Moving from a lecture-based classroom to an active-learning classroom is a big change for science professors who have spent their whole careers lecturing and have little experience designing and facilitating group activities for students in their classrooms. Just thinking of questions and activities or finding them from other sources is only the first step. One major challenge is to evaluate these activities as they are taking place in the classroom to effectively manage student behavior, improve student learning, and consider ways to improve the activity for a future use. In this presentation the results of using various in-class formative assessment techniques will be shared to help instructors learn to evaluate their own new or modified activity. Additionally, this project gives many examples of active-learning activities that have been classroom-tested in either an upper-level cell biology class or an introductory biology class unit focusing on cell biology topics. Both successful and not successful classroom active-learning activities as evaluated by the formative assessment techniques will be included.

Developing Future Biologists: creating and assessing a portable short course to engage underrepresented students in developmental biology.
J.M. Pinskey1, E.A. Dulka2, S. Barolo1;  
1Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, 2Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI

Many barriers prevent underrepresented students from choosing a career in science. In order for undergraduate students to decide to pursue graduate education, they must first be exposed to a particular subject, develop an interest in that topic, and accumulate related coursework and research experience. Unfortunately, many students from underrepresented groups lack exposure to the field of developmental biology due to limited course offerings and finite resources at smaller institutions. To address this disparity, graduate students at the University of Michigan created a portable short course focusing on developmental biology, titled “Developing Future Biologists” (DFB). This week-long educational initiative provides students with hands-on laboratory sessions, interactive lectures, and professional development workshops, aiming to teach students the core concepts of developmental biology and increase awareness of scientific career options. To evaluate course effectiveness, we developed a pre-post assessment, incorporating key concepts in developmental biology outlined in the BioCore Guide (Brownell et. al., 2011). Here we present results from two separate iterations of the course in Ponce, Puerto Rico (2016) and Ann Arbor, Michigan (2017). We show that student understanding of core developmental biology concepts and perceived experience in developmental biology significantly increased as a result of DFB, despite the abbreviated nature of the course. Pre-post scores improved in all five of our main content areas, including early embryonic development, gene expression, cell signaling, organogenesis, and developmental disease. Furthermore, item analysis of our assessment tool suggested that items on the post-tests were less difficult for students than pre-test items, while simultaneously being better at discriminating between high- and low-performing students in the course. The DFB portable short course model and assessment strategy could easily be adapted to

Monday-7
any number of topics and locations in order to connect undergraduate students with opportunities for advanced study and help lower the barriers that exist for underrepresented students in science, technology, engineering, and mathematics.

Development of a learning progression on cellular membranes and transport mechanisms for high school through undergraduate students.
M.L. Aranda¹, S. Guzey¹,²;
¹Biological Sciences, Purdue University, West Lafayette, IN, ²Curriculum and Instruction, Purdue University, West Lafayette, IN

A learning progression (LP) is defined as a hypothetical model of student learning that contains multiple levels. This provides a framework to understand the development of students’ conceptual understanding within a domain. Cellular biology has been an area students traditionally have struggled, since they find it difficult to conceptually understand the theoretical and abstract nature of many cellular biology concepts. Therefore, a LP serves to understand student needs within this domain. To develop this LP, a cross-sectional study took place in two high schools and a public university. This included approximately forty participants who either completed a high school biology class, an undergraduate sophomore level cellular biology course or a more advanced undergraduate junior/senior level cellular biology course. Assessments were given in the form of semi-structured interviews, and responses were then audio-recorded and transcribed. In this study, we focused our attention on the development of assessments and a LP that are effective in eliciting students’ thinking and describes students’ sophisticated ways of reasoning on cell membrane structure and function and cellular transport. Our LP can be categorized into the following concepts in three levels: cell membrane structure and function, plant and animal cellular membranes, active and passive cellular membrane transport, organelle membrane transport and molecular membrane transport. Our results revealed that within cell membrane structure and function, the lowest level of the LP described how membranes keep “things” in and out, but the upper levels describe the various components and the chemical and physical properties within the bilayer. When interviewed on knowledge on plant and animal cellular membranes, analysis revealed that only the upper level of the LP describes how membranes are found in both organelles and the outer cell membrane. For active and passive transport, the upper levels describe their exact forms of energy and mechanisms, whereas the lowest level only describes whether energy is needed or not. Organelle membrane transport is relatively unknown in the lowest LP level but the upper levels describe both the mechanism and purpose of these trafficking mechanisms—such as regulation. Finally, molecular membrane transport, such as endocytosis, is superficially known in the lowest level of the LP where the upper level describes much more sophisticated reasoning behind the two processes. Collectively, this LP describes how students’ reasoning develops from high school throughout undergrad. This is an ideal tool for educators to employ in their own curriculum development to better align with the future needs of students as they progress through their biology courses.

Promoting Leadership Development Within Undergraduate STEM Curricula.
L.F. Barton\(^1\), K.S. McCain\(^2\);
\(^1\)Biology Department, Austin College, Sherman, TX, \(^2\)Institutional Effectiveness, Austin College, Sherman, TX

Scientists need to work together to find innovative solutions to complex problems greater in scale and magnitude than what society has faced before. In today's complex global world, where science impacts nearly every aspect of our daily lives, scientists will be expected to lead. The STEM Teaching and Research (STAR) Leadership Program at Austin College is designed to develop five behaviors necessary for effective leadership in science: communicating ideas, problem solving, collaborative work, foresight and planning, and acting responsibly. STAR achieves this goal through integrated leadership theory and activities in science courses at all levels of the curriculum that allow students to develop, practice, and reflect on these skills. The presenter will discuss specific examples of how the STAR curriculum enhances the teaching of cell biology in both introductory and advanced undergraduate courses, including a discussion of course integration informed through program assessment. Preliminary assessment data from the STAR program demonstrate significant increases in all student learning outcomes through their undergraduate experience. Additionally, no gaps in attainment of leadership behaviors by students have been observed from factors that may typically associate with achievement gaps in STEM (i.e. first generation status, race/ethnicity, or gender) Qualitative data from the cell biology courses demonstrated student learning gains in self and situational awareness and emphasized understanding the importance of communication and collaboration in science. The STAR program has led to enhanced student engagement and collaboration in cell biology coursework which may also translate to retention and success in STEM disciplines. At Austin College, we also believe that the STAR model of education enables students to be agents of change for science in the future.

Learning in Large Introductory Biology Courses Is Effectively Facilitated by Trained Undergraduate Learning Assistants.
R.P. Donaldson\(^1\);
\(^1\)Biological Sciences, George Washington University, Washington, DC

The purpose of the GWU undergraduate Learning Assistant (LA) program (modeled after the University of Colorado program) is to facilitate learning in active classroom environments. The LA’s take a pedagogy class taught by a STEM education specialist and meet weekly with their lead instructor. The GWU LA program is associated with courses in Biology, Chemistry, Physics and Math. Here we report on teams of LA’s who participated in the daily teaching of students in Bisc 1111 Introductory Cell & Molecular Biology classes taught 2013-2016. There were 168 students in the Fall 2016 LA class and 170 in a traditional lecture section. Each LA in the Biology classrooms worked with a specified group of 10-18 students, facilitating discussions of clicker questions, worksheet problems and practice quizzes. Each group of 3 students would submit their daily worksheet to their LA for written comments and formative assessment. Students evaluated the effectiveness of the course activities for their learning (the % of students reporting a positive effect in parentheses): assigned readings (93%), weekly online homework (70%), daily in class clicker questions (89%), daily group problem solving (89%), LA facilitation (91%), brief lectures (57%), studying alone (43%), practice quizzes (82%). Most of the students (93%) reported
that they would take another course with LA’s and 77% felt that the overall course format facilitated their learning. Learning was assessed in short answer exams and by administration of the Introductory Molecular and Cell Biology Assessment concept inventory (Shi et al, 2010, CBE Life Sci. Ed). Students in the LA supported class performed better on this assessment (74%) vs. students in the traditional lecture (64%). Published reports from other universities show that the LA program increases student retention (Talbot et al, 2015, J. College Sci. Teaching).

Assessing the Effectiveness of Student Learning and Engagement in a Content Heavy Flipped Class.
J.W. Monen¹;
¹Biology, Ramapo College of New Jersey, Mahwah, NJ

Studies have shown that greater student learning gains are achieved during active learning, when students must apply their understanding solving problems, in application exercises, in discussion-based activities, and during team-based learning. Because these active learning approaches can take up valuable class time, leaving less time for content, it is often difficult to integrate them into a content heavy lecture course. Using a “flipped classroom” approach, student-centered learning activities can be routinely integrated into the classroom while not having to sacrifice content. To test the effectiveness of the flipped classroom approach, this study assesses a 300 level Genetics class by comparing outcomes of students in a flipped class to outcomes of students in a more traditional lecture class. To control for student population differences and to ensure that student populations between the classes were comparable, portions of the flipped class experimental group (flipped group) were taught utilizing approaches similar to those in the traditional groups [Units 1 & 3 (Control Units)], whereas other portions of the course were taught utilizing the flipped classroom approach [Unit 2 (Experimental Unit)]. Exam scores during the Control Units showed no statistical difference between traditional groups and the flipped group (Unit 1, p=0.266 & Unit 3, p=0.698); whereas the flipped group performed significantly better than the traditional groups during the Experimental Unit (Unit 2, p < 0.005). Additionally, student surveys indicated that students were more engaged in the class, came to class better prepared, dedicated more time working out problems, felt more confident with the material, better paced themselves, and overall preferred the flipped class over the traditional class. This study suggests that flipping a content heavy course can improve student engagement and result in greater learning gains.

A Flipped Classroom Approach in a Sophomore-Level Cell Biology Course to Enhance Concept Integration and Critical Thinking Skills.
K.W. Adams¹;
¹Biological Sciences, Bridgewater State University, Bridgewater, MA

With the advent of the Internet and established online mediums through which information can be communicated to an audience, many teachers at colleges and universities nationwide are transitioning to a flipped classroom approach in their coursework. The basic structure in a flipped classroom entails students watching recorded lectures on new content before arriving to class and then spending class time engaging in interactive discussions and/or activities in the presence of the course instructor.
Several studies comparing the effectiveness of more traditionally-structured courses to courses with a flipped classroom demonstrate that this approach can yield greater student learning and success. With this in mind, this presentation will discuss a flipped classroom approach developed for an undergraduate, sophomore-level Cell Biology class. Its design was based on the following rationale: By watching lectures of new content before class, • students have more time to process the information and identify points of confusion, which they can bring to class for clarification; • class time can be more effectively spent helping students to integrate the new information with concepts already learned; • class time can be used to develop critical thinking skills through group discussions, problem sets, and/or other activities under direct guidance from the teacher. In this course, each class meeting entails the following four-step sequence: 1. Ahead of each scheduled class period, students are assigned a “Video Lecture” corresponding to the topic that will be discussed during the upcoming class meeting; 2. Students are provided a list of questions (“Guide Questions”) for each Video Lecture, which they should be able to answer after watching and studying the Video Lecture content. 3. Each scheduled class period begins with a 10-question quiz on the material covered in the corresponding Video Lecture. 4. The remainder of class time is then spent addressing questions students have from the Video Lecture, engaging in group discussions on how the content relates to previously learned information/concepts, and working on problem sets designed to reinforce and integrate course material.

**The Effects of In-Class Group Problem Solving Sessions on Student Learning and Study Behaviors and Attitudes in Biochemistry.**

E. Fisher¹, M. Reese², K. Tifft³;

¹Department of Biology, Johns Hopkins University, Baltimore, MD, ²Center for Educational Resources, Johns Hopkins University, Baltimore, MD

Active learning approaches including group work have been shown to be effective for student learning. We tested the effects of a specific active learning approach, in-class group work on problem sets, on student performance and student behavior and attitudes about study strategies in a large undergraduate biochemistry course. We assigned the same problem set either as an independent homework assignment or as in-class group work where students worked together in groups of five. We found that the average exam score on one exam was increased in the class with a related in-class problem session compared to the class with an independent homework assignment. Performance on specific similar questions covering content from the problem set was also increased in the class with the in-class group work. Study surveys conducted before, during, and after the class revealed self-reported student study behaviors and attitudes regarding different study methods throughout the semester. The in-class group work did not correlate with any substantial changes in student behaviors or attitudes about studying. We conclude that in-class group problem solving sessions may have short-term impact on learning compared to individual homework assignments, but did not have large effects on student behaviors and attitudes about studying.

Building a core scaffold to achieve a real understanding of the cell by medical students.
A. García de Galdeano, N. Andollo; 1Cell Biology and Histology, University of the Basque Country UPV-EHU, Leioa, Spain

For more than ten years now we have been using a learning activity focused on the vesicular trafficking, one of the main features of the animal cell. The task is performed at the midterm of the course by students of Medicine during their first year. Briefly the activity can be described as follows: students working in small groups make a poster of a cell showing the involvement of the internal membrane system in the biosynthetic activity of the cell. All the usual interactions between compartments have to be depicted, however each group has a different assignment and is asked to focus on a certain compartment, a specific type of cell and, at least, two specific molecules. Recently we have also added a disease or pathological condition related to the cell or to the molecules assigned. The posters will be presented and discussed in a collaborative way during the final session. Important learning objectives are achieved: 1) highlight the dynamic/fluid nature of membranes 2) discover the endosome and the relevance of this compartment and the vesicular trafficking in disease, 3) understand that common components of animal cells are being continuously synthesized and replaced. In summary, confronting the students with the task of linking the vesicular trafficking to the synthesis of specific molecules allows the student to gain insight into the complexity of the eucaryote cell and induces a clear shift in the learning process. According to this, all the student groups surveyed were highly satisfied about the design and usefulness of the activity. In addition, performing the task provides the scaffold required for adding new cellular components, as the cytoskeleton, or complex processes as signaling and intracellular regulation, the last topic in this course. We have also used an active learning approach to teach this topic: using mostly resources from the internet, students are guided through a journey of enquiry moving along different sides of the signaling process. All the answers and evidence are collected in a portfolio that will be used for the assessment. The task promotes the integration of the whole activity inside the cell and can be easily reused or adapted just choosing different signaling molecules or pathways. In fact the design of both tasks takes advantage of the increasing number of molecules and pathways being currently described in eucaryote cells, most trying for the teacher of Cell Biology when using the lecture method, but which provides endless combinations. Although different approaches can be equally useful, the design we propose is easy to perform, does not require technical resources, allows effective learning of core concepts in Cell Biology and helps to understand disease at the cellular level.

Graduate Students in a Hybrid Histology and Cell Biology Course.
H.M. Tavangar, G. Butera, L. Friedman, A. Ren, R.A. Jurjus; 1Department of Anatomy and Regenerative Biology, George Washington University, Washington, DC

Introduction: In a world that is becoming increasingly dependent on technology, the implementation of online and computer resources has permeated graduate medical education. These technological advances have necessitated the evolution of curricula and reformatting of class structure. In particular, histology and cell biology teaching have been highly influenced and are in a state of flux in various graduate and medical curricula. A growing trend is that many institutions are now offering an online resource of digitized histological images as opposed to the traditional glass light microscope preparations. Previous studies have reported equal if not improved performance and benefits of these
online histology and cell biology resources such as slide consistency, flexibility, ease of use, and efficiency of faculty time. An online, interactive histology atlas has been developed for undergraduate, graduate, and medical students at George Washington University in Washington, D.C. This online resource offers numerous digital preparations at both light and electron microscope levels in reference to the in-class teaching syllabus of the clinically relevant organ, tissue and cell systems. The atlas teaches both structure and proper identification techniques, and also offers accompanying texts containing background information and image clarification. Furthermore, the online resource offers testing and labeling practice to enhance the learning process. The purpose of the study is to examine the efficiency, perception, and helpfulness of the online resource in a new course format. Methods: We evaluated such measures by anonymously surveying the 2016 fall cohort of graduate students in George Washington University’s Graduate Certificate of Anatomical and Translational Sciences (GCATS) and Masters of Anatomical and Translational Sciences (MATS) programs. Practical exam grades were also reviewed to assess learning of the material. Preliminary Results and Conclusions: A preliminary survey found that 66% of students thought the atlas very useful, 75% stated the online laboratory exercised to be an effective use of time, and 100% mentioned the online component enhanced their learning of the material. Students scored very well on the final practical exam in the course. Given the feedback from our survey, combined with other studies’ findings, we hope to implement changes to make the online laboratory more effective for student use and to enhance the overall learning dynamic for cell biology and histology.

Benefits of adaptive on-line learning modules.
C. Priano1, L. Jayant1;
1Science, Borough of Manhattan Community College, New York, NY

Dynamic on-line learning modules that accompany textbooks are designed to provide individualized feedback to students based on the accuracy of their answers to questions and their reported level of confidence in those answers. Student response and success were assessed for traditional community college Anatomy and Physiology (A&P) courses that employed adaptive on-line learning platforms. In each class, weekly homework assignments included interactive on line quizzes that were to be completed prior to a lecture. Lectures were then followed up with standard review questions to reinforce inclusive topics. All assignments were mandatory with specified due dates. In an Anatomy and Physiology (A&P) II course, data was collected for 134 students over six semesters from spring 2015 through summer 2017. Scores for on-line assignments were compared with test and quiz grades throughout the semester and with final exam scores. Results were comparable for all classes. For 71% of all students, test scores remained consistent throughout a given semester. For 18% of all students, test scores increased greater than 10 points from week 4 of the semester to the final exam in week 15. Nearly 80% of these students demonstrated continued improvement in test/quiz scores throughout the semester and completed more than 72% of the on-line assignments. For 11% of all students, test scores decreased more than 10 points from week 4 of the semester to the final exam. Nearly 40% of these students with poor performance demonstrated no notable improvement in test scores throughout the term and completed less than 32% of on-line work. Over the six semesters, the greatest benefit has consistently been observed for students who scored low on exams early in the semester but completed on-line assignments throughout with relatively high scores. Similar data compiled from A&P I classes have not been as consistent. Although assignments were also mandatory, compliance was generally lower among these students. It is possible that the more consistent results obtained in A&P II classes reflect increased motivation and maturity of students who have successfully progressed to the more
advanced level. Data will continue to be collected from A&P I classes to increase sample size and obtain more meaningful comparisons. Overall, results from A&P II classes suggest that dynamic learning modules have the potential to make a significant impact on grade improvement and academic success.

Board Number: B21
MAMS - a cell biology and interprofessional education rich bridge program to health professional school.
M.A. Taylor\textsuperscript{1,2};
\textsuperscript{1}Biomedical Sciences, Pacific Northwest University of Health Sciences, Yakima, WA, \textsuperscript{2}Science, Heritage University, Toppenish, WA

The Master of Arts in Medical Sciences (MAMS) degree at Heritage University, a predominantly Native American and Hispanic-serving institution, is a one-year bridge or pipeline program to graduate health professional schools. MAMS students are typically first generation, minority, late-blooming, or disadvantaged individuals. Coursework taken alongside first-year medical students at Pacific Northwest University of Health Sciences as well as first-year pharmacy students at Washington State University coupled with standardized exam preparation, service-learning opportunities, mentorship, study strategies, and access to medical, physician assistant, and pharmacy school faculty/staff provide MAMS students with the capability to strengthen their applications as well as demonstrate their readiness for professional school. The curriculum is cellular sciences rich and focuses on the molecular basis of health and disease. Nearly one half of the coursework is cellular sciences in nature and covers topics such as histology, immunology, embryology, microbiology, biochemical metabolism, genetics, pharmacogenomics, medical physiology, and research theory. Additional instruction is provided in medical skills and the psychosocial basis of disease and treatment. Delivery of course content utilizes lectures, in-class discussion, case-based learning, small-group learning, computer-facilitated learning, and laboratory activities to maximize student comprehension of fundamental basic science principles. Since the program’s inception in 2012, 100% of students have graduated, 41% of students have been minorities, nearly 90% of graduates have gained admission into a health professional school of their choice, and 99% of MAMS students in professional schools have remained in good academic standing. MAMS students have been admitted to medical, dental, optometry, pharmacy, podiatry, and physician assistant schools. MAMS students admitted to professional schools have achieved equivalent or superior class grades and board scores compared to other admitted students. Overall student satisfaction is running approximately 88%.

Engaging community college students in an inquiry-based learning experience using NIH IRACDA postdocs expertise.
C. Inda\textsuperscript{1}, S.K. Donnelly\textsuperscript{2}, N. Nunez Rodriguez\textsuperscript{1}, T. Tomita\textsuperscript{2}, E. Steidle\textsuperscript{2};
\textsuperscript{1}Natural Science Dept, Hostos Community College, City University of New York, New York City, NY, \textsuperscript{2}Anatomy and Structural Biology, Albert Einstein College of Medicine, New York City, NY

This work highlights the positive impact of exposing community college students to inquiry-based learning activities designed by NIH IRACDA postdocs. This initiative also shares creative ways to develop postdoc teaching skills and meaningful ways to engage students in the science learning process. The postdoctoral scholars are part of the NIH IRACDA-BETTR program that Albert Einstein College of
Medicine has in partnership with Hostos Community College and Lehman College, two CUNY Hispanic-serving institutions in the South Bronx, New York. Students were exposed to state of the art technology in molecular biology and had the opportunity to gain insight into projects developed in research-intensive institutions. These activities and discussions during recitations with postdoc researchers are intended to develop student interest in science, as well as their skills in analytical and critical thinking. Specifically, we developed recitations by engaging students in case scenarios and inviting guest speakers to talk about their scientific projects. Based on this we are developing pre and post- speaker presentation questions about the research topic to generate dialogue between students and speakers, as well as discussing a relevant scientific paper using a journal-club approach. Individual surveys were used to document the impact of the initiative on the students’ interest and willingness to learn scientific content. Furthermore, lab reports and exam questions related to the above inquiry activities demonstrated the positive impact the initiative had on student skill development. Overall, this project fostered student curiosity and ability to solve problems in research settings. While we continue to develop these activities and apply them as part of the curriculum, we also aim to increase the number of visits to nearby research-intensive institutions in addition to implementing more individual undergraduate research projects and hands on activities. Together these activities will inspire the students and eventually help them to find their paths in science. Overall, this experience sheds light on the need to actively expose underserved population students to motivating STEM experiences that include young scientists with similar cultural and ethnic backgrounds.

**Bio-Bridge: A Research and Study Skills Bridge Program for Transfer Students.**
J. Hurst-Kennedy1, C. Achat-Mendes1, R. Simmons1;
1School of Science and Technology, Georgia Gwinnett College, Lawrenceville, GA

Bio-Bridge, a bridge program targeting transfer students from local two-year institutions, has recently been implemented at Georgia Gwinnett College (GGC). The Bio-Bridge project aims to increase academic success of GGC transfer students in introductory STEM courses. To accomplish this, students participate in a semester-long research projects, under the guidance of GGC Biology seniors serving as peer mentors, with embedded lessons on study and research skills. Specifically, each Bio-Bridge participant designs and conducts an independent study investigating the antioxidant properties of a chosen herbal supplements and their effects on cultured, mammalian cells. The Bio-Bridge curriculum was piloted during the spring and fall 2016 semesters. Students gained experience in many laboratory and research techniques including literature searches, creation and analysis of graphs, experimental design, spectrophotometry, serial dilutions, redox reactions, antioxidant detection assays, and mammalian cell culture. Assessment of the curriculum was conducted using the Colorado Learning Attitudes about Science Survey (CLASS) and Introductory Molecular and Cell Biology Assessment (IMCA) surveys to gauge attitudes and understanding of introductory biology concepts, respectively. Here, we present our curricular design, analyses of the pilot study data, and future plans to grow and develop the Bio-Bridge program at GGC.

The SIE Program: Supporting Inclusive Excellence in Biology, Biochemistry, and Neuroscience.
C.B. Favero1,2, K.A. Goddard3, J.E. Round1,2, R.E. Kohn1,2;
1Biology Department, Ursinus College, Collegeville, PA, 2Neuroscience Program, Ursinus College, Collegeville, PA

The Supporting Inclusive Excellence (SIE) program at Ursinus College supports student success in Biology, Neuroscience, and Biochemistry and Molecular Biology. Scholarship recipients take the same introductory sequence of Biology courses and have additional overlap in some introductory Chemistry and upper level STEM courses. The cohort nature of the program allows them to form community as they pursue challenging majors. The main goal of the scholarship program is to recruit and retain low-income and high-achieving STEM majors and prepare them for STEM careers. Specific objectives of the scholarship program include 1) Increasing the ability of low-income students to complete degrees in STEM, 2) Increasing the number of STEM graduates who are low-income and high-achieving and are also from underserved groups, 3) Providing a diversified curricular and co-curricular support structure conducive to completion of STEM degrees, and 4) Increasing the number of low-income high-achieving students who attain careers in STEM. Several support structures are already in place at Ursinus College to assist in transition to college, provide academic support through tutoring and peer-mentoring, and research opportunities. New programs have been developed including 1) A bridge program between the first and second semesters of introductory Biology during the January break, 2) A co-curricular intensive advising program to support students’ success in STEM coursework, 3) A learning circle for faculty to discuss evidence-based inclusive pedagogy in introductory biology and chemistry courses designed to improve retention of low-income students. The SIE program was founded in 2015 through an NSF STEM grant and we have matriculated two cohorts to date. The 20 scholarship students who attend Ursinus College include 80% females, 25% Pell grant recipients, 15% African Americans, 20% Latina/os, and 45% first generation college students. Four students have participated in the HHMI funded FUTURE program in the summer before or just after their first year, two students are Bonner scholars, and one student was selected to be a Fellow for the Center for Science and the Common Good (CSCG), an HHMI center at Ursinus College. CSCG Fellows explore issues at the intersection of science and society through hosting speakers, organizing discussions, doing internships, and taking courses together that explore the application of science to the common good. Thus, the SIE program is enhancing representation of students from traditionally underserved groups in research and service projects.

Yale Ciencia Academy: Leveraging a Hispanic Science Network to Enhance Graduate Biomedical Training, Career Success, and Diversity.
G. Guerrero-Medina1,2, M. Feliú-Mójer3,4;
1Office of Diversity and Inclusion, Yale University School of Medicine, New Haven, CT, 2Ciencia Puerto Rico, San Juan, PR, 3Biology, San Francisco, CA, 4University of California, San Francisco, San Francisco, CA

Higher rates of attrition of women and minorities from scientific paths at the doctoral level are an ongoing concern. Several factors contribute to this drain of talent: (i) socio-cognitive stress (e.g. feelings of isolation); (ii) limited access to career advice networks, particularly during academic transitions; and (iii) tension between personal values and perceived culture and expectations of academic research. Studies show that minority-serving institutions and undergraduate programs that offset the sense of
isolation can increase persistence in science. Applying these interventions at later training stages and at research-intensive institutions presents obvious challenges. Through the NIH-supported Yale Ciencia Academy, we have leveraged a large and dynamic Hispanic science network, the Ciencia Puerto Rico community (www.cienciapr.org), to enhance the training and retention of minority graduate students in science. Specifically, we: 1) create online learning communities that close the geographic gap between graduate students and role models, mentors, and peers from similar cultural backgrounds; 2) provide training that addresses common gaps and provides skills for professional development; and 3) enable trainees to contribute to their community of origin through science outreach. Now in its second cohort, the Yale Ciencia Academy has recruited a total of 62 scientific role models, and 74 life and behavioral sciences graduate students from 36 universities in Puerto Rico and the U.S. to date. We are examining the impact of the program with respect to (a) enhanced feelings of competency in science and positive expectations for a scientific career; (b) larger and more focused individual professional networks; (c) competency in important academic and professional skills; and (d) awareness of social value as scientists. Preliminary results indicate high satisfaction with program components; increased science communication, scientific teaching, and mentoring and networking skills following workshop trainings; and higher confidence and clarity in career goals, higher confidence in career navigation skills, and better interactions with mentors, compared to the start of the program. Scientists participating in the program as panelists, facilitators, and instructors also rated their experience very highly.

