplish the various biological and programming challenges.

The workshop was viewed as a pilot for curriculum modules, and we are receiving feedback from participating teachers on how these lessons can be incorporated into the classrooms. All the lesson plans and materials were made available to the teachers to facilitate an introduction to cellular engineering in biology classrooms. The workshop presented a strong model for implementing the three-dimensional teaching described in the Next Generation Science Standards to biology teachers. Special emphasis was laid on integrating engineering practices into the teaching of biology, which can be challenging for high school life science teachers who rarely have experience with engineering. Moreover, we view this type of project-based learning as having potential for broadening student participation and increasing diversity in science by engaging underrepresented students in authentic science and engineering tasks.

Board Number: B5
Broadening Interest in STEM in High School Students through Foldscope-Based Interdisciplinary Activities.
Q.L. Aoh¹, A. Schmitz², N. Conklin³;
¹Biology, Gannon University, Erie, PA, ²Biomedical Engineering, Gannon University, Erie, PA, ³Physics, Gannon University, Erie, PA

Data from the US Bureau of Labor Statistics predicts that by 2022, occupations in science, technology, engineering, and math (STEM) are projected to grow to more than nine million. This growing workforce is expected to make up over five percent of all jobs. Indeed, many predict that the new global economy will be built on STEM careers. However, recent studies suggests that a significant number of high school students begin to lose interest in STEM fields as they get older, in part because of lack of exposure to STEM and its applications and a lack of confidence in their ability to pursue STEM-related careers. To bolster interest and confidence in self-efficacy to pursue STEM fields, we have developed a one-day outreach program that focuses on the engineering, theoretical basis, and application of the Foldscope paper microscope. Among a population of college-bound, but at-risk matriculating high school students, we found that this outreach program increased student interest in STEM in general, improved confidence in their ability to learn STEM, and increased students’ openness to careers in STEM fields. Interestingly, students most enjoyed the construction and use of the Foldscope, and least enjoyed understanding the basic optics behind the Foldscope. These results are consistent with student data that show more interest in applied than basic study of STEM fields.

Board Number: B6
Science, Biotechnology and Society, an active learning course for non-STEM undergraduates: A comparative study between first year and higher level students in term of their outcomes.
G. Arroyo¹, A. Gomez¹, G. Ayarza¹, R. Trinidad¹, C. Ayarza¹;
¹Biological Sciences Department, University of Puerto Rico, San Juan, PR

The Department of Biological Sciences (DBS) is offering the active-learning course Science, Biotechnology and Society (CIBI 3028) to introduce non-STEM undergraduates to biotechnology and trends in this scientific field. During the semester, the students engage in the discussion of current socioeconomic, environmental and bioethical issues related to biotech. At the laboratory, the students have the opportunity of conducting microbiology and molecular biology sequential experiences resembling the methodology used in research projects. In this study, second year and higher level undergraduates (sample 1, n = 52 participants) are compared with first year students (sample 2, n = 43 participants) in term of their outcomes in knowledge and comprehension of biotechnology concepts and processes. These aspects were evaluated with a pre/post-test instrument. A t-Test was conducted to establish the data significance level. A pre/post questionnaire was used to determine if there was a transition in the students’ interest toward biosciences, post-graduate studies and research in their future careers. The questionnaire results were analyzed through mean and kurtosis. Test results show a significant gain in knowledge and comprehension for both participant samples. In term of the participant interest toward the Biological Sciences, the first year students (sample 2) show the most remarkable positive shift. This study would be the first step to evaluate the possibility to integrate an authentic research project in CIBI 3028.

Board Number: B7
Light, Imaging, Vision: An interdisciplinary undergraduate course.
P. Nelson; 
1Physics, Univ. Pennsylvania, Philadelphia, PA