Board Number: B26
Academic boot-camps for undergraduate anatomy and physiology and introductory biology courses: paving pathways for student success.
I.V. Ellison\textsuperscript{1,}, A.L. Dell\textsuperscript{2};
\textsuperscript{1}Health Science, Mercy College, Dobbs Ferry, NY, \textsuperscript{2}Biology, St. Francis College, Brooklyn, NY

During the first semester of freshmen year, biology and prehealth professional students are often enrolled in anatomy and physiology or general biology. These rigorous and fast-paced courses require students to build upon fundamental knowledge of chemistry and biology, as well as to have exceptional study science skills in order to succeed. This poses a challenge, as many students are underprepared, lacking firm foundations in science, as well as overwhelmed by the pacing and demands of college-level coursework and ownership of their own learning. As a result, these courses often result in low levels of student success with high D, F and withdraw (DFW) rates. To address these challenges and the associated impacts on student success, academic boot-camps were developed for Anatomy and Physiology and General Biology courses for students at two New York undergraduate institutions that focus on educational access to traditional and nontraditional students, including many who are racially/ethnically diverse, low income and first-generation: Mercy College and St. Francis College. The boot-camps, which took place prior to or within the first week of the semester start and were offered free of charge to the students, introduced course pacing, effective study and testing strategies, course and college resources, peer instruction and teambuilding through intensive programming. The purpose of this study was to examine the impact on and effectiveness of these academic boot-camps on student success, specifically the course DFW rates. The boot-camps resulted in improved student success. Mean exam grades were significantly higher (p<0.0001) for students who attended the bootcampus vs. those who did not attend. In addition, 88% of students who completed the full program and 72% of students who completed even a portion of the program, completed the course with a grade of B- or above vs only 30% of students who did not attend earning similar grades. 67% of the students who
While the formation of knowledge has previously drawn the interest of historians and sociologists of science, how knowledge forms remains largely unknown. This lack of understanding is perhaps best exemplified by an inability to predict “hot” research topics and the career paths of individual scientists. Here we show that biomedical research becomes predictable when one considers hundreds of properties of genes and gene products. We connect gene-specific biology with disambiguated authorship information and citation analysis for all publications since the 1970s. Using this approach, we can predict the number of publications that will appear for individual genes in MedLine in a given year, the ability of scientists to retain federal funding, and the likelihood of transitioning from first authorship positions to a role as principal investigators. We demonstrate that the number of genes contained within one publication is indicative of its probability of becoming a highly cited publication, and we explain why the majority of all human genes remains unstudied. We find that early “discover-ability” and the presence of model systems account for today’s research on individual genes and identify the gene-specific biological and chemical properties that had favored an early discovery. Finally, we demonstrate that the gene-specific historical biases of biomedical research have propagated to current computational predictions of biological function and to large, heavily used biological databases.

Although our study marks the first predictive description of any scientific discipline, we believe that its main novelty lies in the ability to equally inform policymakers and individual scientist working on specific genes.

The RNA-guided DNA endonuclease Cas9 has emerged as a powerful new tool for genome engineering. Cas9 creates targeted double-strand breaks (DSBs) in the genome. Knock-in of specific mutations (precision genome editing) requires homology-directed repair (HDR) of the DSB by synthetic donor DNAs containing the desired edits, but HDR has been reported to be variably efficient. Here, we report that linear DNAs (single and double-stranded) engage in a high-efficiency HDR mechanism that requires only ~35 nucleotides of homology with the targeted locus to introduce edits ranging from 1 to 1000 nucleotides. We demonstrate the utility of linear donors by introducing fluorescent protein tags in...
human cells and mouse embryos using PCR fragments. We find that repair is local, polarity-sensitive, and prone to template switching, characteristics that are consistent with gene conversion by synthesis-dependent strand-annealing (SDSA). Our findings enable rational design of synthetic donor DNAs for efficient genome editing.

CASTING: A rapid method to generate pooled clone libraries for functional genomics investigations.
M. Meurer1, B.C. Buchmuller1, E. Sass2, K. Herbst1, D. Kirrmaier1,3, E.D. Levy2, M. Knop1,3;
1Zentrum für Molekulare Biologie der Universität Heidelberg, Heidelberg, Germany, 2Department of Structural Biology, Weizmann Institute of Science, Rechovot, Israel, 3Deutsches Krebsforschungszentrum (DKFZ), Heidelberg, Germany

Yeast strain libraries have revolutionized the study of eukaryotic gene expression, protein function, localization, and protein-protein interactions. Usually, they are composed of arrayed strain collections, in which each strain has a specific modification at a different genomic locus. The creation of new genome-wide libraries, however, is prohibitively expensive, labor-intensive, and requires specialized lab-equipment to handle the strain arrays. Here, we introduce a conceptually reversed approach by using a pooled format for library construction, high-throughput functional profiling, and next-generation sequencing. By making use of low-cost pooled oligonucleotide synthesis platforms and exploiting an RNA-guided endonuclease to facilitate the precise, site-directed integration of a tagging cassette by homologous recombination, libraries can be constructed in a single reaction tube.

We applied this strategy for C-terminal tagging of open reading frames in the yeast *Saccharomyces cerevisiae*. Integration efficiency was increased several orders of magnitude compared to conventional means, allowing for a genome-wide design. An entire library could be constructed within 4 to 5 days. Quantification of expected and observed genotypes enabled us to retrieve parameters determining library heterogeneity.

Also we exemplify the analysis of such pooled clone libraries which involves their sorting (e.g. using FACS or growth competition) followed by a target enrichment next-generation sequencing protocol to characterize the identity of strains in the individual fractions.

The CASTING approach expands the functional genomics toolkit and will serve the research community as a valuable resource.

Targeted RNA Expression Profiling for Biomarker Discovery in Complex Biological Samples.
A.A. Chenchik1, P. Diehl1, A. Komarov1, M. Makhanov1, C. Frangou1;
1Cellecta, Inc., Mountain View, CA

New rapid and robust transcriptome-based methods for cellular characterization of the tumor microenvironment and biomarker discovery are required to improve prognosis and treatment of cancer and other diseases. However, challenges with current approaches for the above applications include high sample requirements, poor sensitivity, low dynamic range, and limited throughput. To address these limitations, we have developed the Driver-Map targeted RNA expression profiling assay using a genome-wide set of 19,000 validated primer pairs that leverages the sensitivity of multiplex RT-PCR with
the throughput and digital readout depth of Next-Generation Sequencing (NGS). Starting from just 10pg (single-cell) to 100ng (10,000 cells) of total RNA is sufficient to quantify over 5 orders of magnitude variation in gene expression levels with performance similar to conventional qRT-PCR. Further, the use of gene-specific primers enables direct analysis of total RNA isolate and obviates the need for globin and rRNA depletion from whole blood samples. In this study, we present the performance of the assay for immunophenotyping of immune cells in whole blood samples from sepsis patients and assess the immune responses to complex immunomodulatory stimuli in ex vivo model system. We will also present profiling results that demonstrate how this assay can be used to analyze the level of immune cell infiltration in tumor samples, and identify active pathways in tumor and xenograft samples. Preliminary studies demonstrate the assay’s unparalleled specificity and sensitivity resulting in better detection of low abundance mRNA transcripts as well as an improved cost-effectiveness for high-throughput pre-clinical applications.

Access and Discover Biological Pathway Information from Pathway Commons.
E. Demir, I. Rodchenkov, Ö. Babur, A. Luna, J.V. Wong, C. Sander, G. Bader; 1Department of Computational Biology, Oregon Health Science University, Portland, OR, 2Department of Computational Biology, University of Toronto, Toronto, ON, 3Department of Cell Biology, Harvard Medical School, Boston, MA, 4Dana-Farber Cancer Institute, Boston, MA

Pathway Commons (www.pathwaycommons.org/) serves researchers by integrating data from public pathway and interaction databases and disseminating it in a uniform fashion. The knowledge base is comprised of metabolic pathways, genetic interactions, gene regulatory networks and physical interactions involving proteins, nucleic acids, small molecules and drugs. Alongside attempts to increase the scope and types of data, a major focus has been the creation of user-focused tools and resources that facilitate access, discovery and application of existing pathway information to facilitate day-to-day activities of biological researchers. For those wishing to browse and discover pathways within the collection, we offer a web-based ‘Search’ application that enables users to query by keyword and visualize ranked search results. ‘PCViz’ is a web tool that accepts gene names and returns a customizable interaction network visualization based upon pathway data resources. These complement existing desktop software add-ons linking Pathway Commons to the Cytoscape (CyPath2) network analysis tool and the R (paxtoolsr) programming language. To facilitate analysis and interpretation of experimental data - for instance, enrichment studies that distill pathway alterations from underlying gene expression changes - pathway data file downloads can be directly used in software tools such as Gene Set Enrichment Analysis. For those wishing to learn more about pathway resources and analysis, an online ‘Guide’ includes case studies and guided workflows. Ongoing development of web apps will enhance the accessibility to pathways and integrate support for visualization and interpretation of experimental data.

Single-cell protein and gene expression profiling of stem memory T cells by BD Ab-seq.
C. Chang¹, E.Y. Shum¹, J. Martin¹, J. Ghadiili², M. Corselli³, D. Jensen¹, J. Hu¹, D. Rosenfeld¹; H.C. Fan¹; ¹RD, BD Genomics, Menlo Park, CA, ²RD, BD Biosciences, San Diego, CA, ³RD, BD Technologies and Innovation, Durham, NC

High-throughput single-cell RNA sequencing recently emerged as a powerful tool to profile complex and heterogeneous cell populations and dynamics. However, the lack of information on protein expression can make identifying cell types that have conventionally been defined by cell-surface markers challenging, as mRNA and protein expression are often not tightly correlated. T cells in particular contain relatively low abundance of transcripts, and different T-cell subsets often exhibit highly similar transcriptional profiles.

Here we utilized BD Ab-seq, a novel protein sequencing technology enabled by oligo-conjugated antibodies, to study stem memory T cells (Tscm), a rare long-lasting memory T-cell population with stem cell-like properties. An oligo-conjugated antibody panel against immune-relevant cell-surface markers was created and used for protein profiling alongside gene expression profiling in single cells. From human PBMCs, we enriched for Tscms, naïve T cells, central memory T cells and effector memory T cells by FACS sorting. The sorted samples were labeled with antibodies barcoded with unique sample IDs, which allowed us to pool multiple samples into one single-cell experiment, and de-multiplex the samples after sequencing. The antibody-specific oligos and sample ID-specific oligos were captured, amplified and sequenced alongside mRNAs in a single workflow on BD Rhapsody™, a massively-parallel single-cell analysis system. The resulting sequencing data provided a combined output of gene expression, protein expression and sample identity.

The detection of protein expression by BD Ab-seq was highly sensitive and specific, and we observed consistent protein expression patterns when comparing BD Ab-seq data to FACS data of the same samples. The addition of protein marker expression provided more distinct and robust clustering of single-cell data compared to clustering by gene expression alone. We were also able to correlate gene expression differences between the four T-cell subsets with protein marker expression at the single-cell level to examine heterogeneity within the Tscm subset. Our study demonstrates the power of combining BD Ab-seq with RNA-seq to gain a more comprehensive understanding of cell lineage and function at the single-cell level.

Identification of Protein-Protein Interaction Hotspots in the Hippo Signaling Pathway.
A.N. Still¹, V. Nara¹, A. Dailing¹, R. Magni¹, L. Liotta, MD¹, A. Luchini¹; ¹Center for Applied Proteomics and Molecular Medicine, George Mason University, Manassas, VA

Protein-protein interactions constitute potential drug targets for cancer due to their involvement in cell signaling, but have thus far proven difficult to target for a host of reasons. One significant challenge has been identification of interaction “hotspots” due to a lack of simple, rapid methods for detection. Protein painting, a technology developed at George Mason University, is a simple, versatile tool for determining the protein-protein interactions sites of protein complexes. The solvent accessible surfaces of proteins and protein complexes can be “painted” with small, organic dyes and differential analysis used to determine the “unpainted” regions of the complex, or the interaction “hotspots”. We applied this technique to the Hippo signaling pathway, including proteins such as YAP1 (a transcriptional
regulator), TJP1 (also known as ZO-1, involved in tight junction assembly), and LATS1 (a kinase). Current research shows that inhibition of YAP can result in unintended tumor growth; therefore, disrupting inhibitory YAP complexes is a potential therapeutic strategy. We probed recombinant protein YAP complexes YAP1-TJP1 and YAP1-LATS1, and identified unique regions on each protein corresponding to interaction “hotspots”, which are evolutionarily conserved and promising sites for further inhibitor development. We also validated our method by identifying the protein interaction hotspot of the BRCT domain of BRCA1 (a DNA repair protein with mutations implicated in breast cancer development) with a peptide inhibitor, whose co-crystal structure has been solved. Future work on functional validation of identified hotspots, inhibitor design, and adaptation to whole cell models will lead to potential new therapeutic approaches to treating cancer.

**Regulation of the Mouse Alveolar Macrophage Toponome by Surfactant Protein-A.**

D.S. Phelps¹, X. Zhang³, D. Shearer², J. Weisz², J. Floros¹;

¹Pediatrics, Penn State College of Medicine, Hershey, PA, ²Obstetrics and Gynecology, Penn State College of Medicine, Hershey, PA

We have shown that the innate host defense molecules, human (h) surfactant protein-A1 (SP-A1) & SP-A2, differentially affect the proteomic expression profile and function of alveolar macrophages (AM). Sex differences were also observed in male and female mice. In this study, we “rescued” male SP-A knockout (KO) mice with a treatment of in h the AM were harvested by bronchoalveolar lavage, plated onto slides, fixed, and frozen for later analysis. KO mice treated with vehicle alone served as controls. We analyzed the slides using the Toponome Imaging System (TIS) that enables studying the AM toponome (combination of the “proteome” and “interactome”) within intact cells. TIS is a robotically controlled serial immunostainer that enables sequential immunostaining and imaging of a single slide with multiple FITC-conjugated antibodies. The resulting images are analyzed pixel-by-pixel to identify the proteins present in each pixel. The group of proteins present in each pixel is designated as a combinatorial molecular phenotype (CMP), which represents organized protein clusters that are postulated to contribute to a specific cell function. We analyzed 19 cells from each mouse immunostained with 13 antibodies and three mice per condition. Focusing on the 20 most abundant CMPs for each cell we tabulated the incidence of each of the 13 markers studied. Phenotypes were defined as cells exhibiting similar patterns of expression of these markers. We found that the AM populations were extremely diverse and that each sample contained cells with multiple phenotypes. Of the 114 cells analyzed, no two cells were identical. However, we did find groups of cells with similar phenotypes. Some phenotypes were found predominantly in vehicle-treated KO mice, and others found mostly in SP-A1-treated mice. There were also phenotypes that were equally abundant in both groups. These patterns suggested that SP-A had both positive and negative regulatory on the incidence of some phenotypes, whereas others were unaffected by the presence or absence of SP-A. In summary, using this novel microscopic technology to analyze individual cells within populations of AM we have confirmed that AM from a given individual are very diverse, consisting of several subpopulations, and that no two cells are identical. We have also demonstrated that AM phenotype is dependent, at least in part, on the presence of SP-A in the alveolar space. These findings suggest that SP-A may be useful for the therapeutic manipulation of AM function in vivo. Supported by AHA 15IRG22890004.

Proteomic and interactome analyses of SEPT9 in MCF7 breast cancer cells reveal isoform-specific pro-oncogenic functions.
L. Devlin1,2, G. Perkins2, C. Montagna3, E.T. Spiliotis1;
1Biology, Drexel University, Philadelphia, PA, 2Analytical, Sanofi Pasteur, Swiftwater, PA, 3Departments of Genetics and Pathology, Albert Einstein College of Medicine, Bronx, NY

Septins comprise a large family of GTP-binding proteins involved in a broad spectrum of cellular processes, including organization of the cytoskeleton, exocytosis, and regulation of cytokinesis. Thirteen distinct septin genes have been identified in humans, many of which exist as multiple isoform variants, that are categorized into four groups (SEPT2, SEPT6, SEPT7, and SEPT3) based on sequence similarity. Overexpression of ubiquitously expressed SEPT9, which belongs to the SEPT3 group, has been reported in various cancers, including colorectal, breast, and prostate. SEPT9 is alternatively spliced into 18 different mRNA variants, which encode protein isoforms that vary chiefly in the length and amino acid sequence of their N-terminal extension that precedes the GTP-binding domain. Differential expression of SEPT9 variants has been observed across many commonly used breast cancer cell lines, implying an isoform-specific role of SEPT9 in cancer biology. Substantial differences in the N-terminal extensions suggest unique binding partners which may provide insight into the isoform-specific roles of SEPT9. Therefore in this study, we compared the interactomes of the long-form SEPT9-i1, and short-forms-i4, and i5, in stably-transfected MCF7 human breast cancer cells using affinity purification coupled with LC-MS/MS. Our results showed isoform-specific interactomes for SEPT9i1, i4, and i5 which yielded 205, 122, and 136 unique binding partners, respectively. Isoforms 1 & 4, 1 & 5, and 4 & 5 shared 24, 30, and 86 binding partners, respectively. Notably, 94 proteins were shared among all three isoforms. Subsequent bioinformatics analyses of the isoform-specific interactomes yielded pro-oncogenic biological process enrichments for SEPT9i1, which were absent for both interactomes of SEPT9i4 and i5. Pro-oncogenic enrichments in the SEPT9i1 interactome included cholesterol/lipid biogenesis, histone methylation, centriole assembly, regulation of cell shape, nuclear envelope assembly, heat shock response, and sugar/ATP metabolism. These results point toward a biological role of the N-terminal extension of full-length SEPT9 and point to new functions and mechanisms of action for SEPT9 isoforms in cancer biology.

Novel Platform for Profiling Ubiquitin Specific Proteome.
C. Song1, P. Foote1, X. Lu1, R. Singh1;
1RD, Lifesensors Inc, Malvern, PA

Ubiquitylation regulates most of cellular activities including cell cycle, differentiation, apoptosis, and stress response. The coding is encrypted by ubiquitin modification sites and chain linkages. Proteomics provides an effective approach for decoding the ubiquitin signals. Ubiquitylation is a extremely dynamic process and ubiquitylated proteins are low in abundance and stoichiometry. Enrichment of ubiquitylated proteins is essential for improve quantitative, reproducible and sensitive proteomics analysis. The common approach is to use DiGlyGly-lysine antibody to pull down ubiquitin remnant. However, ubiquitylation from ubiquitin-like proteins such as NEDD8 and ISG15 which are undistinguishable by DiGlyGly-lysine antibody. Here we demonstrate a novel ubiquitylation specific proteomics approach. This method utilizes UbiSite antibody that recognizes the ubiquitin C-terminus which creates the specificity for ubiquitin remnant. Human liver carcinoma cell line, Hep2 and T Leukemia cell line, Jurkat,
were chosen as model systems. The alteration of polyubiquitinated proteins is either induced by b-AP15, the inhibitor of a proteasome associated DUB, USP14 or bortezomib, a 26S Proteasome inhibitor. Cell lysates were digested with Lys C and immunoprecipitated with UbiSite antibody. Enriched ubiquitinated peptides were further digested with trypsin and analyzed by LC-MS/MS. The total proteome and ubiquitome were compared among these samples. In addition, the ubiquitinomes at proteins and site-specific levels were also compared with other published studies. This novel approach will facilitate discovery of pharmacological markers for drugs, and open doors for cell biologists to specifically identify patterns of poly-ubiquitylated proteins.

Development of a pharmaco-proteomics platform for monitoring changes in thrombin-mediated signaling and aggregation of human platelets treated with dabigatran.
J. Gonzalez1, A. Babinska2, M. Dzieciatkowska 3, E.L. Ewul4, E. Timpo2, M.O. Salifu2, C.C. Clement4,5; 1Department of Natural Sciences, LaGuardia Community College, Queens, NY, 2Division of Nephrology, Department of Medicine, State University of New York, Downstate Medical Center, Brooklyn, NY, 3Biological Mass Spectrometry Core Facility, University of Colorado Denver, Aurora, CO, 4Chemistry, Lehman College CUNY, Bronx, NY, 5Pathology, Albert Einstein College of Medicine Inc, Bronx, NY

Dabigatran is an oral anticoagulant, and a reversible direct inhibitor of thrombin (DTI). Thrombin is known to induce the activation of platelets to aggregate by binding to and cleaving with the extracellular N-terminal domains of protease-activated receptors 1 and 4 (PAR1 and PAR4). To date many DTI have proved to be potent inhibitors of thrombin-mediated activation of platelet aggregation. Such DTI are useful drugs for managing acute coronary syndrome (ACS). Recently it was shown that dabigatran can inhibit platelet aggregation by acting directly on platelet thrombin receptors (PAR-4), by inducing a reduced expression of GPIIb/IIIa, CD63, and P-selectin on platelets after dabigatran treatment. The research presented herein further explored the molecular and cellular pathways modulated by dabigatran in the thrombin-activated human platelets from healthy donors by employing label-free proteomics approaches. We hypothesized that a global proteomics analysis of thrombin-activated human platelets treated with dabigatran would reveal the integrin-linked kinase (ILK) and integrin-mediated signaling as pathways significantly down-regulated by the DTI dabigatran. To test our hypothesis we developed a pharmaco-proteomics platform that monitors changes in protein expression profiles of platelets purified from healthy human donors, and ex-vivo activated with thrombin in the presence or absence of dabigatran. The proteomics platform employed the nanoL C-ESI MS/MS sequencing of tryptic/Glu-C/Lys-C generated peptides from platelets releasates, as well as a Q-Exactive quadrupole orbitrap mass spectrometer coupled with the label free quantification (LFQ) module provided by PEAKS 8.0 (Bioinformatics Solutions Inc.). A quantitative analysis of these biochemical pathways was accomplished with ingenuity pathway analysis (IPA; Ingenuity Systems) using the protein ratios extracted from LFQ analyses. Our hypothesis was confirmed by the bioinformatics analysis that predicted that many proteins involved in ILK and integrin signaling pathways, the actin-mediated cell signaling and cellular movement and rhoA and rhoGDI signaling were at least two-fold statistically significant down-regulated (p<0.05) in the dabigatran-treated platelets than in the control, untreated, and thrombin activated platelets. Remarkably, the LFQ analysis validated the dabigatran-mediated downregulation of some of the previously published biomarkers of the integrin mediated signaling pathways, e.g., GPIIb/IIIa, a finding which could explain the dabigatran-mediated inhibition of thrombin-activated platelets aggregation. Our results further advocate for the implementation of platelets proteomics as a reliable assay for monitoring the efficacy of selected drugs for ACS treatment.

Quorum: Crowdsourcing image tracing through an engaging painting game.
J.H. Iwasa¹, K. Santiago¹, J. Lin¹;
¹Biochemistry, University of Utah, Salt Lake City, UT

Recent advancements in biological research, particularly the development of high-throughput methodologies, have allowed researchers to collect huge quantities of data at prodigious rates. For data that is visual or graphical in nature, data analysis often poses a significant challenge. Segmentation or tracing of specific features within microscopic images, for example, is often difficult to completely automate due to noise and variations in sample quality and image collection. Images must often be analyzed manually, which can be a laborious and time consuming process. In order to address this issue, we have developed a game platform for crowdsourcing visual data analysis called Quorum. Quorum is an interactive, engaging painting game that allows members of the public to trace images or other visual data. As an open platform, Quorum will allow any researcher to upload images using a custom web-based interface and specify a segmentation challenge. After the images have been traced by gamers, the researchers can retrieve their analyzed data on the Quorum website. Quorum is free to use and open-source, allowing anyone to play or modify the platform.

Improving the nutritional quality of the common bean: Producing reagents for bean transformation.
C.M. Morales¹, S. So¹, M.B. Zavala¹;
¹Biology Department, California State University Northridge, Northridge, CA

Legumes are an important source of protein for 600 million people. However, the most abundant seed proteins are low in sulfur containing amino acids. The purpose of these experiments is to improve the nutritional value of Phaseolus vulgaris, the common bean by altering the amino composition of one class of its highly abundant seed proteins, the lectin phytohaemagglutinin PHA-E and PHA-L (NCBI). We are focusing on PHA-E. Lectins are sugar-binding proteins that have antifungal and insecticidal properties, which can help the plant survive. The lectin PHA-E contains eleven isoleucine (ATC), five of which I am transforming into methionine (ATG). Negro Jamapa is one of the few common beans that can be transformed and regenerated. Negro Jamapa was germinated and DNA extracted from the leaves. PHA-E ends were modified and the gene amplified using Polymerase Chain Reactions. The product was inserted into a 2.1PCR Vector™ and modified. The modified PHA-E cassette was inserted into the binary vector with CaMV35S with mcherry or with a seed promoter with mcherry and then we transformed into Phaseolus vulgaris. Currently, we have the T0 generation for four lines with a putative modified PHA-E, and are in the process of testing T1 generation of these four lines. Future work will include verifying the expression and accumulation of the mutant PHA-E, and determining whether these modifications alter plant growth, reproduction and improve the nutritional quality of the seeds. This work was supported by a GM 063787.

The NIH Common Fund’s Extracellular RNA (exRNA) Communication Program.

L. Kuo\(^1\);

\(^1\)National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, VA

The NIH Common Fund’s Extracellular RNA (exRNA) Communication Program has been developed to address critical issues in the exRNA research. The overarching objective is to generate a multi-component community resource for sharing fundamental scientific discoveries, protocols, and innovative tools and technologies. Key components include (a) generating a reference catalogue of exRNAs present in body fluids of normal healthy individuals that would facilitate disease diagnosis and therapies, (b) defining the fundamental principles of exRNA biogenesis, distribution, uptake, and function, as well as developing molecular tools, technologies, and imaging modalities to enable these studies, (c) identifying exRNA biomarkers of diseases, (d) demonstrating clinical utility of exRNAs as therapeutic agents and developing scalable technologies required for these studies, and (e) developing a community resource, the exRNA Atlas, to provide the scientific community access to exRNA data, standardized exRNA protocols, and other useful tools and technologies.

Recent progress to be presented include showcasing new community-wide tools for researchers. ExRNA data sets are being generated and shared to be interoperable, transportable, and maximally useful to the public. Tools and technologies under development include the exRNA Atlas, RNA-seq data analysis pipelines, tools for expression quantification, and data visualization platforms. Altogether, the goal is to enable community-wide exRNA data and resource sharing.

\(^1\)National Institute of Mental Health, NIH, Rockville, MD

Recent technological advances in high throughput analyses of molecular, anatomic, and physiological measurements at the single cell level promise to open a new era calling for a unified brain cell census. In 2014, the NIH BRAIN Initiative awarded 10 grants to pilot classification strategies and generate data/metadata for this comprehensive brain cell census. From these pilot projects, multiple brain regions from different organisms are being studied using a variety of advanced technologies, and awardees are collaborating on defining standards to describe experiments and data sets.

In 2017, NIH expanded support for cell census data and relevant tools by launching a coordinated set of awards under the auspices of a BRAIN Initiative Cell Census Network (BICCN). The overarching goals of the consortium are to (1) create a comprehensive 3D common reference mouse brain cell atlas that integrates molecular, anatomical, and physiological annotations of brain cell types, and (2) generate reference brain cell atlases from postmortem healthy adult human and/or non-human primate brain samples.

The BICCN is composed of a group of Centers and Collaboratories supported via four companion funding opportunities: Comprehensive (U19) Center(s) that will focus on building up a comprehensive mouse brain cell atlas; A Specialized (U01) Collaboratory that will contribute cell census data for endpoints in the mouse brain not otherwise covered in the U19 Center(s); A Specialized (U01) Collaboratory that will...
begin to collect cell census data from human or non-human primate brains; and finally, the U24 BRAIN Cell Data Center (BCDC) that will integrate, visualize, and disseminate the cell census data generated by the U19 and U01 Centers and Collaboratories as well as create a brain cell knowledge base. The expected outcomes of the BICCN include: fundamental knowledge on diverse cell types and their three dimensional organizational logic in the brain; an open-access 3D digital brain cell reference atlas with molecular, anatomical, and physiological annotations of brain cell types in mouse; a comprehensive neural circuit diagram in mouse brain; reagents for cell-specific targeting; validated high throughput and low cost approaches to characterizing cell diversity in human and/or non-human primate brain samples. The BICCN will operate as a cooperative network to promote collaboration and coordination with any research entities that have similar goals. It is expected that funded projects in the BICCN will work together to achieve the overall goals. Thus, the BICCN will leverage existing atlases and common coordinate systems to facilitate collaborative efforts for the data annotation and 3D spatial mapping.

An Image-based data generation pipeline to model stem cell organization and dynamics.
.. AICS Team¹;
¹Allen Institute for Cell Science, Seattle, WA

We are generating tools and data to create multi-scale visual models of cell organization that capture and predict experimental observations. This relies on high replicate, dynamic image data on cell organization and activities using endogenous fluorescently tagged human induced pluripotent stem (hiPS) cells. The endogenous fluorescent tags allow us to visualize the locations and dynamics of major organelles and other cellular structures in healthy, living human cells. To capture this organization and dynamics under diverse but defined conditions, we developed a light microscopy pipeline that images each tagged hiPS cell line in a highly standardized fashion. We describe here three imaging workflows used in our imaging pipeline to study the effect of cell division, local environment and perturbations induced by pharmacologic agents with known mechanisms on the spatio-temporal localization behavior of major structures within the cell. In its current configuration, the microscopy pipeline uses Zeiss spinning disk confocal microscopy to generate 500-3000 replicate 3D images at 120x magnification for the localization of each cellular structure in relation to markers for the plasma membrane and DNA/nucleus. Lower magnification 2D time series images are used to study the dynamics of cellular structures during processes like cell division and colony formation. The microscopy pipeline applies automation and robotics for cell preparation and microscopic imaging to generate thousands of 3D image stacks or time-lapse image series every month. Image stacks or time-series are then sent to an automated image processing pipeline generating over 10,000 individually segmented 3D cells per month. To circumvent the impossible task of viewing all structures simultaneously in the same cell, we utilize computational strategies to combine image data obtained from different cell lines to produce an integrated cell model. The cell lines, data collection and integrated cell models are made available through our website (http://www.allencell.org) and can be used to visualize and understand the fundamental organization of cells and how they change in disease.

Toward the creation of the first 3D image-based data collection of drug induced signatures of endogenous fluorescently tagged human induced pluripotent stem cells lines.
.. AICS Team1;
1Allen Institute for Cell Science, Seattle, WA

We are building predictive models of the dynamic organization and behavior of cells using, image-based 3D data sets of fluorescently tagged structures in human induced pluripotent stem cells (hiPSC). As a part of this project, we are developing a scalable and reproducible imaging pipeline that identifies signature profiles for a range of well-characterized small molecules commonly used to perturb specific cellular processes or pathways in gene-edited hiPSC from the Allen Cell Collection (see related abstract from the Institute). Our goal is to develop a systems view of the effects of these small molecules on cellular organization and dynamics. These unique data will be used to train predictive models to identify the effects of perturbing target pathways, ascertain “off-target” effects and the mode of action of unknown compounds, and identify likely pathways influenced by mutations. The pipeline was prototyped using a small suite of well-characterized compounds that include brefeldin A, paclitaxel, rapamycin, wortmannin and staurosporine. We used low-resolution imaging (24x magnification) to test a matrix of concentrations and time points for each compound of interest, allowing us to establish an initial set of conditions for each perturbation. hiPSC colonies were monitored for morphologic changes using transmitted light and an endogenously GFP-tagged structure, such as microtubules. After establishing an end point response for several compounds, high-resolution (120x magnification) imaging of multiple cell lines from the Allen Cell Collection was performed under standardized perturbation parameters, in the presence of dyes to label the nucleus and cell membrane for reference purposes. These perturbations showed alterations roughly analogous to those seen in other cell types. For example, the microtubule stabilizing agent paclitaxel increased microtubule bundle thickness and altered the shape and position of the mitotic spindle during hiPSC cell division. In addition, paclitaxel, also induced aberrant reorganization of the ER in cells undergoing mitosis, while showing minimal effects on the bulk organization of the actin bundles and cell junctions. Other drugs, such as staurosporine, a broad kinase inhibitor, had major effects on colony and cell morphology, inducing rearrangements in cell packing and shape. It also induced re-localization of desmosomes, indicating that the cell-cell junctions undergo substantial rearrangement. By building complete combinations of image-based observations of many structures/lines in the presence of a large number of standardized biochemical perturbations, we aim to generate a comprehensive database of drug signatures on hiPSC cells in their normal, pathological and regenerative (developmental) states.

Label-free ptychographic imaging reveals a role for VGSV-mediated membrane potential depolarisation in enhancing the migratory capability of breast cancer cells.
R. Suman1,2, M. Yang1, A. Glen1, W. Brackenbury1;
1Department of Biology, University of York, York, United Kingdom, 2Biological Applications, Phasefocus Ltd, Sheffield, United Kingdom

Breast cancer is the most common cancer in women worldwide and in ~30% incidences becomes metastatic and incurable. In numerous cancer cell types, the migratory and invasive capabilities required for metastasis have been reported to be linked to the expression of functional voltage-gated sodium
channels (VGSCs). Although previous reports have highlighted that cancerous cells exhibit a more depolarised resting membrane potential (Vm) than somatic cells, no evidence exists that attributes this phenomenon to the pro-migratory action of VGSCs. Here, we utilised timelapse Ptychographic microscopy to study the role of VGVSV-mediated Vm depolarisation upon the migration of MDA-MB-321 breast cancer cells via a scratch wound assay. Ptychographic microscopy is a label-free imaging technique that retrieves the phase of light in order to yield high-contrast images of cells that are amenable to automated segmentation. The quantitative nature of the image enables changes in the cell volume of the population to be monitored, which provides an inbuilt measure of proliferation in the assay. After performing the scratch, cells were imaged for 16h in the presence of one of two drugs that hyperpolarise the Vm in distinct ways: (i) tetrodotoxin (TTX), which blocks VGSCs; (ii) NS-1619, which causes hyperpolarisation without altering the native conductance or intracellular concentration of sodium. Analysis of Ptychographic images revealed that TTX and NS-1619 treatments result in significantly longer half-times for wound closure compared to untreated control cells. No significant difference was found in the rate of change in the normalised cell volume of the population. This demonstrated that the rate of cell proliferation was unaffected by addition of the drugs; a finding that was supported by a traditional MTT assay. When considered together, these results show that TTX and NS-1619 act to reduce the migration of breast cancer cells by means of Vm hyperpolarisation. Finally, a matrigel invasion assay was performed, which showed a significant reduction in cell invasion upon treatment with TTX but not with NS-1619. This implies that Vm depolarisation is not the cause of enhanced cell invasion in vitro. Overall, cell migration and proliferation metrics extracted from images acquired by Ptychographic timelapse microscopy proved to be powerful aids in determining that the high level of motility in breast cancer cells is caused by the constitutive action of VGSCs that maintain a Vm depolarisation.

Rapid inactivation of RNaseA by high irradiance UV LEDs.
T.L. Thompson1, J. Pasquantonio1, G. Eliason1;
1Phoseon Technology, Hillsboro, OR

While it has long been known that UV can inactivate enzymes (1), inactivation of RNase is an ongoing challenge for sequencing and other studies reliant upon RNA. A further challenge is the timely inactivation of RNase on laboratory equipment and surfaces. The majority of inactivation strategies require significant investment of time that could be better spent gathering data. UVLED sources can deliver higher directed radiant power than standard mercury lamps. In this study, we constructed an adjustable high intensity 275nm UVLED source and used it to expose RNaseA contaminated dry surfaces (1 µl 0.02 U/ml RNaseA) from a distance of 25 mm. The RNaseA sample was recovered from each surface in RNase free water and the suspension fluorometrically assayed for RNase activity (RNaseAlert IDT). Samples were exposed to 275 nm UVLED for various times and at different irradiances. RNaseA was totally inactivated (as compared to a negative control) with a 3 minute exposure to an irradiance of 38.5 mW/cm² at the exposed surface for a total dose of 6.94 J/cm² . Unexpectedly the same total dose at a lower irradiance 18.74 mW/cm² did not inactivate the enzyme to the same extent. Instead a total dose of 22.49 J/cm² delivered over 20 minutes was required to reach negative control levels of enzymatic activity. Further, when the irradiance of the UV LED source was varied from X mW/cm² to Y mW/cm² for a set 5 min exposure time at a fixed distance from the source, the relationship between decreasing enzyme activity and increasing irradiance was nonlinear. This is consistent with numerous studies of bio-inactivation of enzymes and microorganisms (2) that are logarithmic. We conclude that
high irradiance UVLED sources can provide faster, more complete control of enzymatic activity in such a way that is impractical with lower-intensity UV sources.

Cold plasma eradication of Escherichia coli and Staphylococcus aureus biofilms.
N. Zhao¹, L. Nguyen¹, C. Toorkey¹, K. Fitzgerald¹, N. Hickok¹, T. Freeman¹;
¹Orthopaedic Research, Thomas Jefferson University, Philadelphia, PA

Introduction: Screws, rods and implants made of titanium are commonly used in orthopaedic surgeries and are a favorable target for bacterial colonization and biofilm formation. Bacteria in biofilms are relatively impermeable to both antibiotics and the body’s immune system. To compound the problem, the global crisis of antibiotic resistance makes infections even harder to treat; thus other solutions must be found. High-energy electrons produced within cold plasma discharges generate Reactive Oxygen and Nitrogen Species (ROS, RNS) that have antimicrobial effects by means of cell membrane leakage and DNA damage. Our goal was to test the effectiveness of cold plasma treatment on killing Gram (+) and (-) bacteria and biofilms. Methods: Escherichia coli or Staphylococcus aureus biofilms were formed on 5mm2 pieces of titanium metal before direct treatment with cold plasma of various conditions (power, gas flow, time). Indirect treatment, (saline or water treated by cold plasma then placed on the biofilm) or combinations of direct and indirect treatments were also tested. A crystal violet solution (600 ppm) was tested as a pretreatment of S. aureus. Results: Direct cold plasma treatment was applied to both E. coli and S. aureus at 24 Watts (W) and 28W of power, with a He gas flow of 5L/s for 30 sec. At 24W, E. coli showed greater susceptibility with a 103-fold decrease in the number of colony forming units per mL (CFU/mL), while S. aureus only decreased 102 fold. To determine if a crystal violet (600 ppm) solution would attract the cold plasma to the S. aureus cell wall, the titanium biofilm was applied for 1 min before the plasma treatment. This resulted in a 104 fold reduction of S. aureus, presumably due to cell wall disruption. At 28W, both Gram (+) and (-) bacteria were reduced by 104. Direct treatment of 40W at 5L/s for 10 sec, also consistently reduced both by 104 fold. Indirect treatment using plasma treated saline for 1 min had little or no effect, a 5 min treatment showed a 102 fold reduction; and 20 min session showed a 103 fold reduction. Plasma treated water for 1 min decreased bacterial levels 102 fold. Complete eradication of biofilms of both species was observed when a combination of direct and indirect treatments was tested. Conclusion: We have taken the first steps towards developing a simple and effective antibiotic-free treatment protocol to eradicate both Gram (+) and (-) bacteria in biofilms. While the cell wall provides greater protection of S. aureus from direct cold plasma treatment, higher power or the combined direct and indirect treatment eradicates both bacterial populations (at least 105 fold). Individual treatment with either cold plasma, saline, or distilled water is insufficient for complete eradication.

Phage assisted continuous evolution (PACE) is a powerful tool for in vivo directed evolution.
S.S. Bent\textsuperscript{1}, I.G. Cuellar\textsuperscript{1}, F.C. Enriquez\textsuperscript{1}, M.O. Hunter\textsuperscript{1}, H.S. Sinks\textsuperscript{2}, A. Tutar\textsuperscript{3}, S.R. Bilby\textsuperscript{3}, L.D. Doolan\textsuperscript{3}, C.C. Mackley\textsuperscript{3}, C. Watson\textsuperscript{3}, J. Poet\textsuperscript{4}, T.T. Eckdahl\textsuperscript{3}, L.J. Heyer\textsuperscript{3}, A.M. Campbell\textsuperscript{1};
\textsuperscript{1}Biology, Davidson College, Davidson, NC, \textsuperscript{2}Mathematics and Computer Science, Davidson College, Davidson, NC, \textsuperscript{3}Biology, Missouri Western State University, St. Joseph, MO, \textsuperscript{4}Computer Science, Mathematics and Physics, Missouri Western State University, St. Joseph, MO

PACE allows investigators to use directed evolution in vivo to identify new DNA sequences that encode modified proteins with a desired new function. PACE was first developed by the David Liu laboratory at Harvard University. PACE uses both positive and negative selection of filamentous phage M13 that infect \textit{E. coli}. A chemostat is used to direct mutations to phage populations instead of \textit{E. coli} host cells. Undergraduates from Davidson College and Missouri Western State University adapted PACE to evolve new riboswitches that respond to xanthine instead of theophylline. We began with two well-studied theophylline riboswitches that regulate protein production by controlling transcription or translation. We inserted each riboswitch into a modified M13 genome between the \textit{gene III} promoter and an exogenous T7 RNA polymerase (RNAP) gene that replaced the endogenous \textit{gene III}. A plasmid in \textit{E. coli} carried the essential \textit{gene III} downstream of a T7 promoter. Protein III is required for phage release from, and infection of, host cells. Students performed positive and negative selection during PACE to isolate mutated riboswitches. After PACE with the translational theophylline riboswitch, a variant that had a seven base pair deletion in the aptamer domain dominated the phage population. This variant was tested to ascertain the effect of the mutation on riboswitch function. Populations of new riboswitches taken from different M13 samples after PACE were subjected to next generation sequencing to obtain a library of variants that had evolved over the course of PACE. The populations will be tested further to determine if a xanthine specific riboswitch evolved through PACE. Our results support the claim that cell biologists can use PACE to direct the evolution of a wide variety of RNA, DNA, and protein sequences.

Nano-Channel Electroporation System for Protein Delivery into Single Cells.
J. Hwang\textsuperscript{1}, C. Yun\textsuperscript{1}, M. Kim\textsuperscript{1}, C. Park\textsuperscript{1}, Y. Choi\textsuperscript{1};
\textsuperscript{1}Biotechnology, CHA university, Seongnam-si, South Korea

Proteins as receptors, kinases, and transcription factors are biomolecules that are particularly important for most cell signaling pathways. However, intracellular protein transfer is difficult due to its polarity and high molecular weight. We have developed a dose-controllable nanotube electroporation system consisting of PDMS (polydimethylsiloxane) and glass to accurately deliver the desired protein to mammalian single cells. A three-dimensional microfluidic channel was created using a femtosecond laser for the glass material and connected to the PDMS channel (called a Nanoinjector). We injected red fluorescent protein (RFP) into a single cell using a Nanoinjector. By controlling the duration of the electrical pulse of the Nanoinjector, we were able to control the amount of RFP injected into the cell. In addition, the protein-injected cells remained healthy. In the future, it will be possible to use the Nanoinjector to transform cells without using a viral vector or to inject macromolecular substances into cells.

Synthetic biocompatible hydrogels with user-defined spatiotemporal control to easily create structured cellular microenviroenvironments.
A.M. Dang\textsuperscript{1}, R.M. Gilbert\textsuperscript{2}, J.P. Gleghorn\textsuperscript{2};
\textsuperscript{1}Chemistry Biochemistry, University of Delaware, Newark, DE; \textsuperscript{2}Biomedical Engineering, University of Delaware, Newark, DE

Much progress has been made in the past few decades to understand how the local three-dimensional cellular microenvironment regulates cell phenotype and behavior. Recently, more complex heterogeneous hydrogel material platforms have been coupled with microfabrication tools and techniques to create structured cellular environments. These are then used to investigate cellular interactions within and between different cell populations in response to well-defined physical or chemical cues. However, these material platforms and technologies are complex, difficult to create, and limited to few research labs with the skills to develop such tools. To overcome these challenges, we have chemically modified naturally derived polysaccharides to produce a hydrogel that is shear thinning and self-healing to more easily generate structured cellular microenvironments. Alginic acid and chitosan were chemically modified using “Click” chemistry to generate copolymer hydrogel backbones with dynamic covalent cross-linking sites. The cross-linking site density was modified by adjusting the concentration of dynamic Schiff base participants to tune the stiffness and permeability of our hydrogel. To prove cytocompatibility in our hydrogel, NIH 3T3 fibroblasts were encapsulated and cultured for 24 hours within the hydrogel, and cell viability was confirmed with Live/Dead assay. We created structured microenvironments by dissecting hydrogels encapsulated with different cell populations. These dissected blocks were stacked in various geometries and the self-healing property of the hydrogel healed the cut interfaces when incubated for 40 minutes at 37°C. The result was a single hydrogel consisting of different cell populations in defined spatial orientations. With the addition of a series of orthogonal photoresponsive “Click” chemical reactions to our crosslinking moiety, we are able to create a hydrogel suitable for 3D cell culture that permits user-defined spatiotemporal control over hydrogel stiffness. This system can be integrated with microfabrication technologies to create intricate, heterogeneous hydrogel networks and complex hierarchical tissue constructs. Additionally, our biomimetic model can serve as a more sophisticated tool than current systems to elucidate the impact of various environmental cues on cellular processes, and produce more physiologically relevant \textit{in vitro} data.

Single cell RNA sequencing of zebrafish intestines reveals enhanced inflammatory signatures in chemically-induced intestinal injury.
S. Nayar\textsuperscript{1}, L. Chuang\textsuperscript{1}, P. Labrias\textsuperscript{1}, N. Hsu\textsuperscript{1}, M. Giri \textsuperscript{1}, J. Cho \textsuperscript{1};
\textsuperscript{1}Genetics and Genomics, Icahn School of Medicine at Mount Sinai, New York, NY

The current research in Inflammatory Bowel Disease (IBD) modeling has been primarily performed using the mouse system. However, mammalian systems have limited capacities to trace bacterial infection, host-cell migration, and cell biology in real-time. For these reasons, we have established a robust and cell-type specific \textit{in vivo} zebrafish model to study intestinal cellular function during inflammation in real-time. Zebrafish embryos are translucent, allowing for easy visualization of host-pathogen interactions. Additionally, they produce large clutch sizes, and many zebrafish mutant phenotypes are reminiscent of
human disease states. Specifically, utilization of the zebrafish embryo system provides the power to assess changes of the innate immune system during disease, as the zebrafish possesses exclusively innate immunity before 21 days post fertilization (dpf). It has been suggested that the interplay between host-pathogen interactions during IBD largely involves innate immune mechanisms. Using previously reported doses of dextran sodium sulfate (DSS) (Oehler et al., 2012), we established a single injury-induced model of inflammation in the zebrafish embryo. We recapitulated the shortened intestine length observed in mice in the DSS-treated fish, and also showed impaired lysosomal function in these injured embryos. However, to understand cell-type specific changes in the intestine under inflammation, in conjunction with the model established above, we show here for the first time the ability to dissect zebrafish embryonic intestines to profile baseline and inflammatory single cell transcriptomes. Embryonic intestines from wildtype and DSS-induced inflamed fish were dissected, pooled and processed to obtain single cell suspensions. We performed live and dead cell counts with Propidium Iodide, via flow cytometry analysis, which revealed 2.5 x 10^5 live single cells. Ten thousand cells per sample were processed for library preparation and single cell RNA sequencing, with an estimated targeted cell recovery of five thousand. 300 million reads were obtained from five samples, where 83% of reads were above the Q30 score. We compared our previous human single cell RNA sequencing profiles, obtained from involved and uninvolved intestinal resections, to zebrafish embryonic intestine profiles, and found gene signatures specific to the uninflamed and inflamed profiles in both organisms. We can now extend this intestine-specific single cell RNA sequencing in the zebrafish to uncover more signatures in the inflamed context, particularly those involved in innate immunity. This will aim to uncover previously unidentified cell types, molecular players and pathways that are important in understanding host-pathogen interactions during IBD-associated inflammation.

Comparison of osteogenic differentiation supported by silk fibroin films derived from various silkworms for potential bone defect treatment.
M. Dittmar1, J.A. Klavens1, D.J. Gigliotti1, F. Giginis1, A. Wellik2, D. Jao3, Y. Xue3, X. Hu4, C. Iftode5; 1Biological Sciences, Rowan University, Glassboro, NJ, 2Chemistry and Biochemistry, Rowan University, Glassboro, NJ, 3Biomedical Engineering, Rowan University, Glassboro, NJ, 4Physics and Astronomy, Rowan University, Glassboro, NJ, 5Molecular and Cellular Biosciences, Rowan University, Glassboro, NJ

Protein-based biomaterials are particularly useful in the biomedical field due to their unique, tunable physical properties that can be applied to numerous applications, such as in tissue regeneration and for drug delivery. Silkworm silk, which is derived from the worms’ cocoons and is composed primarily of sericin and fibroin, is an attractive biomaterial due to its versatility and mechanical stability. Specifically, we are interested in the potential of thin films composed of fibroin derived from these silks to be used as substrates for adipose-derived mesenchymal stem cells (AD-MSCs) used to treat bone defects via tissue regeneration. In many applications, these thin films are produced in water-based solutions to preserve their biocompatibility. However, the present water-based fabrication methods are time-consuming and expensive because of the silk proteins’ low solubility in water. We have developed a rapid and cost-effective new fabrication method using a formic acid-based solution to dissolve the protein. In our previous work, five silkworm cocoon-derived silks (Mori, Thai, Muga, Eri, and Tussah) and one corn protein (Zein) produced with this method were tested for cytompatibility via qualitative (Live/Dead staining) and quantitative (alamarBlue) viability assays with AD-MSCs. The Thai, Tussah, and Muga silks were found to support cell viability over 14 days and further assessed for their ability to support AD-MSC differentiation into osteocytes in order to potentially treat bone defects. AD-MSCs
were cultured both with complete osteogenic differentiation medium containing mesenchymal stem cell osteogenic differentiation supplement (MODS), to induce osteogenic differentiation, and with differentiation medium that lacked MODS, to serve as an undifferentiated control. After 20 days, osteogenic differentiation was confirmed for Tussah and Thai through positive staining with Alizarin Red S. Due to nonspecific staining with Alizarin Red S, successful differentiation for Muga could not be established conclusively. To verify that gene expression was consistent with the osteocyte phenotype, we conducted RT-PCR with ALPL, ON, Runx-2, and ZBTB16 used as gene markers for successful osteogenic differentiation. We can conclude from RT-PCR alone that the cultures induced to differentiate to osteocytes for all three silks clearly showed a much greater level of expression of ZBTB16 than the control. The levels of expression for the other markers were only slightly higher, so we are currently reconfirming our successful differentiation with RT-qPCR. Our future work includes further confirmation of successful differentiation with immunohistochemical studies targeting the products of our selected gene markers.

**3D culture of human iPSCs using Vitrogel 3D.**  
J. Huang¹, P. Rajanahalli²;  
¹The Well Bioscience, LLC, Newark, NJ, ²Pathology, University of Florida, Gainesville, FL

Recently, human induced pluripotent stem cells (hiPSCs) has gained tremendous interest for its use in drug discovery, regenerative medicine, basic sciences and most importantly in disease modelling and clinical trials (like diabetes, ALS, autism, retinoblastoma, cardiomyopathies and retinal degeneration). Human iPSCs cultured in 2D has been promising, but missing a plethora of details including morphology in 3D, cell-cell contact and interaction, polarity and size. In order to better understand the disease state as is, it is of best interest to grow hiPSCs in a well-defined and simple 3D culture system. Here we show that Vitrogel 3D® provides an adequate environment to grow hiPSCs in 3D. These cells were positive for alkaline phosphatase and stem cell regulatory factors Oct4, Nanog, SOX2, SSEA3 and SSEA4. The cells differentiated into all 3 germ layers of the body (ectoderm, endoderm and mesoderm). The cells were positive for Nestin (ectoderm marker), Sox17 (endoderm marker) and Brachyury (mesoderm marker). Further studies pertaining to gene expression changes due to 3D architecture, methylation status and histone modifications of important stem cell regulatory genes will be explored. The Vitrogel 3D system can be easily utilized for 3D cultures of hiPSCs.

**Predicting the Mechanical Response of DNA Origami Structures of Different Nick Stiffness.**  
T.T. Walker¹, O. Samuel-Ojo¹, S. Gaitanaros¹, Y. Chen¹;  
¹Mechanical Engineering, Johns Hopkins University, Baltimore, MD

Although the techniques of DNA origami have been applied to build nano-sized structures of a variety of geometries, ranging from rectangular boxes intended for drug delivery to robots capable of dynamic displacement, the mechanical properties of the DNA origami structures have not been carefully studied, making it difficult to predict their long-term functionality, especially in vivo. As a first step to gain insight of the mechanics of DNA origami, we aimed to understand how placement of nicks and Holliday Junctions in the DNA origami structure affect its stiffness and tensile strength in silico. Nicks, areas where one staple strand ends and another begins, and Holliday Junctions, areas on the design where a
staple strand extends from one double-helix bundle to another, introduce discontinuity thus uncertainty into origami amidst the intact double strand DNA, whose mechanical properties have been extensively examined.