Students in physical and life science, and in engineering, need to know about the physics and biology of light. In the 21st century, it has become increasingly clear that the quantum nature of light is essential both for the latest imaging modalities and even to advance our knowledge of fundamental processes, such as photosynthesis and human vision. But many optics courses remain rooted in classical physics, with photons as an afterthought.
I describe a new undergraduate course, for students in several science and engineering majors, that takes students from the rudiments of probability theory to modern methods like fluorescence imaging and Förster resonance energy transfer. After a digression into color vision, students then see how the Feynman principle explains the apparently wavelike phenomena associated to light, including applications like diffraction limit, subdiffraction imaging, total internal reflection and TIRF microscopy.
Then we see how scientists documented the single-quantum sensitivity of the eye seven decades earlier than `ought' to have been possible, and finally close with the signaling cascade that delivers such remarkable performance.
In short, using imaging and vision as common threads helps motivate undergraduates to learn a lot of cell biology and physics. A new textbook, published in 2017, allows others to replicate this course. The book has supplemental sections that also make it suitable for graduate-level courses.
Outcomes include student reports of improved ability to gain research positions as undergraduates, and greater effectiveness in such positions, as well as students enrolling in more challenging later courses than they would otherwise have chosen. I'll show data based on a survey of students, in some cases several years after they took the course, documenting those outcomes, and connect to current ideas in education research. Finally, PhD students staffing the class gain experience with a new mode of teaching not featured in our other TA positions.

P1872
Board Number: B8
Use of community service projects in an introductory non-majors biology class.
F. Norflus, A. Miller; 
1Biology, Clayton State University, Morrow, GA, 2Psychology, Clayton State University, Morrow, GA

Clayton State University currently has a university-wide academic community engagement initiative to involve students in community service projects that also enhance learning of concepts covered in the classroom. This mechanism of learning teaches students a variety of skills that can be beneficial to them in succeeding in various aspects of their careers. This approach was used in a non-majors introductory biology class where students had the option to volunteer at either the American Cancer Society Hope Lodge facility that provides temporary housing for patients who have cancer or the Alzheimer’s Service Center which is a day-care center for patients with dementia or Alzheimer’s disease. The objective of this project was to introduce students to community service and evaluate any changes in their attitudes towards civic engagement and identity. Additionally, the study evaluated any changes in career-building skills while also having students learn content relevant to the class. The students wrote pre- and post-reflection papers. The instructor graded their responses as benchmark, milestone 1, milestone 2 or
capstone. It was found that there were significant increases in various parameters including civic engagement and identity, problem solving and critical thinking. These increases only rose to the level of milestone 2 presumably since it was performed in an introductory class. A community series attitude scale test (CSAS) was also given to the students early in the semester and then after the completion of their projects. This test asked questions based on perception of a need to respond, moral obligations to respond, reassessment of potential responses and engagement in helping behavior. There were no significant changes in any of the areas.

Board Number: B9

Using animation to improve student learning of difficult concepts in undergraduate biology classrooms.

J.P. Chan\textsuperscript{1}, L.V. Paliulis\textsuperscript{2};
\textsuperscript{1}Biology, Juniata College, Huntingdon, PA, \textsuperscript{2}Biology, Bucknell University, Lewisburg, PA

Active learning has dominated recent discussion on how to improve science teaching and learning on college and university classrooms. Most teaching strategies that include active learning approaches increase student engagement with course material, improve student performance, and foster classroom inclusivity. On two campuses, Bucknell University (PA) and Juniata College (PA), we examined the impact of one strategy, animation production as a mode of learning, on student performance and attitudes. Students produced an animated science video to deconstruct difficult topics like misconceptions and reading of primary literature. They wrote a script for their video, generated storyboards, and then produced a video animation using an iPad or tablet. We posited that animation production would help students learn material more accurately, exercise creativity, and improve their communication skills by telling stories. To address whether animation production improved learning of important scientific concepts, we surveyed upper level biology students at both institutions on their attitudes on using animation production to learn. At Juniata, students produced a 1-2 minute animation to communicate a main hypothesis and results of a primary paper. A survey, using a Likert scale, showed that students either strongly agreed or agreed that using animations improved their “understanding of the hypothesis” of the primary literature and caused them to “more critically analyze the research paper more than a normal reading assignment.” Moreover, students thought that opportunities for creative expression were important in biology classes. However, students also expressed that making the animations required a lot of class time. At Bucknell, students used animation to tackle misconceptions in biology. Students produced a short animation of mitosis, then watched time-lapse videos of mitosis to reveal their misconceptions about the process. Students then reanimated mitosis based on their view of the process. A quiz given two months after the animation projects were completed revealed that students created accurate drawings of chromosome distribution in mitosis, retaining what they learned from watching time-lapse videos and preparing new animations. Further application of animation production in science classrooms may lead to gains in student knowledge and communication.