CADnano software was used to designed DNA origami structures. Three sets of DNA origami structures in the shape of beams were designed in sequence. The first set of beam structures were 74 base-pairs in length and had varying cross sections of 6, 8, 10, and 12 DNA double-helix bundles. The second set of six double-helix beam structures with varying lengths (74 base pairs and 139 base pairs) were created to test for a scaling attribute. The third set of structures were created, of the same six double-helix cross section with different nick stiffness, were created, to test the effect of nick stiffness. We then simulate the process of applying stretching forces to the DNA origami structure with one end fixed using ADINA where strain responses during the pulling process were recorded. We found that DNA origami structure exhibited strain response ranging from 0.0045 to 0.022, depending on the, the number of nicks introduced, the magnitude steps and the nick stiffness, when a stretching force of 30 pN is applied. Our results departed from the conventional theoretical prediction and may explain the discrepancy between theoretical values and experimental data reported previously.

²Department of Biological Science and Technology, National Chiao Tung University, Hsinchu, Taiwan,
³Institute of Bioinformatics and Systems Biology, National Chiao Tung University, Hsinchu, Taiwan

Peripheral nerve injury is a common medical problem that can have devastating consequences to a patient’s life. The standard therapy for severe peripheral nerve injury is to bridge the injury site with an autograft. However, several drawbacks limit the use of nerve autografts. First, the requirement for an additional surgery to harvest nerve from the donor site may cause the loss of function at donor site. Second, the diameter or the fascicular arrangement of the nerve autograft may not match that of the injured nerve. Third, the use of autografts can sometimes lead to infection or formation of painful neuroma. For these reasons, nerve guidance conduits (NGCs) have become increasingly popular for treating patients with peripheral nerve injuries. However, most of the existing commercialized NGCs lack a scaffold to guide the outgrowth of the regenerating nerves. To address this problem, we aimed to establish a platform that can facilitate axon regeneration and guidance. We have successfully generated submicrometer-sized grooves on the surface of a biocompatible polymer using thermoplastic nanoimprint lithography (T-NIL) technology. We found that neurons from both the central nervous system (cortical neurons) and peripheral nervous system (dorsal root ganglion neurons) were able to survive on the grooved surface. Additionally, we observed that the growing direction of axons strikingly followed the submicrometer-sized grooves. We also discovered that by controlling the stiffness and the width of the grooves, this surface topology could specifically guide the axons, but not the dendrites. This specific guiding property may serve as a potential barrier to discourage the influx of unwanted non-neuronal cells into the NGC. In addition, we observed that neurons grown on the grooved surface are capable of regeneration after injury. And the grooved surface enhances the longitudinal growth of the regenerating axons compared to the flat surface. Together, our data demonstrate that the nanoimprinted submicrometer-sized grooves have a potential to guide and promote the regenerating axons.

Pharmaco-genetic toolsets for cell-specific subcellular cGMP and calcium manipulation in vivo.
O. Ros¹, K. Loulier¹, S. Ribes¹, S. Couvet¹, Y. Zagar¹, D. Ladarré², Z. Lenkei², X. Nicol³;
¹Vision Institute, Sorbonne Universités, CNRS, Inserm, Paris, France, ²Brain Plasticity Unit, PSL Research University, ESPCI, CNRS, Paris, France

Second messengers are mid-point relays in signaling cascades governing a wide range of cellular functions. Calcium is central in multiple cellular responses ranging from metabolism and survival to vesicle release and motility. The blockade of calcium signals currently relies on pharmacological strategies to block calcium influx into the cell or chelate extracellular or intracellular calcium. Since calcium is crucial for a wide range of signaling pathways and for the function of a wide range of components of the extracellular matrix, those strategies lack cellular specificity and are plagued with a variety of side effects when applied to patients. Similarly, cGMP is involved in a wide range of signaling pathways and cellular processes including neurotransmission, calcium homeostasis, phototransduction, lipid metabolism and cation channel activity. The diversity of these processes suggests that cGMP signals are tightly controlled in space and time to achieve specific modulation of its downstream pathways. However, manipulating cGMP is mostly achieved using pharmacological approaches either altering the synthesis or degradation of this cyclic nucleotide or manipulating downstream signaling pathways. These techniques lack both cellular and subcellular specificity.

We have developed a pair of genetically-encoded buffers that alter physiological changes in the concentration of cGMP and calcium respectively. These tools enable disrupting signaling cascades with cellular and subcellular resolution. We provide evidence that the cGMP and calcium scavengers, both in soluble form and targeted to the lipid raft or non-lipid raft compartments of the plasma membrane, are able to locally buffer changes in the respective second messenger concentration and to alter downstream cellular processes including axon pathfinding events. When in utero electroporated in the developing brain, the cGMP and calcium buffers interfere with the migration of newly generated cortical neurons in vivo and highlights a non-cell autonomous impact of second messenger manipulation. These genetically-encoded cGMP and calcium scavengers paves the way to investigate subcellularly-localized signaling in vivo, combined with cellular resolution and to directly manipulate these second messengers for therapeutic use.

Matrix remodeling and stress relaxation are impaired in vascular smooth muscle from Acta2-/- mice.
M.P. Masset¹, H. Gibbs², S. Padgham³, H. Sreenivasappa³, J. Chen⁴, A. Yeh³, D.M. Milewicz⁴, A. Trache²³;¹Department of Health and Kinesiology, Texas AM University, College Station, TX, ²Department of Biomedical Engineering, Texas AM University, College Station, TX, ³Department of Medical Physiology, Texas AM University Health Science Center, College Station, TX, ⁴Department of Internal Medicine, University of Texas Health Science Center at Houston, Houston, TX

Mutations in genes that encode the contractile proteins in vascular smooth muscle (VSM) cells causing an abnormal smooth muscle behavior have been found in thoracic aneurysm and aortic dissection.

Monday-36
(TAAD) patients. Missense mutations in ACTA2, the gene encoding smooth muscle α-actin (SMα-actin), increase susceptibility to TAAD in humans resulting from a dominant negative effect on SMα-actin filament formation. Our study investigates how dysregulation of SMα-actin affects VSM contractility in cells and aortic rings isolated from Acta2/- mice, an animal model used to study TAAD. Cells and tissue from wild-type (wt) littermates were used as control. To determine how disruption of SMα-actin affects cytoskeletal tension development, two different contractility assays in a 3D collagen matrix were performed. Acta2/- or wt cells in suspension were dispersed within rat tail collagen I gel before polymerization and attachment to 24-well plates. After 48 hours, collagen pellets were released and pellet diameter was measured over a 48-hr period, or discrete collagen fiber remodeling around the embedded cells was measured by second harmonic generation (SHG) non-linear microscopy. Results showed that collagen pellets containing Acta2/- cells contracted 2-fold less than the pellets containing the wt cells. In addition, SHG imaging revealed that Acta2/- cells remodeled the collagen matrix fibers to a lesser extent than wt cells. To determine the mechanical properties of the aorta, stress relaxation was assessed in thoracic aortic rings from Acta2/- and wt mice using a wire myograph. Aortic rings were stretched in 4 mN increments until an estimated transmural pressure of 100 mmHg was attained. Stress relaxation was measured as the magnitude of decrease in force from peak force to equilibrium after 60 sec. Piece-wise fitting of stress relaxation curves suggested two functional regimes. Significantly lower stress relaxation was recorded in aortic rings from Acta2/- mice at tensions below 10 mN compared with wt, likely driven by cytoskeletal-dependent contractility. However, no significant differences were recorded between the two animal groups above the 10mN threshold, since at higher tension the matrix-dependent contractility may be predominant. In addition, our results showed that at any given level of stretch, transmural pressure is lower in aortic rings from Acta2/- mice. Taken together, these results are consistent with Acta2/- mice having lower blood pressure compared with wt littermates and support a reduced contractile phenotype of VSM caused by the dysregulation of SMα-actin function.

“Silent code” regulation: diverse functions of closely related actin isoforms are defined by their nucleotide, rather than their amino acid sequence.
P. Vedula¹, S. Kurosaka¹, N.A. Leu¹, J. Wang¹, A. Kashina¹;
¹Biomedical Sciences, University of Pennsylvania, Philadelphia, PA

β- and γ-cytoplasmic-actin are nearly indistinguishable in their amino acid sequence, but are encoded by different genes that play non-redundant biological roles. The key determinants that drive their functional distinction are unknown. Here we tested the hypothesis that β- and γ-actin functions in vivo are defined by their nucleotide, rather than their amino acid sequence, using targeted editing of the mouse genome. Although previous studies have shown β-actin is essential for cell migration and embryogenesis, we demonstrate here that γ-actin protein expressed by the edited β-actin gene is functionally capable of substituting for β-actin without any significant impact on organism survival. Our data show for the first time that the differences in in vivo functions of β- and γ-actin actin are determined solely by their nucleotide sequence.

The actin cytoskeleton a complex polymer network that gives cells structure and allows them to move and to divide. This network is constantly turning over, with the polymers assembling and disassembling on the time scale of seconds to minutes. In order to control with spatial and temporal resolution the amount of actin polymer, cells use other proteins to nucleate formation of new polymers, including the Arp2/3 complex, which forms branched actin networks, and ENA/VASP, which is involved in the formations of cell protrusions known as filopodia. Actin monomers are large globular proteins with four major domains. Monomers adopt a twisted conformation in solution, and a flat, planar conformation when in a filament. In this work, we will show how the conformational free energy landscape in terms of this macromolecular twist angle can be sampled using metadynamics simulations, and discuss our recent methodological advancements that make this computation tractable. We will then show how the conformational landscape changes when the protein is in a filament, and how this landscape changes when actin is associated with helical peptides known as WH2 domains, involved in nucleation processes such as by Arp2/3 and ENA/VASP. Finally, we will discuss how these molecular level changes might influence the thermodynamics and kinetics of filament assembly.

Characterization of CARMIL-GAP, a Dictyostelium CARMIL isoform harboring a GTPase activating domain for Rac.
G. Jung¹, M. Pan², T. Jin², J.A. Hammer III¹;
¹National Heart,Lung and Blood Institute, National Institutes of Health, Bethesda, MD, ²National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD

CARMILs (Capping protein Arp2/3 Myosin I Linker) are ∼1000 residue, multi-domain scaffold proteins expressed from protozoa to man that have been studied extensively with regard to their ability to bind Capping Protein (CP) and reduce its affinity for the actin filament barbed end. CARMIL proteins also appear to play important roles in signal transduction, as they exhibit genetic and physical interactions with the Rac GEF Trio (Liang et al MBoC 2009; Vanderzalm et al. Dev. 2009), and T cells lacking CARMIL-2 exhibit a profound block in signaling downstream of CD28, the major co-receptor for T cell signaling (Liang et al Nat. Immunol. 2013). In previous work (Jung et al JCB 2001), we showed that Dictyostelium CARMIL binds CP, the Arp2/3 complex and myosin I (through its SH3 domain), and it is required for actin-dependent processes such as chemotaxis and micropinocytosis to be robust. Here we describe initial studies of CARMIL-GAP, a second Dictyostelium CARMIL that contains, in addition to all the normal CARMIL domains (including the CP binding domain), a ∼130 residue insertion that, by homology, is a GTPase activating (GAP) domain for Rho-GTPases. This domain is probably functional given that full length CARMIL-GAP can only be over-expressed if it’s GAP domain contains a point mutation (R737A) that blocks GAP activity in all characterized GAP proteins. Like CARMIL, CARMIL-GAP localizes to actin-rich structures and is expressed in both vegetative and starved, developing cells. Consistently, CARMIL-GAP null cell lines created by homologous recombination exhibit pronounced defects in several actin...
based processes, including phagocytosis, motility and chemotactic aggregation. Current efforts are directed at rescuing KO cells with versions of CARMIL-GAP mutated in different domains to identify key functions, and at identifying the Rac isoform(s) regulated by CARMIL-GAP.

The Drosophila Cortactin Binding Protein 2 (CTTNBP2/CTTNBP2NL) homolog, Nausicaa, regulates actin dynamics in a Cortactin-dependent manner.
M.E. O'Connell¹,², D. Sridharan³, T. Driscoll⁴, I. Krishnamurthy⁵, W.G. Perry⁶, D.A. Applewhite⁷;
¹Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ²Biology, Reed College, Portland, OR, ³Biology, Boston College, Chestnut Hill, MA, ⁴Cardiovascular Medicine, Yale University, New Haven, CT

Drosophila CG10915 is a previously uncharacterized protein coding gene with sequence similarity to human Cortactin Binding Protein 2 (CTTNBP2), a protein that interacts with both actin and microtubules for proper dendritic spine development, and Cortactin Binding Protein 2 N-terminal like (CTTNBP2NL), which redistributes Cortactin to actin stress fibers in epithelial cells. Here we have named this gene Nausicca (naus) and characterize it through a combination of quantitative live-cell TIRF microscopy, RNAi depletion, and genetics. We found that Naus co-localizes with F-actin and Cortactin in the lamellipodia of Drosophila S2R+ and D25c2 cells and this lamellipodial localization is lost following Cortactin or Arp2/3 depletion or by mutations that disrupt a conserved proline patch found in its mammalian homologs. Using Permeabilization Activated Reduction in Fluorescence (PARF) and FRAP, we find that depletion of Cortactin alters Naus dynamics leading to a decrease in the half-life of Naus in the lamellipodia by 2.1-fold and 2.2-fold, respectively. This demonstrates that appropriate localization and dynamics of Naus are regulated by interactions with Cortactin. Remarkably, we also discovered that when Naus is depleted in S2R+ cells, lamellipodial actin density increases 1.5-fold and retrograde flow speeds decrease 1.4-fold as compared to controls. In addition to these alterations to actin dynamics, Naus depletion led to a decrease in the fluorescence half-life of Cortactin by 1.3-fold, suggesting that Naus also acts to regulate Cortactin’s dynamics. Further, Naus depletion in a Drosophila imaginal disc-derived cell line, D25c2, led to decreases in migration and directionality suggesting these changes in actin dynamics also translate to changes in cell migration. Finally, we used Naus RNAi in Drosophila 3rd instar larvae neurons and observed a decreased arborization and branch length similarly to what was reported for Naus’ mammalian homolog CTTNBP2. Our results point to a possible mechanism where Naus regulates lamellipodial actin dynamics through interactions with Cortactin. We hypothesize that Naus decreases Cortactin’s off-rate possibly leading to precocious activation of the Arp2/3, increased branch nucleation, and a corresponding alteration of actin dynamics.

Mutation of arrd-15, a gene encoding an alpha-arrestin, suppresses actin disorganization phenotypes in unc-78 AIP1 mutants in C. elegans.
K. Ono¹, S. Iwase¹, Z. Qin², D.L. Baillie³, S. Ono¹;
¹Pathology, Emory University, Atlanta, GA, ²Molecular Biology and Biochemistry, Simon Fraser University, Burnaby, BC

Actin depolymerizing factor (ADF)/cofilin and actin-interacting protein 1 (AIP1) promote disassembly of actin filaments and play important roles in dynamic reorganization of actin cytoskeleton. AIP1
specifically targets ADF/cofilin-bound actin filaments to enhance filament severing. However, regulatory mechanisms for this reaction are poorly understood. To identify a gene that may be involved in the regulation of AIP1, we analyzed an extragenic suppressor of AIP1 mutants in the nematode C. elegans. The C. elegans unc-78 gene encodes AIP1, and unc-78 mutant worms have disorganized muscle actin filaments and move much slower than wild-type. Previously, Francis and Waterston screened for a suppressor mutant for unc-78 and isolated sup-13 (Waterston, 1988). The unc-78;sup-13 double mutants show nearly normal worm motility and have a normal appearance of sarcomeric actin filaments. The sup-13 single mutants were superficially indistinguishable from wild-type animals. Using whole genome sequencing, we identified that sup-13 is an allele of arrd-15, which encodes a previously uncharacterized arrestin-domain-containing protein (also known as a-arrestin). The arrd-15 gene contains three alternative first exons, and at least one of them was expressed in the body wall muscle as determined by a promoter-reporter analysis. In the body wall muscle, green fluorescent protein (GFP)-tagged ARRD-15 partially colocalized with vinculin and alpha-actin at the dense bodies. C. elegans has another AIP1 gene aipl-1, which is partially redundant with unc-78. Depletion of both unc-78 and aipl-1 caused embryonic lethality. However, the sup-13/arrd-15 mutation did not suppress the lethality in unc-78;aipl-1 depleted worms, suggesting that aipl-1 is required for the suppressor phenotype. The data suggest that ARRD-15/SUP-13 may be a novel regulator of AIP1-dependent actin dynamics.

The tropomyosin isoform composition of cellular actin filaments is not a simple function of relative isoform abundance.
J.C. Meiring\(^1\), N.S. Bryce\(^1\), J.H. Stear\(^1\), E.C. Hardeman\(^1\), P.W. Gunning\(^1\);
\(^1\)School of Medical Sciences, University of New South Wales, Sydney, Australia

The actin cytoskeleton of animals and fungi contains a mixture of filaments composed of actin alone and those which are a co-polymer of actin and tropomyosin (Tpm). We have determined the absolute amounts of individual Tpm isoforms and total actin in human fibroblasts representative of 3 types of culture cells - primary, immortal and transformed. We found that all 3 cell types contain more than sufficient total Tpm to saturate every actin filament. To determine whether Tpm isoform level reflects actin filament engagement, we sub-fractionated the cells into soluble (actin filament-free) and insoluble (actin filament-associated) fractions and measured the absolute levels of Tpm isoforms and actin in each fraction. The Tpm isoforms fell into two groups in all 3 cell lines. The high molecular weight (HMW) Tpms 1.6, 1.7, 2.1 and 4.1 were primarily found in the insoluble fraction (65-85% insoluble) whereas the low molecular weight (LMW) isoforms Tpms 1.8, 1.9, 3.1/3.2 and 4.2, were primarily found in the soluble fraction (70-80% soluble). This preferential partitioning of HMW Tpms into the actin filament-containing fraction provides an explanation of how cells accommodate an excess of Tpm, viz., HMW Tpms are selectively chosen to interact with actin filaments. Furthermore, we discovered that HMW Tpms not associated with actin filaments are susceptible to degradation by the proteasome. Disruption of actin organisation with Latrunculin A led to almost complete transfer of Tpms into the soluble pool and a substantial decrease in the levels of HMW, but not LMW Tpms. The reduction in HMW Tpm levels is blocked by the proteasome inhibitor MG132. We conclude that the Tpm isoform composition of actin filaments in cells is not a simple function of relative isoform abundance and that the class of Tpm isoform, HMW vs LMW, determines its association with actin filaments as well as ability to exist in a soluble pool.

Regulatory elements within the C-terminus of human cardiac troponin T.
D. Johnson¹, J.M. Chalovich²;
¹Biochemistry Molecular Biol., Brody School of Medicine at East Carolina University, Greenville, NC

Striated muscle contraction requires actin activation of myosin ATPase activity. Actin stimulates the rate of ATP hydrolysis by roughly 100-fold. Tropomyosin binding to actin lowers the ATPase activity to about 60% of the value with actin alone. Tropomyosin binds along the length of actin filaments and can occupy several positions relative to the surface of actin. One position is favorable for stimulation of ATPase activity (M state) and two others inhibit actin activation of ATPase activity (C and B states). In the absence of other effectors, tropomyosin is in rapid equilibrium between the M and C states. The addition of troponin at low calcium concentrations reduces the ATPase rate greatly as the B state is stabilized and the M state is greatly diminished. Calcium binding to troponin increases the ATPase rate but only to about the level seen with actin-tropomyosin. The addition of rigor type myosin (i.e. NEM modified myosin S1) increases the rate to about 6x that seen with actin alone. That condition gives full stabilization of the M state.

Mutations in cardiac troponin can change the calcium dependent distribution of actin states and can lead to cardiac dysfunction. Our lab previously showed that deletion of the last 14 residues of the C-terminus of troponin T (a hypertrophic cardiomyopathy mutation) eliminates the inactive B state at low calcium and increases the population of the active M state at high calcium relative to wild type troponin. The C-terminus of troponin T is therefore an important regulatory element.

We estimated changes in the distribution of actin states at low and high calcium as different segments of the C-terminus of troponin T were truncated. Those studies resolved the C-terminus of troponin T into three regions. Changes in the inactive B state at low calcium were measured using acrylodan labeled tropomyosin fluorescence. The amplitude of the signal following rapid ATP-induced dissociation of myosin S1 from regulated actin was proportional to the amount of the inactive B state. Changes in the B state were associated with truncations between residues 275-278 and 285-288 of troponin T. Changes in the active M state at saturating calcium were estimated by measuring ATPase rates relative to rates obtained with full stabilization of the M state. Residues 275-278 of Troponin T were primarily responsible for destabilizing the active state. The region 275-278 is common to both activities and the region 279-284 has little effect on either activity. The difference in residues required for each activity suggest that the C-terminal region of troponin T has different interaction partners at low and high calcium concentrations.

E-cadherin regulates cell-cell adhesion and tissue sorting by spatially regulating contractile actin filament assembly and activity.
J.L. Davis¹, L. Cruz³, E.M. Bonder¹, A.J. Rodriguez¹;
¹Biological Sciences, Rutgers University-Newark, Newark, NJ

Recent work has identified an important function for E-cadherin as a tension-sensitive mechano-sensor in epithelial tissues. Specifically, E-cadherin directs actin filament assembly by locally activating formin, a linear actin filament assembly factor, at cell-cell contact sites in response to tension. Additionally, E-cadherin also locally activates myosin II motor protein activity at cell-cell contact sites in response to tension. Together, these activities drive the assembly and activation of contractile actin filaments.
required for adherens junction assembly. Interestingly, using E-cadherin knockdown and function blocking antibodies, we found E-cadherin expression and homophilic binding function are also required to specify cell-cell contact localized β-actin monomer synthesis. Importantly, we found the E-cadherin dose-dependent reduction in cell-cell contact localized β-actin monomer synthesis correlates with reduced adherens junction assembly. Moreover, we found the E-cadherin dose-dependent reduction in cell-cell contact localized β-actin monomer synthesis inversely correlates with tissue permeability. Mechanistically, β-actin monomer synthesis sites are specified by reversible mRNA/Zipcode Binding Protein-1 (ZBP1) interactions. The E-cadherin dose dependent reduction in cell-cell adhesion generates a tissue organization characterized by areas of high E-cadherin expressing cells and low E-cadherin expressing cells consistent with the differential adhesion hypothesis. Incredibly, perturbing the amount of localizable β-actin transcripts through genetic manipulation of the β-actin mRNA zipcode or the amount of the translational regulatory protein ZBP1 causes a similar cell sorting phenotype based on relative expression levels. Specifically, cells were likely to adhere to other cells with similar ZBP1 protein or zipcode-containing β-actin transcripts levels. In fact, ZBP1 knockdown causes cell sorting defects where cells with “high” ZBP1 expression form normal adhesions characterized by β-actin, β-catenin, and E-cadherin transcripts localization to cell-cell contact sites. By contrast, cells with “low” ZBP1 expression form disrupted adhesions characterized by delocalized β-actin, β-catenin, and E-cadherin transcripts. Together, these data demonstrate an important unappreciated function for E-cadherin in directing adherens junction formation by assembling contractile actin filaments at cell-cell contact sites by spatially localizing β-actin monomer synthesis, formin-induced linear actin filament polymerization, and myosin II motor activation in response to tissue tension to balance tissue tension with contractility.

Ena/VASP proteins participate in the maintenance of actin network polarity.

M. Abou-Ghali¹, J. Plastino¹;

¹Institut Curie, Paris, France

Polarity in moving cells is established, in part, by the directional assembly of actin networks at the leading edge membrane. Branched actin filaments form at the leading edge due to the activity of the main actin polymerization nucleator in the lamellipodia, the Arp2/3 complex, which is activated by the WASP/WAVE family of proteins downstream of signaling in the membrane. Added to membrane-localized nucleation is the action of capping protein that limits filament growth to the vicinity of the membrane. The end result is that networks are oriented with new growth occurring predominantly beneath the leading edge membrane to push it out.

We sought to investigate how the balance between actin nucleation and capping defined actin network polarity, and how the actin polymerization enhancing protein, Ena/VASP protein, affected this balance. To do this, we used an in vitro bead system to reconstitute actin network polymerization at a surface. Beads were coated with Arp2/3 complex activators and incubated in a minimal mix of proteins for polymerization, with and without capping protein, with and without Ena/VASP. We followed the polarity of the network using a two-color actin approach. We found that Ena/VASP proteins preserved surface-directed polarity in the absence of capping protein, and increased actin network density in the presence or absence of capping protein. This mimicked what was observed when aggressive actin nucleation was produced at the bead surface by an ultra-efficient activator, suggesting that Ena/VASP indirectly increased Arp2/3 branching activity perhaps via its barbed end elongation enhancement activity. We are currently modeling our results in collaboration with theoreticians to understand how elongation enhancement by Ena/VASP could sustain actin network polarity even when capping protein concentrations are inadequate.

Characterizing the processive mechanism of Ena/VASP on diverse F-actin bundles.
A.J. Harker, J.D. Winkelman, C.A. Anderson, D.R. Kovar; 1Biochemistry and Molecular Biology, University of Chicago, Chicago, IL, 2Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, 3Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

Processive Ena/VASP proteins continuously bind near actin filament barbed ends, increasing F-actin’s elongation rate and sterically inhibiting capping protein. Ena/VASP localizes to dynamic actin networks in cells, including the leading edge and tips of fingerlike projections called filopodia. Ena/VASP is known to facilitate filopodia formation and maintenance, though fundamental questions about its underlying molecular mechanism remain unanswered. We recently discovered Drosophila Ena is 2- to 3-fold more processive on F-actin bundled by the filopodial crosslinker fascin. Using multi-color TIRF microscopy, we further characterized Ena/VASP’s processivity by measuring elongation rates and residence times of Drosophila Ena, C. elegans Unc34, and human VASP on single and fascin bundled filaments. All three Ena/VASP isoforms (1) bind processively to barbed ends and increase F-actin elongation rate 2- to 3-fold, (2) have a 2- to 3-fold increase in residence time on two-filament fascin bundles, and (3) processively bind an additional 1.3- to 1.5-fold longer on fascin bundles with three or more filaments compared to two-filament bundles. Though the absolute residence times of the isoforms differ, increased processivity is conserved from worms to flies to mammals, indicating it is important for Ena/VASP’s function in cells. Strikingly, this change in processivity is not observed in the presence of α-actinin or fimbrin bundles, suggesting that enhanced processive properties are specific to bundles formed by the filopodial crosslinker fascin.

Ena/VASP is a tetramer, whose four ‘arms’ likely contribute to its increased processive run length on fascin bundles. To test the importance of DmEna’s oligomeric state on its processive properties, we designed and purified dimeric and trimeric DmEna constructs using alternative oligomerization domains. We quantified the residence time of the dimeric and trimeric DmEna constructs on single and fascin bundled filaments as well as the filopodia phenotypes of cultured Drosophila D16 cells transfected with the constructs. Both the processive run length on individual filaments and the magnitude of the increase of processivity on fascin bundles positively correlates with the number of DmEna arms. Therefore, processive behavior of Ena/VASP is dependent on the number of arms and, thus, available actin binding sites. We have discovered that Ena/VASP’s processive molecular mechanism is dependent on the crosslinker and size of actin bundles, as well as its tetrameric state.

Single Molecule Analysis of B Cell Receptor Motion during Signaling Activation.
B.A. Wheatley1, I. Rey Suarez2,3, P. Koo4, S. Zhou5, S. Mochrie6, W. Song5, A. Upadhyaya1,7;
1Institute of Physical Sciences and Technology, University of Maryland, College Park, MD, 2National Institute of Biomedical Imaging and Bioengineering, NIH, Bethesda, MD, 3Biophysics, University of Maryland, College Park, MD, 4Molecular and Cellular Biology, Harvard University, Cambridge, MA, 5Microbiology, University of Maryland, College Park, MD, 6Applied Physics, Yale University, New Haven, CT, 7Physics, University of Maryland, College Park, MD

B cells are an essential part of the adaptive immune system. They patrol the body looking for signs of infection in the form of antigen on the surface of antigen presenting cells (APC). B cell receptor (BCR) binding to the antigen induces a signaling cascade that leads to B cell activation and spreading. During activation, B cell receptors form signaling microclusters that later coalesce as the cell contracts. We have studied the dynamics of BCRs on activated murine primary B cells using single particle tracking. The tracks obtained are analyzed using perturbation expectation-maximization (pEM), a systems-level analysis, which allows the identification of different short-time diffusive states from a set of single particle tracks. We have identified four dominant diffusive states, two of which show low diffusivities and correspond to BCRs interacting with signaling molecules. For wild-type cells, the number of BCR in signaling states increases as the cell spreads and then decreases during cell contraction. In contrast, cells lacking the actin regulatory protein, NWASP, are unable to contract and the BCR in signaling modes are sustained for longer times. PEM analysis of single molecule trajectories of CD19 indicates that this signaling coreceptor has decreased mobility and resides mostly in signaling states. Conversely, the inhibitory receptor, Fc-gamma-RIIB is found to have a higher mobility compared to BCR. These observations strengthen the notion that actin cytoskeleton dynamics modulate BCR diffusion and clustering. Our results provide novel information regarding the interactions between actin regulation, BCR motion and signaling molecules.

Twinfilin promotes Capping Protein association with actin filament barbed ends by attenuating the inhibitory effects of CARMIL.
D. Hilton1, A. Johnston1, A. Simone1, P. McConnell2, J.A. Cooper2, B.L. Goode1;
1Molecular Cellular Biology, Brandeis University, Waltham, MA, 2Biochemistry Molec Biophysic, Washington University in St. Louis, St. Louis, MO

Nucleation and elongation of actin filaments represent the two critical control points in the cellular regulation of actin network assembly. Until recently, our view of actin elongation regulation was that the growing barbed ends of filaments were either rapidly bound by capping protein, terminating growth, or ‘captured’ by processive elongators such as formins and Ena/VASP, resulting in accelerated growth. However, work in recent years has clearly demonstrated that cells have multiple mechanisms for spatially and temporally controlling capping and elongation. CARMIL and other CPI motif-containing proteins can rapidly displace capping protein from barbed ends, and other factors can directly attenuate or enhance formin-mediated elongation. Additionally, formins and capping protein can lock horns at the barbed end, catalyzing each other’s displacement. Here, we build on this emerging view of complex molecular interplay controlling barbed end growth by addressing the functional significance of Twinfilin binding interactions with capping protein. We find that Twinfilin directly competes with CARMIL for
binding capping protein and attenuates CARMIL-mediated displacement of capping protein, enabling capping protein to remain on barbed ends. Consistent with these biochemical effects, Twinfilin silencing in B16F10 melanoma cells leads to an increase in actin assembly and in filopodia density, phenocopying the loss of capping protein. Together, these results show that Twinfilin promotes capping protein association with barbed ends by attenuating CARMIL effects, thus tuning actin network assembly at the leading edge.

**Synergy between anti-tropomyosin and anti-microtubule drugs reveals an interaction between actin and microtubule networks.**

Y. Wang1, A. Swain1, J.H. Stear1, N.S. Bryce1, V.B. Dugina2, I.B. Alieva2, T.P. Cripe3,4, J.R. Stehn1, E.C. Hardeman1, P.W. Gunning1;

1School of Medical Sciences, University of New South Wales, Sydney, Australia, 2Belozersky Institute of Physico-Chemical Biology, Lomonosov Moscow State University, Moscow, Russia, 3Centre for Childhood Cancer and Blood Diseases, Nationwide Children’s Hospital, Columbus, OH, 4Division of Hematology/Oncology/Blood and Marrow Transplantation, Nationwide Children’s Hospital, Columbus, OH

We have developed a new therapeutic cancer strategy based on targeting a core component of the cancer cell actin cytoskeleton, tropomyosin Tpm3.1 [1]. The first-in-class series of anti-tropomyosin (ATM) compounds prevent the cancer-associated tropomyosin Tpm3.1 from stabilizing actin filaments, leading to the collapse of the actin cytoskeleton in cancer cells [1]. We have recently demonstrated that ATM agents strongly synergize with anti-microtubule (anti-MT) chemotherapeutics that are among the most widely used front-line treatment strategies for multiple cancer types [2]. Such synergy has been observed in childhood solid tumors (e.g. neuroblastoma) and adult cancers (e.g. cervical, prostate and lung cancer) both in vitro and in vivo. Here, we examined the mechanism by which the Tpm3.1 inhibitor TR100 synergizes with the anti-MT drug vincristine (VCR) in HeLa cells, a model more suitable for imaging analysis. Isobologram analysis of the degree of synergy between TR100 and VCR in HeLa cells revealed strong or very strong synergistic combinational effects (combination index CI < 0.3 at ED50; CI < 0.02 at ED95) on inhibiting cell proliferation and inducing apoptosis. Interestingly, TR100 alone exhibited no impact on HeLa cell cycle progression, however it significantly promoted the VCR-induced cell cycle arrest of mitosis, particularly at prometaphase and metaphase. By 3D-SIM super resolution microscopy imaging and live cell imaging we observed that this drug combination disrupted spindle assembly, promoted multipolar spindle formation, and induced astral MT defects extending to the cell cortex. Given that Tpm3.1 preferentially localizes at the cell cortex during mitosis, we hypothesized that Tpm3.1 plays a role in the orientation of the mitotic spindle possibly via interacting with astral MTs or MT-associated proteins at the cell cortex. To test this hypothesis, we performed co-immunoprecipitation analysis and found that Tpm3.1 and the MT plus-end-tracking protein EB1 formed a complex in HeLa cells. Upon co-treatment with both drugs this Tpm3.1-EB1 complex was highly enriched. Such enrichment was not seen in VCR treatment at high doses, indicating that the strengthened Tpm3.1-EB1 interaction is not simply due to an increased mitotic arrest but more likely reflects a combined disruption of both the Tpm3.1-associated actin cytoskeleton and MT networks. In summary, our results highlight a novel connection between Tpm3.1-containing actin filaments and microtubules, and provides a clearer understanding of how targeting these structures may lead to improved cancer therapy.

Direct observation of actin structural deformation in response to mechanical force.
P.S. Gurel 1, Y. Takagi 2, J.E. Bird 3, J.R. Sellers 2, G.M. Alushin 1;
1 The Rockefeller University, New York, NY, 2 Cellular Biology and Physiology Center, National Heart, Lung, and Blood Institute, Bethesda, MD, 3 National Institute of Deafness and Other Communication Diseases, Bethesda, MD

The ability of a cell to respond to the mechanical properties of its environment (“mechanosense”) influences core cellular processes including division, migration, differentiation, and survival. Misregulation of mechanical signal transduction (“mechanotransduction”) has been implicated in malignant transformation, tumorogenesis, and metastasis, highlighting this process as a key component of cancer progression, yet the underlying molecular mechanisms remain largely unknown. Cellular mechanics are governed by an intricately coordinated contractile network consisting of the actin cytoskeleton, myosin motor proteins, and actin binding partners (ABPs). Actin filaments are flexible polymers that can adopt multiple conformational states, and recent evidence suggests that forces can regulate interactions between actin and ABPs. Here, we explore how mechanical stimuli alter the actin filament structural landscape, potentially serving as an upstream event in mechanotransduction by regulating ABP binding. We have developed a novel reconstitution system to place actin filaments under mechanical load suitable for structural studies with cryo-electron microscopy (cryo-EM). We immobilize active myosin-V (barbed-end directed motor) or myosin-VI (pointed-end directed motor) onto the film of holey-carbon cryo-EM grids, and then tether pointed-end biotinylated actin filaments onto grids such that filaments are attached to the surface through one end and free to engage with the myosin throughout the rest of the filament. Using time-lapse fluorescence microscopy, we observe morphological changes in individual actin filaments consistent with myosin V generating compression along the filament axis, while myosin VI generates tension, consistent with the directionality of the motors. Cryo-EM images reveal a novel, persistent actin structural state found in the presence of force generation that is characterized by oscillating areas of high curvature within the filament, which we term “squiggles”. Intriguingly, both compressive and tensile forces produce these “squiggle” structures, which cryo-electron tomography reveals to be 3-dimensional spirals. We hypothesize that both compression and tension introduce defects in longitudinal contacts along the filament, and that preferential propagation of defects along one strand induces squiggle formation. Resolving the structure of squiggles at high-resolution will provide insight into the molecular mechanisms of mechanically regulating actin-ABP interactions and advance the development of targeted therapeutics against specific actin conformational states.

A Novel Actin Filament Sliding and Compaction Mechanism Jointly Catalyzed by Srv2/CAP and its Interacting Partner Abp1.
S. Guo 1, J. Gelles 2, B.L. Goode 3;
1 Department of Biology, Brandeis University, Waltham, MA, 2 Department of Biochemistry, Brandeis University, Waltham, MA

Dynamic remodeling of filamentous actin networks is a critical step in cell migration, cell adhesion, and many other actin-based processes. However, we are only beginning to understand the mechanisms used by cells to reorganize actin network architecture. Here, we describe a new remodeling activity, jointly
catalyzed by two conserved actin binding proteins that interact: Abp1 (Actin binding protein 1) and Srv2/CAP (Cyclase-associated protein). In TIRF microscopy assays, these two proteins together induce dynamic crosslinking and sliding of filaments, resulting in filament coalescence and compaction into thick bundles. This activity was observed for both the yeast and mammalian homologs of Abp1 and Srv2/CAP, and for parallel and anti-parallel filaments. Remodeling depended on direct interactions between Abp1 and Srv2/CAP, and on interactions between Abp1 and F-actin. Structurally, Srv2/CAP self-assembles into a hexameric wheel-shaped hub with six Abp1-binding sites, making the combination of the two proteins a robust actin crosslinker. Using multi-wavelength TIRF microscopy with labeled Abp1 and Srv2/CAP molecules, we directly visualized Abp1-Srv2/CAP complexes gliding diffusively along filaments and accumulating in regions of highest filament overlap, in turn leading to further coalescence. These observations define a new mode of actin network reorganization, driven by the unique molecular architecture of Srv2/CAP hexamers and their interactions with Abp1. These activities may underlie previously suggested genetic roles for yeast Abp1 and Srv2/CAP in actin organization and for mammalian Abp1 and Srv2/CAP in organizing actin filaments in sarcomeres.

Vinculin forms a directionally asymmetric catch bond with F-actin.
D.L. Huang¹, N.A. Bax², C.D. Buckley³, W.I. Weis², A.R. Dunn³;
¹Biophysics, Stanford University, Stanford, CA, ²Structural Biology, Stanford University, Stanford, CA, ³Chemical Engineering, Stanford University, Stanford, CA

Vinculin is an actin-binding protein thought to reinforce cell-cell and cell-matrix adhesions. However, how mechanical load affects the vinculin–F-actin bond is unclear. Using a single-molecule optical trap assay, we found that vinculin forms a force-dependent catch bond with F-actin through its tail domain, but with lifetimes that depend strongly on the direction of the applied force. Force toward the pointed (-) end of the actin filament resulted in a bond that was maximally stable at 8 piconewtons, with a mean lifetime (12 seconds) 10 times as long as the mean lifetime when force was applied toward the barbed (+) end. A computational model of lamellipodial actin dynamics suggested that the directionality of the vinculin–F-actin bond can potentially establish long-range order in the actin cytoskeleton. The directional and force-stabilized binding of vinculin to F-actin may be a mechanism by which adhesion complexes maintain front-rear asymmetry in migrating cells.

How do the actin- and microtubule-based transport systems communicate?
A. Oberhofer¹, P. Spieler¹, Y. Rosenfeld¹, W.L. Stepp¹, A. Cleetus¹, A.N. Hume², F. Mueller-Planitz³, Z. Ökten¹;
¹Physik-Department E22, Technische Universität München, Garching, Germany, ²School of Life Sciences, University of Nottingham, Nottingham, United Kingdom, ³BioMedizinisches Centrum, Molecular Biology, Ludwig-Maximilians-Universität München, Planegg-Martinsried, Germany

How the actin- and microtubule-based transport systems cooperate to achieve timely and correct delivery of intracellular cargo has been subject of intense research for decades. This intricate interplay has been extensively studied using pigment organelle transport as a model. Depending on the needs of the cell, these organelles dynamically transfer between the actin and microtubule networks to achieve cell-wide redistribution, with cAMP-dependent protein kinase (PKA) acting as a key regulator of this
process. However, despite substantial efforts the molecular mechanisms governing these microtubule-and actin-based transport processes remain largely unknown. A tripartite complex comprising the membrane-bound small GTPase Rab27a, the adaptor protein melanophilin and the myosin Va motor, was previously shown to be essential for actin-dependent pigment transport in mouse melanocytes. We found that melanophilin, particularly its C-terminal actin-binding domain (ABD), is the only target of PKA in vitro. Notably, in vitro phosphorylation of the ABD closely recapitulated the previously described in vivo phosphorylation pattern. ABD’s phosphorylation, however, showed no effects on the myosin Va-mediated transport of the tripartite complex nor did it affect melanophilin’s interaction with the actin filaments. Instead, we were surprised to find that phosphorylation robustly regulated the interaction between melanophilin and microtubules. Melanophilin interacted with microtubules strictly in its dephosphorylated state via its ABD and this interaction was abolished upon PKA treatment. Remarkably, when microtubules and actin were both present, dephosphorylation was sufficient to competitively relocate melanophilin from actin to microtubules. Indeed, when actin and microtubules were present simultaneously, melanophilin’s phosphorylation state enforced track selection of the Rab27a/melanophilin/myosin Va transport complex. Collectively, our results unmasked the regulatory dominance of the melanophilin adaptor protein over its associated motor and offer an unexpected mechanism for how filaments of the cytoskeletal network compete for the moving organelles to accomplish directional transport on the cytoskeleton in vivo.

Clues to Suppressor of IKK epsilon (SIKE):cytoskeletal interactions: Binding affinities and SIKE’s dimer interface.

H.A. Sonnenschein1, F. Shikwana1, M.L. Machek1, J.E. Bell1, J.K. Bell1;
1Chemistry Biochemistry, University of San Diego, San Dieg, CA

Upon pathogen challenge multiple receptors both inside and on the surface of the cell, recognize pathogen associated molecular patterns (PAMPs) and initiate the production of proinflammatory, antiviral, and apoptotic responses. Pathways converge at key hubs that serve to amplify and regulate the signals, and are often responsible for determining the downstream response. TANK Binding Kinase 1 (TBK1) serves as a catalytic hub in the antiviral TLR3 mediated innate immune pathway. Suppressor of IKK epsilon (SIKE) is a recently identified high affinity alternative substrate of TBK1. It was initially found to inhibit TBK1 activation of type 1 interferon production. Upon subsequent study, it was found that SIKE was phosphorylated at six serine residues. This phosphorylation of SIKE corresponds to the activation of the antiviral response, and mediates the SIKE:TBK1 interaction. The primary function of SIKE remains unknown. Examination of SIKE’s interaction network has established direct interactions with cytoskeletal proteins including tubulin and α-actinin. These studies suggest that SIKE may play a role in cytoskeletal rearrangements associated with innate immune responses such as migration and phagocytosis. The goal of this study is to define the interaction surface of SIKE as well as the binding affinities associated with SIKE: cytoskeletal protein interactions. A quartz crystal microbalance with dissipation (QCM-D) was employed to obtain binding affinities for the SIKE:cytoskeletal protein complexes. The kon and koff values for each cytoskeletal protein were measured and KD derived from these parameters for each complex. Prior to examining SIKE:cytoskeletal protein interactions, SIKE’s oligomeric state was defined by crosslinking studies. Crosslinking with bis(sulfosuccinimidyl)suberate (BS3) has shown that SIKE is a dimer. Chemical crosslinking followed by followed by tandem mass spectrometry was employed to determine the dimeric interface of the SIKE dimer. To interpret these results, a computer model of SIKE was predicted using Modeller software. The SIKE model contains
The geometry of the tissue microenvironment determines the local mechanical stress experienced by cells. It is known that mechanical stress can regulate mechanosignaling and subsequent gene expression. For example, it has been reported that the frequency of breast cancer occurrence is higher at the mammary ducts of higher curvatures. However, the detailed mechanism by which local geometry regulates cellular behaviors is yet to be elucidated. We have thus devised a self-induced rolling membrane (SIRM) platform, a rectangular thin elastic film rolled into a cylindrical roll, to study the effect of various curvatures on cytoskeleton organization in the epithelium. The SIRM is characterized by a continuously varying curvature ranging from a radius of 50 – 500um, allowing various curvature conditions to be investigated in one experiment. First, Mouse mammary epithelial cells (EPH4-EV) were seeded and cultured for 24 hours. The SIRM was then rolled and incubated for another 24 hours to induce the curvature effects on the epithelium. We then unrolled the SIRM for high-resolution microscopy and examined the actin organization of the cells cultured at different curvatures by phalloidin staining. It was observed under fluorescence microscopy that the ratio of cytosolic actin to cortical actin difference between high and low curvature is approximately a factor of 1.2, suggesting that the curvature at the scale 50-500um radius governs the differential organization of the cytoskeleton. In summary, the SIRM is a high-throughput platform compatible with high-resolution microscopy that makes it an ideal system to study curvature effects at tissue level.

Phosphorylation of Sharpin acts as a molecular switch to control Linear Ubiquitination Assembly Complex (LUBAC) and Arp2/3 function.
U. Butt\textsuperscript{1,2}, M.H. Khan\textsuperscript{1,2}, G. Jacquemet\textsuperscript{3}, H. Sanmark\textsuperscript{4}, U. Lamminmäki\textsuperscript{4}, M.J. Humphries\textsuperscript{3}, J. Pouwels\textsuperscript{1};
\textsuperscript{1}Turku Centre for Biotechnology, University of Turku, Turku, Finland, \textsuperscript{2}Turku Doctoral Programme of Molecular Medicine, University of Turku, Turku, Finland, \textsuperscript{3}Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom, \textsuperscript{4}Department of Biochemistry, University of Turku, Turku, Finland

Sharpin is a multifunctional adaptor protein that, for example, inhibits integrin adhesion receptors and is part of the linear ubiquitin assembly complex (LUBAC). In addition, using the first Sharpin interactome
we showed that Sharpin promotes lamellipodium formation through direct interaction with the Arp2/3 complex (Khan et al, J. Cell Sci. 2017). Most Sharpin interactors bind the Sharpin Ubiquitin-like (UBL) domain and, therefore, Sharpin binding specificity is likely regulated by post-translational modifications. However, such modifications of Sharpin are currently unknown. Using mass spectroscopy analyses of GFP-Sharpin, pulled down from cancer cells, and recombinant GST-Sharpin, subjected to in vitro kinase assays, we identified a number of conserved residues that are phosphorylated by oncogenic kinases. Mutation of a selection of these residues identified phosphorylation sites that critically regulate Sharpin-mediated Arp2/3 activation and LUBAC function without affecting Sharpin-mediated integrin inhibition. Interestingly, one of these phosphorylation sites is located in the Sharpin UBL domain, suggesting that phosphorylation of the UBL domain acts as a molecular switch that determines which pathway is regulated by Sharpin at a given time. We now aim to develop phosphorylation-specific antibodies to further study what role these phosphorylation events play in Sharpin function and to identify the kinases that mediate these phosphorylation events. Furthermore, we will determine if Sharpin gets differentially phosphorylated under different experimental conditions. In conclusion, we identify several Sharpin phosphorylation sites in cells and show that some of these events, one of which is in the Sharpin UBL domain, regulate LUBAC and Arp2/3 function.

Molecular mechanism of LIM domain protein recruitment to stressed actin filament networks.
C.A. Anderson¹, J.D. Winkelmann², M.L. Gardel³,⁴, D.R. Kovar¹,⁵;
¹Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, ²Institute for Biophysical Dynamics, The University of Chicago, Chicago, IL, ³Physics, The University of Chicago, Chicago, IL, ⁴James Franck Institute, The University of Chicago, Chicago, IL, ⁵Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL

The cytokinetic contractile ring and stress fibers are comprised of bundled actin filaments that often carry mechanical loads, which can cause strain events that result in bundle thinning. The stress fiber protein zyxin rapidly localizes to strain sites, and in turn recruits the F-actin crosslinker α-actinin, and elongation factor VASP, which mediate repair of the thinning actin bundle. Zyxin is a part of a large family of proteins that contain zinc finger-like LIM (Lin11, Isl-1 & Mec-3) domains, and a large fraction of this family helps regulate actin cytoskeleton network structure and dynamics, especially in relation to mechanical stresses. Zyxin LIM domains are necessary and sufficient for localization to stress fiber strain sites in mammalian cells. Similarly, the LIM domains of the fission yeast protein Pxl1 (paxillin-like) are sufficient for its localization to the contractile ring. This suggests that the mechanism used by LIM domains to recognize mechanical stress may be conserved from yeast to humans, although the underlying molecular mechanism is not understood. The LIM domains may bind F-actin directly, or additional proteins (such as myosin or α-actinin) may be required to mediate the association of LIM domains with actin filament bundles. Therefore, I have initiated in vitro reconstitution assays to elucidate the underlying molecular mechanisms by which LIM domain proteins bind to stressed actin filament bundles. High speed sedimentation assays revealed that fission yeast Pxl1 and mammalian zyxin LIM domains have only a weak affinity for binding F-actin. However, in a minimally reconstituted stressed F-actin network, the binding affinity of zyxin LIM domains increases with the addition of α-actinin and myosin-II. We therefore utilized multi-color flow TIRF microscopy to directly visualize the interaction of fluorescently labeled LIM domains of zyxin and Pxl1 with reconstituted stressed F-actin networks. With the addition of myosin to the bundled actin network, the LIM domains rapidly accumulate along the F-actin. In fact, Pxl1 LIM domains often localize to F-actin bundles immediately prior to the bundle
Beta-Actin, a 42 kDa molecular weight (MW) protein, is a housekeeping protein that is made constitutively in the cell. It is a structurally important protein playing a paramount role in the formation of actin filaments. In addition to its cellular functions, it serves as an internal control both in gene and protein expression studies and allows normalization among biological samples. That's why in numerous studies, Beta-Actin is utilized as an internal control. In this study, we reported evident production of recombinant human Beta-Actin in E. coli W3110, BL21 and M15 strains. The production of the protein involved codon optimization, gene synthesis and cloning of the optimized gene into pQE-2 expression vector for histidine tagging. Although all three strains were successfully expressed the recombinant Beta-Actin, E. coli W3110 strain produced the highest yield. The subsequent purification of the recombinant protein was performed both under native and denatured conditions. When the purification was performed under native conditions, the protein failed to bind to the column indicating that the N-terminal his tag was hidden by the native protein. Under denatured conditions, the his-tag allowed one-step purification of Beta-Actin to almost homogeneity. The chromatogram displayed a relatively sharp single peak and SDS-PAGE analysis of the peak fractions showed the presence of a major protein band with respective MW of 42 kDa. Analysis of the purified band using in-gel tryptic digestion procedure coupled with MALDI-TOF/TOF verified that the purified band indeed belonged to human Beta-Actin protein. More than half of the peptide sequence (62%) was covered by MALDI-TOF/TOF analysis. Our aim in the near future is to create sensitive and specific in-house produced monoclonal antibodies against this protein. Such antibodies will allow us to perform normalization studies in our comparative proteomic and data verification studies.
L253P ABD. This structure, along with co-sedimentation and pulsed-EPR measurements, demonstrates that high-affinity binding caused by the CH2-localized mutation is due to opening of the two CH domains. This enables CH1 to bind actin aided by an unstructured N-terminal region that becomes α-helical upon binding. This helix is required for association with actin as truncation eliminates binding. To explore the in vivo consequence of this mutation, we developed a Drosophila SCA5 model in which an equivalent mutant Drosophila β-spectrin is expressed in neurons that extend complex dendritic arborizations, like Purkinje cells targeted in SCA5 pathogenesis. The mutation causes a proximal shift in arborization, coincident with decreased β-spectrin localization in distal dendrites. We show that SCA5 β-spectrin dominantly mislocalizes components of the endogenous spectrin cytoskeleton, α-spectrin and ankyrin-2. Our data suggest that high-affinity actin binding by SCA5 β-spectrin interferes with spectrin-actin cytoskeleton dynamics, leading to a loss of a cytoskeletal mechanism in distal dendrites required for dendrite stabilization and arbor outgrowth.

Molecular mechanisms underlying formin-associated inherited deafness.
C.C. Costeas¹, T. Jabeen¹, C.L. Vizcarra¹;
¹Department of Chemistry, Barnard College, New York, NY

The sensory epithelium of the inner ear contains precisely patterned cytoskeletal structures, including the paracrystalline array of actin filaments in stereocilia, the actin and microtubule meshwork of the cuticular plate that anchors stereocilia, the tight junctions that maintain ionic composition of cochlear fluids, among others. The importance of these structures for auditory function is apparent from the large number of genes encoding cytoskeletal-associated proteins that are linked to hereditary deafness. One of the first of these genes to be identified was DIAPH1, mutations in which cause autosomal dominant, non-syndromic progressive hearing loss called DFNA1. DIAPH1 is a member of the formin family of cytoskeletal regulators and, like other formins, interacts directly with the actin and microtubule cytoskeletons. Despite the great progress made in understanding the molecular basis of other forms of hereditary deafness, very little is known about the mechanisms underlying DFNA1, and more generally about the role of formins in the inner ear. We are using a biochemical approach to test various hypotheses about the etiology of hearing loss in DFNA1. There are several DIAPH1 mutations identified in affected individuals: one in the N-terminal coiled-coil domain and two in the C-terminal tail region, near the formin homology (FH) 2 domain and the diaphanous auto inhibitory domain (DAD). Our preliminary data indicate that both C-terminal mutant forms of DIAPH1 are stable in vitro and promote actin filament assembly to a similar degree as the WT protein. Further studies will focus on auto-inhibitory interactions, microtubule binding, and F-actin binding.

Actin Filament Associated Protein 1 (AFAP1) and AFAP1L1 have distinct functions in the disassembly of actin stress fibers and the formation of podosomes in response to phorbol ester stimulation.
J.M. Cunnick¹, Y. Cho¹;
¹Basic Sciences, Geisinger Commonwealth School of Medicine, Scranton, PA

Podosomes are actin-rich adhesions localized on the ventral surface of several cell types, including vascular smooth muscle cells (VSMC). Phorbol esters induce podosomes in VSMC through the activation
of protein kinase C (PKC) and canonical signaling pathways. Preceding the formation of podosomes, actin stress fibers and focal adhesions disassemble with the initial dissolution of actin stress fibers occurring at their insertion into focal adhesions. Actin filament associated protein 1 (AFAP1) is localized to both actin stress fibers and podosomes and has been postulated to play a central role in both the disassembly of actin stress fibers and the formation of and lifespan of podosomes. The interaction of AFAP1 with PKCα and the subsequent activation of c-Src have been hypothesized to contribute to the function of AFAP1 in these processes. The AFAP1L1 isoform of AFAP1 shares a similar subcellular localization with AFAP1 and has also been shown to induce podosome-like structures and invadopodia. However, the contribution of AFAP1L1 in the cellular response to phorbol ester stimulation has not been determined. In this report we have examined the contribution of both proteins to the disassembly of actin stress fibers and the formation of podosomes in response to phorbol ester stimulation. By knocking down the expression of AFAP1 with siRNA and utilizing a PKCα binding deficient mutant of AFAP1, we have found that AFAP1 is not required for the dissolution of actin stress fibers in response to phorbol ester stimulation has had been previously reported, but is necessary for podosome formation. Surprisingly, we find that the knockdown of AFAP1L1 completely blocks the disassembly of actin stress fibers and the dissolution of focal adhesions and, therefore, the formation of podosomes, in response to phorbol ester stimulation. Furthermore, the cortactin-rich microdomains located at the insertion of actin stress fibers into focal adhesions, the site at which podosomes initially form in VSCM, remain intact. Overall, our findings suggest that AFAP1 and AFAP1L1 cooperate in the formation of podosomes in VSMC in response to phorbol ester stimulation and PKC activation, but have distinct roles in the process.

Investigations into the Structure and Intermolecular Interface of Human Cofilin-2 Assembled on Actin Filaments Using Magic Angle Spinning NMR.
J. Kraus¹, J. Yeh¹, E. Kudryashova², E. Reisler³, D.S. Kudryashov³, T. Polenova¹;
¹Chemistry and Biochemistry, University of Delaware, Newark, DE, ²Chemistry and Biochemistry, The Ohio State University, Columbus, OH, ³Chemistry and Biochemistry, University of California, Los Angeles, CA, ⁴Molecular Biology Institute, University of California, Los Angeles, CA

Actin is one of the most ubiquitous and conserved proteins and comprises one major component of the eukaryotic cytoskeleton.¹ The coflin/ADF family of proteins play an integral role as regulators of actin polymerization dynamics.² Specifically, they regulate actin filament severing and recycling of monomers in a nucleotide-dependent manner during actin treadmilling. While actin treadmilling is crucial for cell function and is responsible for up to 50% of cellular ATP consumption,³ there is currently a lack of atomic-level information regarding the structure and intermolecular interface of coflin proteins bound to actin filaments. We have previously reported atomic level insights into these assemblies in the ADP nucleotide state through the use of magic angle spinning (MAS) NMR spectroscopy.⁴ Our MAS NMR results for the F-actin binding site were in good agreement to a previous 9A cryo-EM density map,⁵ with three patches identified on coflin for F-actin binding. Other substantial structural changes that occur from coflin binding on F-actin will be clarified upon the determination of an atomic-resolution structure. Herein, we report paramagnetic NMR parameters for coflin/F-actin assemblies, which yield long-range structural information and directly report on the intermolecular interface.⁶ Specifically; we used paramagnetic relaxation enhancements (PRE’s), which we obtained by labeling F-actin with a paramagnetic spin label. In ¹³C-¹³C correlation experiments, we see several peaks corresponding to backbone and side chain atoms disappear, and decrease in intensity.
Peak intensities are correlated to proximity to the unpaired spin, and are used to derive atomic distances. We can use these in conjunction with our MAS NMR data from $^{13}$C and $^{1,6,13}$C labeled coflin as distance restraints required to derive the atomic-resolution structure of coflin/F-actin assemblies, which is currently underway.

Leiomodin-2 regulates thin filament assembly and is necessary for proper contractile force production in the hearts of adult mice.

C.T. Pappas$^1$, G.P. Farman$^1$, R.M. Mayfield$^1$, C.C. Gregorio$^1$;

$^1$Cellular and Molecular Medicine, University of Arizona, Tucson, AZ

Leiomodin-2 (Lmod2) is a striated muscle-specific actin binding protein that has been implicated in the assembly of thin filaments. We have previously shown that Lmod2 is critical for cardiac function in neonatal mice as Lmod2 null mice die 2-3 weeks after birth with severe contractile dysfunction and enlarged ventricular chambers consistent with dilated cardiomyopathy. However, the necessity of Lmod2 in adult mice and the role it plays in the mechanics of contraction have not been studied. To answer these questions, we generated cardiac-specific conditional Lmod2 knockout mice (cKO). These mice die within a week of induction of the knockout with severe systolic dysfunction, but no change in cardiac morphology. Analysis of muscle mechanics at the fiber and single cell levels indicate a significant decrease in maximum force production and a blunting of force increase upon stretch in the cKO. Thin filament length is also substantially reduced in the cKO (~30%). Thus, Lmod2 plays an essential role in maintaining proper cardiac thin filament length in adult mice, which in turn contributes to production of contractile force.

Structural basis of actin monomer re-charging by cyclase-associated protein.

T. Kotila$^1$, K. Kogan$^1$, G. Enkavi$^2$, S. Guo$^3$, I. Vattulainen$^4$, B.L. Goode$^3$, P. Lappalainen$^1$;

$^1$Institute of Biotechnology, University of Helsinki, Helsinki, Finland, $^2$Department of Physics, University of Helsinki, Helsinki, Finland, $^3$Brandeis University, Waltham, MA, $^4$Laboratory of Physics, Tampere University of Technology, Tampere, Finland

Cyclase-associated protein (CAP) is an evolutionarily conserved actin-binding protein that is important for cell migration, morphogenesis, polarization, and endocytosis. Moreover, CAP is upregulated in many malignant cancers. CAP is a large, multi-domain protein that, in concert with coflin, promotes rapid actin dynamics by enhancing filament disassembly and monomer recycling. The most highly conserved function of CAP from Apicomplexan parasites, yeast and plants to animals is its ability to catalyze nucleotide exchange on ADP-actin monomers through its C-terminal region composed of WH2 and CARP domains. However, the structural mechanism by which CAP re-charges ADP-actin monomers with ATP, and the physiological importance of this protein-catalyzed nucleotide exchange have remained elusive. Here, by determining a 2.8 Å crystal structure of the CARP-domain of mouse CAP in complex with ADP-actin, we reveal a unique sandwich-like assembly where the CARP domain homodimer is squeezed between two actin molecules. Unlike other actin monomer binding motifs characterized so far, the CARP domain binds to the ‘back side’ of actin on subdomains 1, 2, and 3, and induces an extended D-loop conformation in actin subdomain 2. Our extensive mutagenesis and molecular dynamics simulations experiments further revealed how the adjacent WH2 domain contributes to interactions with actin.
Interestingly, the C-terminal tail of CAP is in close proximity of the sensor loop of nucleotide-binding pocket of actin, and its deletion results in severe defects nucleotide exchange activity of CAP without compromising its affinity for ADP-actin. This suggests a specific role of the CAP C-terminus in acceleration of nucleotide exchange, and allowed also to examine the physiological role of this activity. Importantly, yeast cells where the wild-type CAP was replaced by a mutant lacking the C-terminal extension displayed severe abnormalities in the organization of the actin cytoskeleton accompanied by growth and polarity defects. Collectively, our work suggests the interactions between the C-terminal tail of CAP and the nucleotide-sensor loops of actin as well as the effects of CAP on the conformation of actin monomer are important for its ability to accelerate nucleotide exchange on actin. Moreover, in vivo studies using the C-terminally deleted CAP demonstrate that proper organization of the actin cytoskeleton and cell polarity/proliferation depend on the rapid nucleotide exchange on actin, catalyzed by the cyclase-associated protein.

Regulation of Actin Dynamics 1

Bridging scales from molecules to movement: how the interplay between actin cappers, depolymerizers, fragmenters and elongators controls actin filament length.
S. Shekhar1, M. Carlier2;
1Biochemistry, Brandeis University, Waltham, MA, 2Biochemistry, Biophysics and Structural Biology, I2BC, CNRS, Gif-sur-Yvette, France

Actin filament barbed ends and sides are the hotspots for regulating dynamics of actin filaments. Although, most actin regulators have so far been only studied individually in vitro, it is well appreciated that complex actin dynamics seen in vivo involves a concerted interplay between the different classes of actin regulators that can simultaneously act on the same actin filament. These regulators together control the size of not only individual actin filaments but also the resulting actin networks (Carlier & Shekhar, Nat. Rev. Mol. Cell Biol. 2017).

Using a novel microfluidics-assisted single-molecule TIRF imaging technique, we can now simultaneously record the dynamics of 100’s of actin filaments and also rapidly change biochemical conditions to which the filaments are exposed to. This system has enabled us to study how multiple molecular regulators simultaneously control actin filament dynamics (Shekhar et al, Current Biology, 2017; Shekhar et al, Nat. Comms, 2015). As an example, formins, the actin filament elongators, and capping protein, the actin filament blockers, have so far been considered to bind filament barbed ends in a mutually exclusive manner. However, we have recently demonstrated that Capping protein can bind and pause a formin-bound barbed end and in the process, controls the length of individual formin-elongating filaments. These results have important implications for the control of size as well as morphology of organelles like filopodia which are formed from formin-elongating filaments (Shekhar et al, Nat. Comms, 2015).

We have also used this approach to study functional coordination between proteins that act on the filament sides and barbed ends. We have recently provided the first visual evidence that Cofilin can not only fragment actin filaments but also enhances their rate of depolymerization, thus allowing us to for the first time observe rapid treadmilling of actin filaments (Shekhar et al, Current Biology, 2017). Upon synergy with Capping protein’s long-predicted but never observed funnelling mechanism, we show that Cofilin’s severing and depolymerization can lead to sky-rocketing of actin filament growth rates. Given the technical advances in multispectral single molecule imaging as well as enabling techniques like microfluidics and micropatterning, we believe that we are now at the cusp of unravelling novel
mechanisms of how a large number of molecular machineries acting on actin filament ends and sides lead to such intricate control of cytoskeletal dynamics.

Length control of branched actin networks.

A. Icheva¹, A. Manhart², C. Guérin¹, T. Klar¹, M. Théry¹,³, L. Blanchoin¹,³, A. Mogilner²; ¹CytoMorphoLab, Biosciences Biotechnology Institute of Grenoble, GRENOBLE, France, ²Courant Institute of Mathematical Sciences and Department of Biology, NEW YORK, NY, ³CytoMorpho Lab, Hopital Saint Louis, PARIS, France

Geometry and growth rate of branched actin networks determine cell protrusion mechanics. These highly dynamic networks maintain a steady length determined by a balance between the actin polymerization and disassembly. We study how the actin network architecture and ADF/cofilin control the interplay between the growth and disassembly rates of a reconstituted lamellipodium. We use a high-resolution surface structuration assay to reconstitute a lamellipodium in vitro, measure treadmill rates and spatial-temporal actin and cofilin distributions in the lamellipodia at varying geometry and density of the lamellipodia, and combine the in vitro analysis with mathematical modelling. We find that a significant local depletion of ADF/cofilin limits effective disassembly rates, and that the length of the actin networks is controlled by its density, width, and the ADF/cofilin-actin ratio. Based on the model, we explain how the geometry and treadmill rate of branched actin networks emerges from the complex interplay between their biochemical, structural and mechanical properties.

Distinct VASP tetramers synergize in the processive elongation of individual actin filaments from clustered arrays.

S. Brühmann¹, D. Ushakov¹, M. Winterhoff¹, R.B. Dickinson², U. Curth¹, J. Faix¹; ¹Institut of Biophysical Chemistry, Hannover Medical School, Hannover, Germany, ²Department of Chemical Engineering, University of Florida, Gainesville, FL

Ena/VASP proteins are expressed in motile cells and act as actin polymerases that drive the processive elongation of filament barbed ends in membrane protrusions or at the surface of bacterial pathogens. Based on previous analyses of fast and slow elongating VASP proteins by in vitro TIRF microscopy (TIRFM), kinetic and thermodynamic measurements we established a kinetic model of Ena/VASP-mediated actin-filament elongation. At steady-state it entails that tetrameric VASP utilizes one of its arms to processively track growing filament barbed ends while three G-actin-binding sites (GABs) on other arms are available to recruit and deliver monomers to the filament tip, suggesting that VASP operates as a single tetramer in solution or when clustered on a surface, albeit processivity and resistance towards capping protein differ dramatically between both conditions. We therefore challenged the model by variation of the oligomerization state and by increase of the number of GABs in individual polypeptide chains. In excellent agreement with model predictions we show that in solution the rates of filament elongation directly correlate with the number of up to 5 free GABs in a synthetic VASP hexamer. In constructs with additional GABs filament elongation became even faster, however, the measured elongation rates increasingly deviate from the theoretical values which turned out to be caused by a new rate-limiting step in the reaction, namely the release of the end tracking arm from the growing filament. We additionally found, that release of the VASP from growing filament ends or its
processivity is dependent on the oligomerization state of the VASP as well as the affinity of its F–actin-binding site (FAB) to the filament side. Strikingly, however, irrespective of the oligomerization state or presence of additional GABs, the filament elongation on a surface invariably proceeded with the same rate as with the VASP tetramer, demonstrating that adjacent VASP molecules collectively synergize in the elongation of a single filament. Additionally, we revisited the controversial issue of profilin on VASP-mediated filament assembly and show that VASP can utilize both actin and profilin–actin. However, as opposed to formins, neither profilin I nor profilin Ila promote actin filament elongation but rather result in diminished elongation rates. Moreover, we reveal that actin ATP hydrolysis is not required for VASP-mediated filament assembly. Finally, we show evidence for the requirement of VASP to form tetramers in clusters and provide an amended model of processive VASP-mediated actin assembly in clustered arrays as found in filopodia.

Spatiotemporal Control of Actin Assembly at the Leading Edge by IQGAP.
G. Hoeprich¹, M.A. Juanes², B.L. Goode³;
¹Department of Biology, Brandeis University, Waltham, MA

Cell migration requires precise spatial and temporal control of the actin cytoskeleton, which is regulated by multiple actin binding proteins. Recent work has revealed adenomatous polyposis coli (APC) is a potent actin nucleator in vitro and works collaboratively with formins to assemble actin filaments by a ‘Rocket Launcher’ mechanism (Breitsprecher et al., 2012). Further, it was found that APC-mediated actin nucleation occurs at focal adhesions, where it is critical for microtubule-induce focal adhesion turnover and directed cell migration (Juanes et al, 2017). These and other observations suggest that APC, formins, and other key binding partners such as CLIP-170 may work in concert to control actin assembly underlying cell migration. Here, we have investigated how IQGAP mechanistically influences actin assembly, alone and together with APC, formins, and CLIP-170. IQGAP is a multi-domain scaffolding protein that bundles F–actin, caps barbed ends, and binds directly to APC, the formin Dia1, and CLIP-170. Using TIRF microscopy, we have begun defining the effects of full-length IQGAP on actin assembly dynamics, alone and in the presence of these other factors. Our preliminary in vitro observations suggest that IQGAP attenuates actin assembly by APC and Dia1, and consistent with these effects, RNAi silencing of IQGAP in HeLa cells led to excessive actin accumulation at the leading edge. Thus, IQGAP may restrain unregulated actin assembly at the leading edge until specific signals are received, and in this manner spatially and temporally control cell migration.

Phase separation enhances Arp2/3 complex-dependent actin polymerization by increasing N-WASP membrane dwell time.
L.B. Case¹, X. Zhang¹, J.A. Ditlev¹, M.K. Rosen¹;
¹Department of Biophysics, UT Southwestern Medical Center, Dallas, TX

Actin regulatory proteins are often organized into higher-order, micron-sized assemblies in cells. For example, the Arp2/3 nucleation promoting factor Neuronal Wiskott-Aldrich Syndrome Protein (N-WASP) is found at punctate structures such as matrix-degrading podosomes, viral induced actin comets, and the podocyte foot process. We previously developed an in vitro reconstitution system in which multivalent interactions between nephrin, Nck, and N-WASP enables their assembly and concomitant phase
separation, forming micron-scale signaling puncta on supported lipid bilayers. While we previously showed that this phase separation increased the specific activity of molecules in the pathway toward Arp2/3 complex, the molecular mechanism by which assembly and phase separation enhances activity is not known.

To understand how phase separation regulates N-WASP activity, we developed a Total Internal Reflection Fluorescence (TIRF) microscopy based assay to measure Arp2/3 complex-dependent actin polymerization on supported lipid bilayers. With 1uM Actin (5% Alexa 647), 3nM Arp2/3 complex, and 6nM CapZ, we observe rapid actin polymerization at puncta composed of nephrin, Nck, and constitutively active N-WASP. The normalized polymerization rate (polymerization rate/local N-WASP density) was significantly faster inside phase-separated membrane puncta, suggesting that the specific activity of N-WASP molecules is increased. We found that this increase in N-WASP specific activity was not due to the increased density of N-WASP molecules, but rather was due to the increased membrane dwell-time of N-WASP in puncta. We propose that N-WASP and Arp2/3 complex membrane dwell time must exceed the rate-limiting step of Arp2/3 complex activation in order for efficient actin polymerization to occur. We found that experimentally increasing N-WASP membrane dwell time through a variety of molecular perturbations was sufficient to increase its specific activity. We are currently using computational and experimental approaches to elucidate the mechanism by which N-WASP membrane dwell time is regulated in clusters. In conclusion, we’ve found that phase separation enhances Arp2/3 complex-dependent actin polymerization by increasing N-WASP membrane dwell time.

The driving forces for cell migration depend on a complex interaction between environmental cues and internally generated feedback loops. The Scar/WAVE complex provides a main control point for actin-based protrusion generation; spatiotemporal activation of this complex via activated Rac1 recruits and activates the Arp2/3 complex, triggering branched actin polymerisation. This is reinforced through a positive feedback loop, but it is unclear how the cell restricts the eventual size of a protrusion through buffering of the positive signals to cause splitting or retraction.

We have identified a highly conserved regulator of Scar/WAVE complex, CYRIPS (Cyfip related Rac interacting pseudopod splitter) from a proteomics screen. CYRIPS shows sequence similarity to CYFIP1/2 in a sequence domain of unknown function DUF1394 and myristoylation at an N-terminal conserved sequence. We demonstrate specific binding of CYRIPS DUF1394 to activated Rac1 in a region of shared homology with CYFIP proteins, establishing DUF1394 as a new Rac1 binding domain. CYRIPS-depleted cells have broad, Scar/WAVE-enriched lamellipodia and enhanced Rac1 signalling. CYRIPS-B knockout D. discoideum and mammalian cells also frequently assume a single leading pseudopod suggesting a role for CYRIPS as a local inhibitor of the positive signals that trigger actin-based motility. Conversely, CYRIPS over-expressers show fenestrated dendritic protrusions with reduced Scar/WAVE accumulation. We have identified the primary Rac1 interaction site and created mutants to demonstrate the importance of Rac1 binding in vivo.
In a 3D-cyst model, Rac1 signal is fundamental for establishment and maintenance of apical-basolateral polarity. CYRIP5-knockdown cells affect lumen formation and Scar/WAVE complex localization and these phenotypes can be partially reverted by chemical inhibition of Rac1. We conclude that CYRIP5 is a new evolutionarily conserved protein that competes with the Scar/WAVE complex for active Rac via its DUF1394 domain.

**The F-BAR protein Hof1 and Bud6: negative and positive regulatory components in a feedback loop controlling formin-mediated actin assembly.**  
M. Garabedian¹, T. Rands¹, B.L. Goode⁴;  
¹Biology, Brandeis University, Waltham, MA

In S. cerevisiae, the formin Bnr1 is anchored at the bud neck, where it assembles a network of polarized actin cables that enter the mother cell compartment and direct myosin-based transport of secretory vesicles, organelles, and other cargo to the growing daughter cell (bud) to enable polarized growth. However, it is still not well understood how Bnr1 activities are controlled spatially and temporally to generate actin cables of the correct length, shape, and architecture to enable efficient trafficking and growth. We previously showed that the F-BAR protein Hof1, which colocalizes with Bnr1 at the bud neck, uses its SH3 domain to directly inhibit the FH1 domain of Bnr1 (Graziano et al, 2014). Here, we report that the F-BAR domain of Hof1 makes a distinct, complementary contribution to inhibiting Bnr1, blocking the activities of the FH2 domain. Consistent with these biochemical effects, deletion of the Hof1 F-BAR domain in vivo leads to defects in cable formation without altering Hof1 localization, as analyzed by confocal and super-resolution microscopy. In addition, purified full-length (FL) Hof1 shows substantially stronger inhibitory effects on Bnr1 ($IC_{50} < 5 \text{ nM}$) than either half of Hof1 alone. Single particle EM analysis of the Hof1-Bnr1 complex lends insights into the mechanism of inhibition. Remarkably, the potent inhibitory effects of Hof1 on Bnr1 are overcome in vitro by the addition of a second formin ligand, Bud6. Further, bud6Δ suppressed hof1Δ defects in cable morphology and vesicle transport. Super-resolution microscopy revealed that Hof1 and Bnr1 both localize in striated patterns at the bud neck, correlating with septin sub-structures. In contrast to Hof1, Bud6 localized to secretory vesicles, suggesting that it promotes the growth of the very actin cables on which it is trafficked. Taken together, we propose that Hof1 and Bud6 function as negative and positive regulatory components in a feedback loop controlling Bnr1-mediated actin cable formation.

**Control of yeast actin cable formation by a novel formin regulator, Bil2.**  
T.J. Rands¹, B.L. Goode⁴;  
¹MCB, Brandeis, Waltham, MA

Yeast actin cable formation is a tightly regulated process. Cables are continuously being polymerized at their barbed ends at $>200$ subunits per second by two formins (Bni1 and Bnr1), balanced by disassembly at their pointed ends. Further, cable length and orientation must match the cellular compartment in which they are assembled in order to optimally transport secretory vesicles to facilitate polarized growth. Previously, we characterized four different binding partners of Bni1 and/or Bnr1 (Bud6, Bud14, Smy1, Hof1), which each influence cable architecture and dynamics in unique ways. We also identified Bil1 as a new Bud6-interacting ligand required for proper cable formation (Graziano et al., 2013). Here,
we report the characterization of Bil2, a new ligand of Bud6, which has novel effects on formin regulation. In bulk and TIRF microscopy assays, purified Bil2 alone inhibited the nucleation effects of Bnr1 but not Bni1. In contrast, full-length Bud6 enhanced the nucleation activities of both formins. In the combined presence of Bil2 and Bud6, Bnr1 was inhibited, while Bni1 was stimulated. Thus, Bil2 appears to have negative regulatory effects on Bnr1, and positive regulatory effects on Bni1. In vivo, a deletion of Bil2 led to disorganized actin cable networks and defects in secretory vesicle transport. Further, we found that Bil2 and Bud6 localize to secretory vesicles. Together, these results suggest that Bil2 and Bud6 may function as components of a ‘split-feedback loop’ mechanism controlling actin cable assembly. Bni1-nucleated cables that successfully transport Bil2-containing vesicles would be reinforced by positive feedback, whereas Bnr1-nucleated cables would be dampened by negative feedback. This might explain how Bni1, despite having much weaker nucleation activity compared to Bnr1, is able to generate increasing levels of actin cables in the expanding bud compartment.

Nance Horan Syndrome-Like 1 (NHSL1) protein is a novel Ena/VASP and Scar/WAVE ligand and negatively regulates cell migration.
A. Law¹, A. Jandke², G. Pula³, A. Guni³, M. Krause³;
¹Randall Division of Cell and Molecular Biophysics, King's College London, London, United Kingdom; ²London Research Institute, Immuno-surveillance Laboratory, Cancer Research UK, London, United Kingdom; ³Pharmacy and Pharmacology Department, University of Bath, Bath, United Kingdom

Controlled cell migration is essential for development, homeostasis and wound healing, and its deregulation has detrimental consequences, which include developmental defects and cancer metastasis. Efficient cell migration requires actin polymerisation, which pushes the plasma membrane of lamellipodia, the leading edge of cells, forward. Precise fine-tuning of actin filament length and branching is important in this process and are regulated by several proteins, which include Ena/VASP for actin elongation and the Scar/WAVE-ARP2/3 complexes for actin branching (see review: Krause and Gautreau, 2014). Both Ena/VASP and the Scar/WAVE complex localise at the leading edge of cells and are key effectors of cell migration.

We have identified Nance Horan Syndrome-Like 1 (NHSL1) protein as a novel Ena/VASP ligand, which contains two Ena/VASP binding sites. NHSL1 dynamically localises to the protruding edge of lamellipodia where it co-localises with Ena/VASP proteins. We also found that NHSL1 directly interacts with the Scar/WAVE complex via the SH3 domain of Abi, a component of the Scar/WAVE complex. We mapped this interaction to three sites within NHSL1. NHSL1 co-immunoprecipitates with both Ena/VASP proteins and the Scar/WAVE complex. Interestingly, both interactions between NHSL1 and Ena/VASP or Scar/WAVE are positively regulated by active Rac, which is a key regulator of cell migration. Surprisingly, we found that NHSL1 significantly decreases 2D random cell migration speed and persistence. Using specific NHSL1 mutants, which cannot bind to Ena/VASP, Scar/WAVE or both, we revealed that on 2D substrates, NHSL1 negatively controls random cell migration speed via Scar/WAVE but not Ena/VASP proteins.

We have previously shown that Lamellipodin, another leading edge protein, which interacts with Ena/VASP and Scar/WAVE, positively regulates 2D cell migration via Scar/WAVE and 3D migration via both, Ena/VASP and Scar/WAVE (Law et al., 2013; Carmona et al., 2016). Here, NHSL1 interaction with Scar/WAVE may provide a negative feedback loop important for the temporal and spatial fine-tuning of lamellipodia protrusion for timely and controlled cell migration.

Rapid and dynamic arginylation of the leading edge β-actin is required for cell migration.
I. Pavlyk1, N.A. Leu1, P. Vedula1, A. Kashina1, S. Kurosaka1;
1Department of Biomedical Sciences, University of Pennsylvania, Philadelphia, PA

β-actin plays key roles in cell migration and is one of the most ubiquitous, abundant, and essential proteins in eukaryotic cells. Our previous work demonstrated that β-actin in migratory non-muscle cells is N-terminally arginylated and this is required for normal lamellipodia extension. Mouse embryonic fibroblasts lacking arginyltransferase (Ate1) show impairments in migration rates and leading edge function, but the exact role of beta actin in this process is not understood. Here we examined the function of β-actin arginylation in cell migration. We found that arginylated β-actin is concentrated at the leading edge of lamellipodia and that this enrichment is abolished after serum starvation as well as in contact-inhibited cells in confluent cultures, suggesting that arginylated β-actin at the cell leading edge is coupled to active migration. Arginylated actin levels exhibit dynamic changes in response to cell stimuli, lowered after serum starvation and dramatically elevating within minutes after cell stimulation by re-addition of serum or lysophosphatidic acid (LPA). This dynamic changes are not seen in confluent contact-inhibited cell cultures and require active translation. Microinjection of arginylated actin antibodies into cells severely inhibits their migration rates. Together, these data strongly suggest that arginylation of β-actin is a tightly regulated dynamic process that occurs at the leading edge of locomoting cells in response to stimuli and is integral to the signaling network that regulates cell migration.

Ras activity stabilizes the actin fusion focus at cell contact sites prior to cell-cell fusion.
L. Merlini1, S.G. Martin1;
1Department of Fundamental Microbiology, University of Lausanne, Lausanne, Switzerland

In fission yeast Schizosaccharomyces pombe, two cells of opposite mating type fuse during the sexual life cycle to form a zygote. This process requires the activation of pheromone signaling that engages a GPCR-Ras-MAPK cascade to trigger sexual differentiation. Cell-cell fusion further necessitates local cell wall digestion, which relies on the stabilization of a dedicated actin-based aster, the fusion focus. This structure underlies the concentration of the pheromone secretion and perception machineries at a focal point. Reciprocally, local activation of the downstream MAPK signaling cascade spatially constrains the focus, leading to its immobilization at facing locations in the two partner cells, thus providing a positive feedback for cell-cell fusion. By constructing a live-reporter of active Ras1 (Ras1-GTP), we discovered that Ras1 is active at polarity sites, with activity peaking on the fusion structure just prior to fusion. Remarkably, constitutive Ras1 activation promoted fusion focus stabilization and fusion attempts irrespective of cell-cell pairing, leading to cell lysis. Ras1 activity is restricted by the GTPase activating protein (GAP) Gap1, itself recruited to sites of Ras1-GTP. While the GAP domain of Gap1 on its own does not suffice for this localization, its recruitment to Ras1-GTP sites is essential to block untimely fusion attempts. We propose that negative feedback control of Ras activity restraints the MAPK signal and couples fusion with cell-cell pairing.

Deconvolution of subcellular protrusion heterogeneity reveals the role of VASP in accelerating cell protrusion.
C. Wang1, H. Choi1, S. Kim1, Y. Bae2, K. Lee3;
1Biomedical Engineering, Worcester Polytechnic Institute, Worcester, MA, 2Pathology and Anatomical Sciences, University at Buffalo, Buffalo, NY

Cell protrusion is morphodynamically heterogeneous at the subcellular level. However, the mechanistic understanding of protrusion activities is usually based on the ensemble average of actin regulator dynamics at the cellular or population levels. Here, we establish a machine learning-based computational framework called HACKS (deconvolution of Heterogeneous Activity Coordination in cytoskeleton at a Subcellular level) to deconvolve the subcellular heterogeneity of lamellipodial protrusion. HACKS identifies distinct subcellular protrusion phenotypes hidden in highly heterogeneous protrusion activities and reveals their underlying actin regulator dynamics. The association between each protrusion phenotype and the actin regulator dynamics is further corroborated by predicting the protrusion phenotype based on actin regulator dynamics. Using our method, we discovered the hidden rare ‘accelerating’ protrusion phenotype in addition to ‘fluctuating’ and ‘periodic’ protrusions. Intriguingly, the accelerating protrusion was driven predominantly by VASP-mediated actin elongation rather than by Arp2/3-mediated actin nucleation. Our analyses also suggested that VASP controls protrusion velocity more directly than Arp2/3 complex, thereby playing a significant role in the accelerating protrusion phenotype. Taken together, we have demonstrated that HACKS allows us to discover the fine differential coordination of molecular dynamics underlying subcellular protrusion heterogeneity via a machine learning analysis of live cell imaging data.

Coordinated formation and disassembly of a contractile actomyosin network mediates content release from large secretory vesicles.
E.D. Scheijter1, D. Segal1, A. Zaritsky2,3, D. Meyen1, T. Rousso1, B. Shilo1;
1Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, 2Lyda Hill Department of Bioinformatics, UT Southwestern Medical Center, Dallas, TX, 3Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel

Coordinated formation and disassembly of contractile actin-based structures has been shown to underlie diverse settings of tissue morphogenesis. Here we propose that such a mechanism mediates the contractile activity necessary for content release from large secretory vesicles. A common feature of these systems is formation of an actin coat around each vesicle following their fusion with the apical cell membrane and recruitment of myosin, which together mediate the forces necessary for vesicle contraction. Using live imaging of cultured Drosophila larval salivary glands, an established model for such secretory systems, we have followed the dynamics of actomyosin coat formation and content release from glycoprotein (“glue”)-filled vesicles into the gland lumen. We previously demonstrated critical regulatory roles for the Rho1 GTPase in both actin coat formation (via activation of the Formin-family protein Diaphanous) and Myosin II-based contraction (via Rho kinase). Surprisingly, we have now found that disassembly of the actin coat, which accompanies vesicle content release, is necessary for contraction of the actomyosin network. This process was monitored using secretion-arrested vesicles, and found to be dependent on Rho1 inactivation, mediated by a dedicated RhoGAP and branched-actin
polymerization. The sequential temporal recruitment of active Rho and its inhibitors is evident by cycles of active Rho1 and actin coat accumulation and depletion in such vesicles, implying that a feedback-based mechanism regulates actin coat disassembly from the vesicle surface. Contraction-driven content release, the final step of this form of exocytosis, is therefore achieved by coordinating formation and disassembly of the contractile machinery.

**Simultaneous Imaging and Functional Studies Reveal a Tight Correlation Between Calcium and Actin Networks.**

C.S. Bascom Jr1,2, M. Bezanilla3, L. Winship4;

1Biology, University of Massachusetts, Amherst, MA, 2UMass Plant Biology Graduate Program, Amherst, MA, 3Biology, Hampshire College, Amherst, MA

Tip growing cells elongate in a highly polarized manner via focused exocytosis. Calcium and actin have been implicated as vital components of a feedback loop regulating the deposition of cell wall material. However, establishing a mechanistic understanding of the interaction between calcium, actin and growth in vivo has remained challenging. Here, we investigated the calcium-actin interplay in the moss Physcomitrella patens, which provides a system with an abundant source of genetically identical tip-growing cells, excellent cytology, and a large molecular genetic tool kit. To visualize calcium, we used a genetically encoded cytosolic FRET probe, revealing a fluctuating tipward gradient with a complex oscillatory profile that was analyzed with wavelet analysis. Wavelet analysis enabled the quantitative comparison of the calcium behavior in cells where growth was inhibited mechanically, pharmacologically, or genetically. We found that cells with suppressed growth have calcium oscillatory profiles with longer frequencies, suggesting that there is a feedback between the calcium gradient and growth. To investigate the mechanistic basis for this feedback, we simultaneously imaged cytosolic calcium and actin. We found that high cytosolic calcium promotes disassembly of a tip-focused actin spot, while low calcium promotes assembly. In support of this, abolishing the calcium gradient resulted in dramatic actin accumulation at the tip. Together these data demonstrate that tip-ward calcium is quantitatively linked to actin accumulation in vivo and that the moss P. patens provides a powerful system to uncover mechanistic links between calcium, actin and growth.

**CAP2 loss activates MRTF/SRF signaling in cardiomyocytes.**

Y. Xiong1, A. Mu2, S. Berritt3, J. Field1;

1Department of Systems Pharmacology and Translational Therapeutics, University of Pennsylvania, Philadelphia, PA, 2Cardiovascular Institute, University of Pennsylvania, Philadelphia, PA, 3Department of Chemistry, University of Pennsylvania, Philadelphia, PA

Sudden cardiac death kills 180,000 to 450,000 Americans annually, predominantly males. A locus that causes developmental disorders and confers a risk for sudden cardiac death and conduction disease is located at 6p22, near the cytoskeletal gene, CAP2. CAP2 regulates actin dynamics in the cytoskeleton by binding actin monomers and assisting filament severing to modulate the balance of filamentous actin (F-actin) and globular actin (G-actin). To determine the role of CAP2 in vivo, we generated whole-body knockout (KO) mice and conditional KO models. CAP2 KO in both models show evidence of cardiac conduction disease and all the cardiomyocyte specific KO mice died suddenly due to complete heart...
block by 26 wks of age. RNA-seq analysis of CAP2 KO hearts revealed over-activation of MRTF/SRF regulated genes such as Myl-9 and Acta-2. The over-activated SRF signaling is specific for heart tissue as well as isolated cardiomyocytes and seen in mice of all ages tested. To test if we could treat CAP2 KO mice, we synthesized and tested an SRF transcription inhibitor CCG-1423-8a. CCG-1423-8a inhibited MRTF translocation in MEF cells and the signaling of an SRF luciferase reporter cells. When tested in mice, CCG-1423-8a reduced expression of Myl-9 and Acta-2 in the heart. Our study suggests that MRTF/SRF may be targeted in some forms of sudden cardiac death and cardiac conduction disease.

Arp 2/3-dependent spatial organization of the B cell receptor (BCR) impacts immune synapse formation, BCR signaling output, and B cell activation.

M. Bolger-Munro\(^1\), K. Choi\(^1\), R. Chappell\(^2\), J. Scurl\(^1\), L. Abraham\(^1,2\), M. Dang-Lawson \(^1\), D. Sheen\(^1\), D. Coombs\(^3\), M.R. Gold\(^1\);

\(^1\)Microbiology and Immunology, University of British Columbia, Vancouver, BC; \(^2\)Mathematics, University of British Columbia, Vancouver, BC

Contact-dependent cell:cell communication is a critical component of many biological processes from development to tissue maintenance to the immune system. The immune synapse (IS) is a contact-dependent cellular communication platform that is important for activating, amplifying and executing immune responses. A B cell IS is formed when antigens displayed on the surface of an antigen-presenting cell (APC) are recognized by the B cell receptor (BCR), triggering dynamic, multi-scale reorganization of the BCR and associated signal transduction machinery. Initially, BCRs are gathered into microclusters that are dispersed throughout the B cell:APC contact site, which are then coalesced into a supramolecular activation cluster (cSMAC) at the center of the contact site. Although the clustering of BCRs into microclusters and the recruitment of signaling enzymes into microsignalosomes increases BCR signaling efficiency, the molecular mechanisms controlling BCR organization during IS formation are not fully understood. Importantly, how the spatial patterning of the BCR promotes the translation of extracellular information (recognition of membrane-associated antigens) into functional outcomes (B cell activation) is not clear. By imaging the B cell:APC contact site in real time, we showed that inhibition of the actin-related protein 2/3 (Arp2/3) complex, which nucleates the formation of branched actin networks, had no effect of BCR microcluster formation but prevented the coalescence of dispersed BCR microclusters into an immune synapse cSMAC. Based on this finding, we tested the hypothesis that this dynamic spatial patterning of the BCR optimizes BCR signaling and the B cell response to membrane-associated antigens. Using both Arp3 siRNA and the Arp2/3 inhibitor CK-666, we found that cSMAC formation is important for amplifying initial BCR signaling reactions that are stimulated by APC-bound antigens. Additionally, Arp2/3-dependent cSMAC formation is important for APC-associated antigens to stimulate BCR-induced transcriptional responses and upregulation of the activation CD69 and CD86. In contrast, Arp2/3 function is dispensable for BCR signaling and subsequent functional response to non-polarized soluble antigens. Therefore, our data indicate that the dynamic spatial patterning of BCRs is controlled by Arp2/3-dependent branched actin networks and that this is important for B cell responses to spatially-restricted antigens that are presented to B cells by APCs. Overall, our work shows that the spatial patterning of receptors can encode information that impacts cellular decision-making.

A geodesic septin lattice is required for actomyosin contractility on micron-scale curved membranes in vivo.

S. Ebrahim¹, A. Shitara², H. Shroff², B. Kachar³, R. Weigert¹;  
¹NCI, NIH, Bethesda, MD, ²NIBIB, NIH, Bethesda, MD, ³NIDCD, NIH, Bethesda, MD

The ability of cell membranes to remodel into various curved configurations is fundamental for processes from cytokinesis to intracellular trafficking. Generation of membrane curvature by proteins is an important biological concept that is well studied in nanometer-scale curved membranes such as endocytic vesicles, where curvature-generating proteins include clathrin, and BAR-domain proteins. However, little is known about the proteins or mechanisms driving the formation and dynamics of larger, micron-scale membrane curvature within the cell such as around the cytokinetic furrow, secretory vesicles, or the ciliary base.

To address this question under physiological conditions we used intravital subcellular microscopy (ISMIC) in live mice to study regulated exocytosis in specialized secretory cells of the salivary gland. During this process large (~1.5 μm) vesicles, called secretory granules (SGs), containing proteinaceous cargo fuse with narrow, tube-like canaliculi at the apical plasma membrane (APM) after GPCR stimulation. A fusion pore then forms to allow flow of SG contents into the canaliculi, and integration of the SG membrane into the APM. The canalicular diameter (~0.3 μm) is almost an order of magnitude smaller than the SG diameter, making membrane integration energetically unfavorable. Thus, we asked how the SG membrane is forced into the APM forming the narrow canaliculi, and found that F-actin and non-muscle myosin (NMII) localize to the fused SG membrane and provide the forces needed for integration. We then asked, how these proteins are recruited to and organized on the curved membrane. Using knockin mice expressing GFP-NMIIA and superresolution microscopy, we describe for the first time that F-actin and NMII organize around SGs as a striking geodesic lattice with triskelia-like tripolar vertices, reminiscent of the clathrin cage around endocytic vesicles. NMIIA and actin within the lattice are partially offset, consistent with the lattice being contractile. We also show that septins, which recognize membrane-scale curvature, also form lattices around SGs, that are in register with NMIIA. Disruption of F-actin assembly causes expansion of SGs, but surprisingly does not impair recruitment of NMII or septins. Pharmacological inhibition of septin, however, results in a significant decrease in activated NMII and myosin light chain kinase (MLCK) on fused SGs.

Based on our data, we propose that the septin-lattice 1) acts as a scaffold to recruit the actomyosin network to the surface of SGs, and 2) is needed for NMII activation, likely through MLCK-mediated phosphorylation. This novel septin-actin-NMII lattice on the SG surface provides new structure-function insights into protein-driven remodeling of micron-scale curved membranes in vivo.

Leukocyte transendothelial migration is key to inflammation. From rolling, leukocytes transfer to adhesion where they firmly bind to the inflamed endothelium followed by diapedesis through the endothelium. Upon inflammation, endothelial cells express small finger-like protrusions that stick out into the lumen. The function and regulation of these structures are unclear. We present evidence that these ICAM-1- and F-actin-rich endothelial finger-like protrusions are filopodia and function as adhesive structures for leukocytes to transit from rolling to crawling, but are dispensable for diapedesis. Mechanistically, these structures require the motor function of Myosin-X, the activity of the small GTPase Cdc42 and PAK4. Moreover, Myosin-X expression is under control of TNFα-mediated c-jun N-terminal kinase activity and upregulated in human atherosclerotic regions. Ex vivo en face and intravital imaging of GFP-positive inflamed murine vessels revealed the filopodia phenotype. This is the first study identifying the regulation of endothelial filopodia being crucial for leukocyte extravasation and could therefore play an important role in the progression of atherogenenesis.

Type I myosin-mediated coupling of actin assembly to the plasma membrane during clathrin-mediated endocytosis.
R.T. Pedersen1, D.G. Drubin1;
1Department of Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Interaction of the actin cytoskeleton with cellular membranes is critical for a variety of essential cellular processes, from migration to membrane trafficking. Thus, understanding how actin is coupled to membranes is central to understanding many fundamental aspects of cell biology. The actin cytoskeleton exerts forces on membranes through assembly and myosin motors. Considerable effort has been made to study each of these two modes of force generation, but less research has focused on how the two are coordinated. Clathrin-mediated endocytosis in the yeast Saccharomyces cerevisiae provides a unique opportunity for studying this coordination owing to a well-documented requirement for both actin assembly and myosin activity and the unparalleled molecular and genetic tools in this organism. During S. cerevisiae clathrin-mediated endocytosis, actin assembly is required to invaginate the plasma membrane into a pit that can undergo scission. Type I myosins are also required for pit formation, conferring at a minimum membrane binding and myosin motor activities to the essential actin assembly complex. Endocytosis was shown previously to fail in the absence of type I myosins. However, how and why endocytosis fails was unknown. Here we performed live-cell two-color imaging of clathrin-mediated endocytosis in yeast cells relying on a series of engineered type I myosin mutant genes. We show that during clathrin-mediated endocytosis, the type I myosin Myo5 couples actin assembly to the plasma membrane.
membrane. Absent this crucial linkage, vesicles fail to be internalized. Actin assembly factors and assembling actin are recruited to endocytic sites but peel away from the plasma membrane before they can initiate invagination, frequently forming actin comets that rocket through the cytoplasm. Intriguingly, the endocytic WASP/Myosin module, previously thought of as a discrete complex, separates in these instances, with the yeast Wiscott-Aldrich Syndrome Protein (WASP) Las17 being left at the plasma membrane and the yeast WASP Interacting Protein (WIP) Vrp1 localizing to the tips of cytoplasmic comets. Our data demonstrate that type I myosins organize actin assembly factors and link them to the plasma membrane during clathrin-mediated endocytosis, coupling actin assembly to membrane deformation. The presence of type I myosins in many cellular actin networks involved in membrane budding leads us to suggest that organization and membrane linkage of actin assembly is a conserved function of these enigmatic motors.

Mechanistic principles underlying regulation of the actin cytoskeleton by phosphoinositides.
Y. Senju1, M. Kalimeri1, E. Koskela1, P. Somerharju1, H. Zhao1, I. Vattulainen2,4, P. Lappalainen1;
1Institute of Biotechnology, University of Helsinki, Helsinki, Finland, 2Department of Physics, Tampere University of Technology, Tampere, Finland, 3Faculty of Medicine, University of Helsinki, Helsinki, Finland, 4Department of Physics, University of Helsinki, Helsinki, Finland

The actin cytoskeleton provides forces for vital cellular processes involving membrane dynamics. Membrane phosphoinositides regulate many actin-binding proteins, including coflin, profilin, Dia2, N-WASP, ezrin and moesin, but the underlying mechanisms have remained elusive. By applying a combination of biochemical assays, novel photobleaching/activation approaches, and atomistic molecular dynamics simulations, we revealed that these proteins interact with membranes through multivalent electrostatic interactions, and hence function as phosphoinositide density sensors at the membrane. However, their membrane-binding kinetics differ drastically. Cofilin and profilin display transient, low-affinity interactions with phosphoinositide-rich membranes, whereas F-actin assembly factors Dia2 and N-WASP reside on phosphoinositide-rich membranes for longer periods to perform their functions. Ezrin and moesin, which link cytoskeleton to plasma membrane, bind membranes with very high affinities and slow dissociation dynamics, and do not require high “stimulus-responsive” phosphoinositide density for membrane-binding. Thus, membrane-interaction mechanisms of actin-binding proteins evolved to precisely fulfill their specific functions in cytoskeletal dynamics.

Ultrastructure of actin-myosin cytoskeleton during mitochondrial fission.
C. Yang1, H.N. Higgs2, T.M. Svitkina1;
1Biology, University of Pennsylvania, Philadelphia, PA, 2Biochemistry, Geisel School of Medicine at Dartmouth, Hanover, NH

Actin-myosin II cytoskeleton and endoplasmic reticulum (ER) play important roles in mitochondrial fission. However, the exact molecular mechanism of fission is not clear due to a lack of ultrastructural insights into organization of relevant molecular components. Platinum replica electron microscopy (PREM) has been very productive in revealing cytoskeleton architecture in various contexts, but visualization of the cytoskeleton together with membrane organelles, such as ER and mitochondria, by PREM is more challenging and has not been achieved before. We now have developed PREM techniques
to simultaneously reveal the cytoskeleton and membrane organelles and used them to analyze organization of ER and the actin-myosin II cytoskeleton around mitochondria in steady-state conditions and after induction of mitochondria fission. The identity of mitochondria and ER in PREM images was confirmed by correlative light and electron microscopy. Localization of important molecular players of mitochondrial fission, such as Drp1 and nonmuscle myosin II, was determined using immunogold PREM. We show that highly constricted mitochondria, which likely represent prefission intermediates, are often associated with a criss-cross array of long and mostly unbranched actin filaments that intersect each other approximately at the constriction site. These actin filaments sometimes appeared to extend from ER to the mitochondrion constriction site and further to another ER segment on the other side of the mitochondrion. The ER-associated actin filaments are likely nucleated by INF2-CAAX, because expression of a constitutively active INF2-CAAX results in the formation of many long actin filaments at the ER surface. Drp1 immunogold label was often found in association with actin filaments present around a mitochondrion or, sometimes, crossing over a mitochondrial constriction. Myosin II, however, was often enriched next to a constricted mitochondrion, but not exactly at the constriction site. We propose that myosin II constricts mitochondria in a corset-like fashion by pulling from a distance on the ER-associated long actin filaments that criss-cross around a mitochondrion

Opposing functions of F-BAR proteins CIP4 and FBP-17 in neuronal membrane protrusion, tubulovesicle formation and neurite outgrowth are largely encoded in their first linker region. K.L. Taylor1, R. Taylor1, B. Huynh2, K. Richters1, J. Carrington2, M. McDermott3, E.W. Dent1,2; 1Neuroscience Training Program, University of Wisconsin Madison, Madison, WI, 2Neuroscience, University of Wisconsin Madison, Madison, WI

In the nervous system, the dynamic processes of membrane protrusion and invagination are necessary for cell migration and differentiation, requiring the coordination of both the plasma membrane and the actin cytoskeleton. F-BAR family proteins are involved in sensing and altering membrane curvature through their F-BAR domain and function in endocytosis. In addition to the F-BAR domain the Cdc42 Interacting Protein 4 (CIP4) subfamily of proteins (CIP4, TOCA1 and FBP17) have an HR1 domain, which binds active Rho family GTPases, and an SH3 domain, that interacts with actin-associated proteins and dynamin. Previous work on CIP4 family proteins has focused on their ability to form elongated tubulovesicles when overexpressed in nonneuronal cells. Our recent work in primary neurons indicates that CIP4 localizes to the protruding edge of neurons, increases veil protrusion and negatively regulates neurite outgrowth. Here we show that expression of FBP17, in contrast, induces tubular structures in primary cortical neurons that colocalize with the endocytic marker Cholera toxin B subunit. FBP17 expression also decreases veil formation and results in precocious neurite formation. To determine how two highly homologous family members localize and function antagonistically in neurons we performed a structure-function analysis by domain and linker region swapping. Surprisingly, we discovered that swapping CIP4 and FBP17 F-BAR, HR1 and SH3 domains had relatively little effect on the localization and function of the two proteins. Rather, the first linker region (L1), between the F-BAR and HR1 domains, is capable of almost fully reversing the localization and function of CIP4 and FBP17. Together, these results suggest that CIP4 and FBP17 work as an antagonistic pair to fine tune membrane protrusion, endocytosis and neurite formation during early neuronal development.

Formin-mediated actin polymerization triggers constriction of both mitochondrial membranes during mitochondrial division.

R. CHAKRABARTI, W. Ji, H.N. Higgs; 1

1Biochemistry and cell biology, Geisel School of Medicine, Hanover, NH

While the roles for actin in cell motility are well characterized, their roles in controlling organelle dynamics are less well described. We have previously shown that actin polymerization through an endoplasmic reticulum-bound formin protein, INF2, mediates mitochondrial division by stimulating recruitment and oligomerization of the dynamin GTPase Drp1. Drp1 activity then drives constriction of the outer mitochondrial membrane (OMM). Here, we show that INF2-mediated actin polymerization plays a second role in mitochondrial division, driving inner mitochondrial membrane (IMM) constriction through a calcium-dependent mechanism. Upon stimulation of U2OS cells with histamine, INF2-mediated actin polymerization is rapidly activated (T1/2 3.8 ± 0.9 sec), followed by an increase in mitochondrial calcium (T1/2 7.5 ± 1.9 sec). The mitochondrial calcium increase is abolished by LatA treatment or INF2 suppression. Electron microscopy shows that INF2 suppression eliminates an increase in stimulus-induced ER-mitochondrial contacts (contact distance <30 nm), which are necessary for efficient transfer of calcium from ER to mitochondrion through the mitochondrial calcium uniporter (MCU). Over-expression of ER-mitochondrial tethering proteins rescues the mitochondrial calcium defect in INF2-KO cells. Mitochondrial calcium entry drives IMM constrictions, and MCU suppression abolishes these constrictions without changing Drp1 recruitment. Live-cell super-resolution microscopy shows that IMM division precedes OMM division. Myosin IIA activity is also required for stimulus-induced mitochondrial calcium increase and IMM constrictions, but this process does not require Arp2/3 complex. These results demonstrate that acto-myosin contractility drives dynamics of both mitochondrial membranes independently during mitochondrial division: IMM constriction through increased mitochondrial calcium, and OMM constriction through Drp1 recruitment.

Generation of mouse models for muscular dystrophic chicken by CRISPR/Cas9-mediated genome editing.

M. Imamura, Y.U. Inoue, T. Inoue, S. Takeda; 1

1Department of Molecular Therapy, National Institute of Neuroscience, NCNP, Tokyo, Japan,
2Department of Biochemistry and Cellular Biology, National Institute of Neuroscience, NCNP, Tokyo, Japan

A missense mutation in the WWP1 gene was reported as the cause of muscular dystrophy of the NH-413 chicken by genetic linkage analysis. WWP1 is a HECT-type E3 ubiquitin protein ligase composed of three functional domain regions, i.e., an N-terminal C2 domain for calcium-dependent phospholipid binding, a central region containing four tandem WW domains recognize substrates with the proline-rich peptide motifs, and a C-terminal HECT catalytic domain for ubiquitin transfer from E2 to substrates. In chicken skeletal muscle, WWP1 is detected as a 130-kDa protein that localizes to various structures, such as the sarcolemma, sarcoplasmic reticulum, mitochondria, and the nucleus. However, in NH-413 chickens, the mutant WWP1 protein was markedly reduced and was faint or absent in the sarcolemma. The missense mutation changes arginine into glutamine in the center of the WW domain cluster, which gives rise to speculation that the amino-acid substitution would lead to critical alterations in WWP1 function by
defect of WW domains. To test the hypothesis, we generated mice with various deletion mutations in the area of WW domain cluster by CRISPR/Cas9-mediated genome editing, and examined the expression of the WWP1 variants. In the skeletal muscle of the mice lacking both the first and second WW domains (WW1-WW2) of WWP1, the remarkable protein reduction and loss of sarcolemmal localization were observed as is the case with NH-413 chicken skeletal muscle. The same result was also obtained in the mice that have a deletion of an entire WW2 domain. On the other hand, WWP1 clearly remained at sarcolemma in the deletion of a part of WW2 domain, although the protein expression was reduced to the same levels as the cases of deletion of WW1-WW2 and a whole WW2 domain. These findings suggested that the degradation and disappearance of mutated WWP1 at sarcolemma would occur independently from each other by defect of the WW domain function. Further studies on the relation between the mutation sites of WW domains and pathological symptom of the mice are needed to understand the molecular mechanism of WWP1-deficient muscular dystrophy.

The collapsin response mediator protein 4 (CRMP4) is enriched at actin structures formed by bacteria at the plasma membrane of epithelial cells.
M.D. Chua¹, J.A. Guttman¹;
¹Department of Biological Sciences, Simon Fraser University, Burnaby, BC

The actin polymerization machinery is recruited to the plasma membrane to create filamentous actin arrays and produce the force required for cell motility. To study this, actin-rich structures generated by bacterial pathogens such as enteropathogenic Escherichia coli (EPEC) pedestals, Salmonella enterica serovar Typhimurium (S. Typhimurium) membrane ruffles, and Listeria monocytogenes (L. monocytogenes) comet tails and listeriopods are often utilized as model systems. Through previous mass spectrometry analysis of EPEC pedestals, we identified a novel actin-associated protein called the collapsin response mediator protein 4 (CRMP4), in bacterially-induced actin structures. By immunolocalizing CRMP4 in infected HeLa cells, we found the protein concentrated at the tip of EPEC pedestals, within S. Typhimurium–generated membrane ruffles and at L. monocytogenes listeriopods. Interestingly, it was not present at L. monocytogenes comet tails. Moreover, CRMP4 does not accumulate around mutant bacteria that can not form actin-rich structures despite being associated with the host plasma membrane. Through this evidence, we suggest that CRMP4 is selectively recruited to membrane bound actin-rich structures made by EPEC, S. Typhimurium, and L. monocytogenes and that CRMP4 may have a novel function at the actin-plasma membrane interface.

Cryo-Electron Microscopy 3-D Analysis of heterodimeric KIF3 Motor Head Domains on Microtubules.
C. Page¹, S. Guzik², I. Rayment³, A. Hoenger¹, S.P. Gilbert²;
¹MCD-Biology, University of Colorado at Boulder, Boulder, CO, ²Biology, Rensselaer Polytechnic Institute, Troy, NY, ³Biochemistry, University of Wisconsin, Madison, WI

In its native configuration, the kinesin-2 KIF3 forms heterodimers between KIF3A and KIF3B, or KIF3A with KIF3C. Heterodimeric motor domains are relatively rare among kinesins, and the advantages of a
hetero- versus homodimer configurations are not fully understood. Here we use cryo-electron microscopy on microtubules that are decorated with either, non-physiological KIF3AA, KIF3BB, and KIF3CC homodimers, as well as native KIF3AB and KIF3AC heterodimers. Since high-resolution data from cryo-EM images are typically a product of intense averaging over numerous, identical image elements, getting to high resolution from heterodimeric constructs pose a particular challenge. Collecting and identifying identical image elements cannot be done by helical diffraction methods since phases of layer lines will be convoluted from the two different motor domains. To this end it will be crucial to identify each head by a specific marker that will allow for a prescreening of repetitive units along microtubules. Therefore, we collect first rounds of 3-D data by cryo-tomography, the only EM-based 3-D analysis process that does not rely on averaging or diffraction. Here we show preliminary data that point to distinct conformations of the various constructs, as well as preliminary high-resolution data that we have obtained from individual head domains.

Intracellular transport of vesicles, organelles, and other cargoes is driven by teams of kinesin, dynein, and myosin molecular motors. Frequently there are multiple motors of each type and directionality on each cargo, but how teams of motors coordinate their activity in order to give rise to the emergent “tug of war” behavior observed in cells remains poorly understood. Even less understood is the observation that knocking down specific motors diminishes transport in both directions, not only in the direction of the inhibited motor. In vitro and intracellular cargo tracking experiments seeking to understand the molecular mechanisms underlying bidirectional transport behavior have thus far been limited by two key factors: (1) the spatiotemporal resolution of existing microscopy techniques, without which short back-and-forth motions of the cargo blur together and average out, and (2) data analysis tools capable of ascribing the dynamics of position-over-time traces to the behaviors of the individual motors taking part in multi-motor transport. In the current work, we seek to address both of these limitations. We first introduce high-speed, super-resolution scattering microscopy techniques to track cargoes with 1-nm and 1-ms resolution. We next create a stochastic differential equation model to represent coupled motor and cargo positions, and apply it to our data using a combination of particle filtering and a stochastic expectation-maximization algorithm. Overall, we work towards quantitatively describing how each motor on the cargo dynamically interacts with the track and with the other motors in order to drive bidirectional transport.

¹Advanced Fluorescence Imaging Biophysics Group, ICFO, Barcelona, Spain, ²Physiology, Perelman School of Medicine (UPenn), Philadelphia, PA

Motor proteins play an essential role in cellular organization by carrying organelles along microtubules and delivering them at the right place. Recently, the clustering of dynein motors has emerged as a novel mechanism of regulating retrograde trafficking of large vesicles. We aimed to determine whether similar clustering mechanisms of retrograde and anterograde motor proteins play a role in the trafficking of small vesicles in intact cells. Using multi-color, 3D super-resolution microscopy and quantitative analysis, we revealed the organization of dynein, Kif5 and Kif3 on the membrane of lysosomes at the nanoscale level. Our results show that all motor proteins are organized in small teams composed of between 1-4 motor proteins on the lysosome membrane. However, the total number of motor teams on the membrane is differentially regulated for the three motors. In addition, this number scales differentially with the size of the lysosome among the different motors. Overall, our results reveal for the first time how various motor proteins are organized on the membrane of small vesicles in intact cells, giving new insights into mechanisms of transport regulation by motor protein clustering.

Kinesin-1, the founding member of kinesin superfamily proteins, is known to use only a subset of microtubules for transport in living cells. This biased use of microtubules is proposed as the guidance cue for polarized transport in neurons, but the underlying mechanisms are still poorly understood. Here we report that there is a positive feedback in the binding of kinesin-1 to the GDP-microtubule, which spontaneously produces high affinity microtubules from other low-affinity microtubules. This high affinity state requires the binding of kinesin-1 in the nucleotide-free state. Microtubules return to the initial low affinity state by washing out the binding kinesin-1 or by the binding of AMPPNP to kinesin-1. X-ray fiber diffraction, fluorescence speckle microscopy and second harmonic generation microscopy, as
well as cryo-EM, collectively demonstrated that the binding of nucleotide-free kinesin to GDP-microtubule changes the conformation of GDP-microtubule to a conformation close to the GMPCPP-microtubule.

Anterograde axonal transport in neurons is mediated by kinesin superfamily proteins (KIFs) which are microtubule-associated motor proteins. Effective axonal transport is required for proper neuronal function, and impaired axonal transport is involved in neurodegenerative diseases. However, it remains controversial how the interaction between cargo receptors and kinesin is regulated during the various stages of cargo transport, including during vesicular cargo formation at the Golgi, transportation in axons, and release in the nerve terminal.

Alcadein α (Alca)/Calsyntenin 1 is a type I membrane protein found as a molecule suppressing the cleavage of amyloid precursor protein (APP) (J. Biol. Chem. [2003] 278, 49448). Alca is also a major cargo of kinesin-1 that is subjected to anterograde transport in neuronal axons (EMBO J. [2007] 26, 1475). Two tryptophan- and aspartic acid-containing (WD) motifs located in its cytoplasmic domain directly bind the tetratricopeptide repeat (TPR) motifs of kinesin light chain (KLC), which activate kinesin-1 and recruit kinesin-1 into Alca cargo (Traffic [2012] 13, 834).

We found that phosphorylation of three serine residues in the acidic region located between the two WD motifs is required for interaction with KLC. Phosphorylation of these serine residues may alter the disordered structure of the acidic region to induce the direct association with KLC. Substitution of these serines with Ala results in a mutant that is unable to bind kinesin-1, which impairs exit of Alca cargo from the Golgi. Furthermore, vesicles containing Alca harboring these Ala mutations were analyzed for axonal transport using TIRF (Total Internal Reflection Fluorescence) microscopy. Alca mutant was still transported, albeit improperly by vesicles following mis-sorting of the Alca mutant with APP containing vesicles. This suggests that APP partially compensates for defective Alca in anterograde transport by providing an alternative cargo receptor for kinesin-1. The present results reveal the functional importance of Alca phosphorylation at multiple sites in regulating the transport of Alca cargo by kinesin-1, and the proper formation of post-Golgi Alca cargo.

Amyloid β-protein precursor (APP) is deeply implicated in Alzheimer’s disease pathogenesis by causing amyloid β-protein (Aβ). One of the most important functions of APP is as a cargo receptor for kinesin-1, a conventional kinesin. Functional kinesin-1 forms a tetramer comprising two kinesin heavy chains (KHCs) and two kinesin light chains (KLCs), and plays an essential role in anterograde transport of many cargos, including membrane vesicles, In neurons, APP is transported by binding to kinesin-1, mediated by JNK-interacting protein 1b (JIP1b), which generates the enhanced fast velocity and efficient high frequency of APP anterograde transport (Mol. Biol. Cell [2014] 25, 3569). The enhanced fast velocity requires a conventional interaction between JIP1b C-terminal region and kinesin light chain 1 (KLC1) tetratricopeptide repeat, whereas the efficient high frequency requires a novel interaction between the central region of JIP1b and the coiled-coil domain of KLC1. However, it remains unclear how the interaction of JIP1b with kinesin-1 is selectively regulated to control APP cargo transport. We found that the conventional interaction of KLC1 with JIP1b is regulated by a phosphorylation of KLC1 but not JIP1b. Substitution of Glu for the phosphorylatable amino acid of KLC1 abolished the conventional interaction and suppressed the enhanced fast velocity of APP cargo, but did not impair the novel interaction responsible for the efficient high frequency. Phosphorylation of KLC1 increased in aged brain and JIP1 binding to kinesin-1 decreased. The elevated phosphorylation of KLC1 that accompanies aging may induce a qualitative impairment of APP axonal transport, potentially promoting Aβ generation and contributing to neurodegenerative disorders such as Alzheimer’s disease.

Kinesin-2 motors adapted their stepping behaviour for progressive transport on axonemes and microtubules.
W.L. Stepp¹, G. Merck¹, F. Mueller-Planitz², Z. Ökten¹,³;
¹Department für Physik, Technische Universität München, Munich, Germany, ²Biomedical Center, Ludwigs Maximilians Universität, Munich, Germany, ³Munich Center for Integrated Protein Science, Munich, Germany

Kinesin-2 is employed in both cytoplasmic and intraflagellar long-range transport. It therefore employs two structurally distinct filament tracks, axonemes in cilia and microtubules in the cell body. We tracked the heads of single kinesin-2 molecules with Fluorescence Imaging with One Nanometer Accuracy (FIONA) on both axonemes and microtubules. The distribution of step sizes and the traces observed show that the motors adapt their stepping behavior to the respective track. While kinesin-2 takes directional, off-axis steps on microtubules, it resumes a straight path on axonemes. This provides a molecular explanation for the direction-dependent allocation of cargo to one side of the same doublet microtubule that has been observed previously. The intrinsic tendency of kinesin-2 to take sidesteps on the microtubule lattice restricts the motor to the B-tubule. These results offer first mechanistic insights
into why heterodimeric kinesin-2 was co-evolved with the ciliary machine to achieve effective two-way traffic on the axoneme in vivo.

**Axonal access is regulated by KIF13/KLP-4 in vivo.**

K.J. Perkins¹, J.N. Pieczynski²;

¹Department of Biology, Rollins College, Winter Park, FL

Cells rely heavily on a polarized and dynamic microtubule system and its associated molecular motor proteins; the (mostly) plus end directed kinesins and minus end directed dyneins, for a multitude of functions. Microtubule motors not only ensure that a cell establishes its proper morphology and polarity, but also allow the cell to have efficient spatial and temporal movement of both organelles and vesicles to facilitate robust signal transduction pathways. This is particularly true in neurons, where a specialized cellular morphology, such as long axonal projections and access to this space, is inherently tied to high degree of dynamic signaling mechanisms. To establish a signaling network along an axon likely requires motors that are highly processive, that is the ability to bind microtubules with high affinity and carry cargo a distance. Motors of the Kinesin-3 superfamily, including the KIF1, KIF13, KIF14, and KIF16 subfamilies, are all expressed in neurons and exhibit highly processive activity in vitro, however questions still remain as to how these highly processive motors contribute to neuronal cell morphology and signal transduction in vivo. Due to its well-described nervous system and quantifiable behaviors, we are using C. elegans to study Kinesin-3 motors and their roles in neuronal signaling in vivo. We began by employing a reverse genetics approach using the worm homologue to KIF13A and KIF13B, klp-4 to determine in vivo function of these motors. We isolated mutant alleles of klp-4 predicted to effect protein function. We hypothesized that klp-4 mutation would effect cellular signaling and therefore animal behavior; and mutation in klp-4 does indeed result in changes in locomotive behaviors such spontaneous reversals and nose touch challenge suggesting a role for KLP-4 in neuronal signaling. Surprisingly, when we used rab-3::eGFP to visualize the presynaptic areas of klp-4 mutants, we discovered that klp-4 mutation lead synapses that were increased number, misorganized, and larger. Additionally, touch receptor neurons also displayed increased abnormal ectopic projections. When assessed for neurotransmitter specific behaviors, klp-4 mutants display significantly increased sensitivity to acetylcholinesterase inhibitors and altered sensitivity to exogenous serotonin. The above data suggests KLP-4 is a regulator of neuronal signaling by mediating synaptic organization and neurotransmitter mediated signaling by restricting cargo movement into and long the axon and that despite their highly processive nature, certain Kinesin-3 motors might function in both moving and restricting cellular cargoes during cell signaling events in vivo.

Motor proteins, such as kinesins and dyneins, are responsible for several fundamental transport functions inside the cell. Impaired functionality of motor proteins, possibly due to mutations, have been linked to disruptions in intracellular transport and neurodegenerative diseases such as Huntington's and Alzheimer's disease, muscular disorders such as heart disease, uterine complications and high blood pressure. A known fact about intracellular transport is that the transfer of cargoes is often facilitated by teams of motor proteins, possibly of same or different types. It is particularly significant to study transport of cargo by both wild-type and mutant motor proteins. An exhaustive experimental analysis of specific mutations and its effect on multiple motor based transport is prohibitively time consuming due to combinatorial nature of the study. Thus, there is a significant need for analytical/computational methods to inform experiments. We addressed this by developing a semi-analytical computational methodology to compute average run-length and velocity when cargo is carried by multiple types of motor proteins. The simulation technique is able to correctly predict existing experimentally observed phenomena regarding the dependence of run-length and velocity on parameters such as ATP concentration and load force, indicating its reliability. Instantiation of this method for a recently reported mutation implicated in Huntington's disease, which indicated reduced single kinesin stall force, revealed surprising insights. Primarily, in cargoes carried by multiple wild-type and mutant kinesin, mutant motors determine the average velocity and run-length even when they are outnumbered by wild type motors in the ensemble when operating under certain external conditions. It is predicted that mutants gain a competitive advantage and lead to increased run-length when load on the cargo is in the vicinity of the mutant's stalling force or multiples of its stalling force. This can have several implications towards understanding the effect of mutations on coordinated transport and knowing which single motor characteristics, when altered, leads to impaired cargo transport. Furthermore, the unique nature of this method enables study of rare events and provides with results whose accuracy is independent of the number of iterations. The approach uses significantly less computational resources than other Monte Carlo based approaches, enabling reasonably-sized ensembles to be studied using standard desktop computers. The methodology can be further extended to study the effect of other single motor mutations on coordinated cargo transport as well as the study of transport by different types of motor proteins, while providing new prognoses to be tested experimentally.

Kinesin-based cargo transport in cells frequently involves the coordinated activity of multiple motors, including kinesins from different families that move at different speeds. However, compared to the progress at the single-molecule level, mechanisms by which multiple kinesins coordinate their activity during cargo transport are poorly understood. To understand these multi-motor coordination mechanisms, defined pairs of kinesin-1 and kinesin-2 motors were assembled on DNA scaffolds and their motility examined in vitro. Although less processive than kinesin-1 at the single-molecule level, addition of kinesin-2 motors more effectively amplified cargo run lengths. By applying the law of total expectation to cargo binding durations in ADP, the kinesin-2 microtubule reattachment rate was shown to be 4-fold faster than that of kinesin-1. This difference in microtubule binding rates was also observed in solution by stopped-flow. High-resolution tracking of gold-nanoparticle-labeled cargo with 1 ms and 2 nm precision revealed that kinesin-2 motors detach and rebind to the microtubule much more frequently than do kinesin-1. Finally, cargo transported by kinesin-2 motors more effectively navigated roadblocks on the microtubule track. These results highlight the importance of motor reattachment kinetics during multi-motor transport and suggest a coordinated transport model in which kinesin-1 motors step effectively against loads while kinesin-2 motors rapidly unbind and rebind to the microtubule. This dynamic tethering by kinesin-2 maintains the cargo near the microtubule and enables effective navigation along crowded microtubules.

Molecular motor-based transport is critical for all eukaryotic cell function and health. Although traditionally examined in the context of single motor experiments, molecular motors often work in small teams together to transport the same cargo in vivo. Factors that control and regulate the group function of multiple motors has remained unclear. Here we used a simple lipid bilayer to couple kinesin motors together, and used microtubule gliding assay to examine the effect of this membrane coupling on the group function of multiple kinesin motors.

Intracellular cargo transport by single-headed kinesin monomers.
K.I. Schimert¹, B.G. Budaitis², K.J. Verhey¹,²,³;
¹Biophysics Program, University of Michigan, Ann Arbor, MI, ²Cellular and Molecular Biology Program, University of Michigan, Ann Arbor, MI, ³Department of Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Kinesins are motor proteins that transport cargoes along microtubules in eukaryotic cells. The canonical view is that dimerization is required for kinesin’s processive motility, as the two motor domains of a dimer step hand-over-hand in a tightly coordinated manner. However, whether dimerization is required for cargo transport in cells remains unclear. Using intracellular cargo trafficking assays, we compared dimeric motors to their monomeric forms containing only the motor domain and the neck linker. Surprisingly, we found that monomeric motors across different kinesin families are able to work in teams to drive cargo transport, despite lacking the single-motor processivity of the dimers. To explore the mechanics of this cooperative monomeric transport, we added structural elements after the neck linker, varying their length and flexibility. In general, kinesin monomers are efficient transporters if they are short and the cargo imposes little load. As the length or flexibility of the stalk increases, monomers become less efficient, and dimerization becomes necessary to pull against load. Together, these results lend insight into the minimal requirements and mechanical modulators of collective kinesin cargo transport. They may also shed light on why most kinesins evolved to function as dimers.

¹Program of Cellular and Molecular Biology, University of Michigan, Ann Arbor, MI, ²Biophysics Program, University of Michigan, Ann Arbor, MI, ³Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI, ⁴Department of Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Cells have a diverse group of kinesin motor proteins to direct key microtubule-based processes such as cell division, cell motility, intracellular trafficking, and cilia function. Despite strong conservation of the motor domain across the kinesin superfamily, how various kinesins have tailored their motility characteristics to best meet their functional needs in cells remains unclear. Previous studies suggest cargo transport in cells is governed by the ability of kinesin motors to resist detachment from the microtubule when under load. We developed assays to study transport of low- and high-load cargo by teams of kinesin motors using an inducible, artificial cargo system in cells. We found differences across the superfamily in the ability of kinesin motors to effectively transport high-load cargo. To delineate key features of the motor domain important for transport of high-load, we used molecular modeling to predict mutations in the kinesin-1 motor domain and tested how these mutations impacted cargo transport. We found that the integrity of the cover-neck bundle, a beta-sheet between the coverstrand at the N-terminus and the first half of the necklinker, is critical for teams of kinesin-1 motors to transport high- but not low-load cargo in cells. Truncations of the coverstrand suggest that single motor motility does not predict the ability of teams of motors to transport high load in cells. Our results indicate that cover-neck bundle formation is not only important for single motors to step against load
under purified conditions, but is also critical for teams of kinesin-1 motors to transport high-load in a cellular context. We plan to extend these studies to additional kinesin families to identify whether there are distinct motility dependencies on formation of the cover-neck bundle.

A fluid membrane enhances the velocity of cargo transport by small teams of kinesin-1.
Q. Li¹, K. Tseng², S.J. King³, W. Qiu³, J. Xu¹;
¹Physics, University of California, Merced, Merced, CA, ²Physics, Oregon State University, Corvallis, OR, ³Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL

Kinesin-1 is a major molecular motor driving the fundamental process of transport in live cells. While the single-molecule functions of kinesin are well characterized, the physiologically relevant transport of membranous cargos by small teams of kinesins remains poorly understood. A key experimental challenge remains in the quantitative control of the number of motors driving cargo transport. Here we utilized “motile fraction” to overcome this challenge, and experimentally accessed transport by single kinesins through the physiologically relevant transport by small teams of kinesins. We use a fluid lipid bilayer to model the cellular membrane in vitro, and employed optical trapping to quantify transport of membrane-enclosed cargos versus traditional membrane-free cargos at the same motile fraction (motor number). We found that coupling motors via a fluid membrane significantly enhances the velocity of cargo transport by small teams of kinesins. Importantly, enclosing a cargo in a fluid lipid membrane does not impact single-kinesin transport, indicating that membrane-dependent velocity enhancement for team-based transport resulted from altered interactions between kinesin motors. Our study demonstrates that membrane-based coupling between motors is a key determinant of kinesin-based transport. Enhanced velocity may be critical for the timely delivery of cargos in live cells.

Origins of thermal stability of kinesin activity in cells.
K. Chase¹, F. Doval², M. Vershinin²;
¹Physics, Oregon State University, Corvallis, OR, ²Physics Astronomy, University of Utah, Salt Lake City, UT

Kinesin-1 is the motor which drives a significant fraction of microtubule-based transport in cells. In addition, because of its accessibility and robustness, Kinesin has been seen as a promising motility driver for nano-engineering. However, degradation of kinesin-1 sets in around 30 C for typical in vitro assays - much below ~40 C which can be sustained by the motor in vivo. Why are the in vivo and in vitro results so different? We have examined kinesin motility assays in the presence of trimethylamine N-oxide (TMAO), which is known to stabilize secondary structure and enzymatic activity of many proteins, and its mode of action in many ways mimic molecular crowding in cells. We show that the addition of TMAO results in a dramatic enhancement of kinesin thermal range (up ~50 C). Hence, intracellular crowding emerges as the likely factor which allows kinesin-1 to function efficiently in cells at mammalian body temperatures. This helps address a long standing discrepancy between in vivo and in vitro kinesin assays and furthermore positions TMAO as a key new ingredient for engineered kinesin-based nanodevices.

Native Kinesin-1 Does Not Bind Preferentially to GTP-Tubulin-Rich Microtubules In Vitro.
Q. Li\(^1\), S.J. King\(^2\), J. Xu\(^3\);
\(^1\)Physics, University of California Merced, Merced, CA, \(^2\)Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL

Molecular motors such as kinesin-1 work in small teams to actively shuttle cargos in cells, for example in polarized transport in axons. Here we examined the potential regulatory role of the nucleotide state of tubulin on the run length of cargos carried by multiple kinesin motors, using an optical trapping-based in vitro assay. Based on a previous report that kinesin binds preferentially to GTP-tubulin-rich microtubules, we anticipated that multiple-kinesin cargos would run substantially greater distances along GMPCPP microtubules than along GDP microtubules. Surprisingly, we did not uncover any significant differences in run length between microtubule types. A combination of single-molecule experiments, comparison with previous theory, and classic microtubule affinity pulldown assays revealed that native kinesin-1 does not bind preferentially to GTP-tubulin-rich microtubules. The apparent discrepancy between our observations and the previous report likely reflects differences in post-translational modifications between the native motors used here and the recombinant motors examined previously. Future investigations will help shed light on the interplay between the motor’s post-translational modification and the microtubule’s nucleotide-binding state for transport regulation in vivo.

In addition to their capacity to slide apart antiparallel microtubules during spindle formation, the mitotic kinesin-5 motor Eg5 has been shown to pause at microtubule plus-ends and enhance microtubule polymerization (Chen and Hancock, Nature Comm. 2015:8160). The goal of the present work is to understand the Eg5 microtubule polymerase mechanism by studying how the motor alters the lateral and longitudinal tubulin-tubulin interactions that stabilize the microtubule lattice. Transient kinetics and single-molecule tracking experiments demonstrate that dimeric Eg5 motors reside predominantly in a two-head-bound strong-binding state while stepping along the microtubule (Chen et al., JBC 2016:291(39), 20283-94). This suggests that when Eg5 pauses at a growing microtubule plus-end, the motor acts as a two-head-bound “staple” to stabilize the longitudinal bonds of incoming tubulin dimers. The on-rate for Eg5 binding to free tubulin is slow, suggesting that end-bound Eg5 motors do not bind free tubulin in solution; rather they stabilize incoming tubulin dimers that have bound to the plus-end. Because tubulin in the microtubule lattice resides in a “straight” conformation, while free tubulin resides in a “kinked” conformation, a second (non-mutually exclusive) model is that Eg5 stabilizes the straight conformation of tubulin. Consistent with this, monomeric Eg5 motors, which bind to the microtubule lattice without crosslinking tubulin dimers, also stabilize microtubules against depolymerization. Furthermore, the affinity of Eg5 for free tubulin is reduced in the presence of “wedge inhibitor” drugs.
that stabilize the kinked conformation of tubulin; conversely Eg5 binding to tubulin diminishes drug binding. Thus, we propose a microtubule polymerase mechanism in which binding by one Eg5 motor domain at the microtubule plus-end straightens tubulin dimers and stabilizes lateral tubulin-tubulin bonds, while the second Eg5 head binds incoming tubulin and acts as a staple to stabilize longitudinal tubulin-tubulin bonds and enhance microtubule growth.

Investigating dynein function in a mouse model carrying a Charcot-Marie-Tooth type 2O linked mutation.

S. Nandini¹, J. Conley Caldeir², T.T. Sablah³, R. Love¹, L.E. King¹, S. King³;
¹Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL

Dynein is a minus-end directed microtubule motor protein that plays a crucial role in the cellular development, maintenance, and survival. A single point substitution of histidine to arginine at amino acid 306 (H306R) in the cytoplasmic dynein heavy chain (DHC) has been linked to the autosomal dominant Charcot-Marie-Tooth type 2O (CMT2O) neuropathy in humans (Weedon et al. 2011). Individuals with CMT2O exhibit peripheral moto-sensory defects such as distal limb weakness, atrophy, skeletal deformities (pes cavus), and gait abnormalities. We have developed and characterized a novel mouse model to understand the mechanism of the mutant dynein in the progression of the CMT2O disease. The knock-in mouse model was generated with the corresponding CMT2O linked mutation (H304R) located in mouse’s dynein heavy chain. With 12-month long behavioral studies on the wild-type, H304R/+ (heterozygous), and H304R/R (homozygous) mice, we established that we had a suitable mouse model to use for further characterization studies. The H304R/+ and H304R/R mice exhibit deficits in the grip strength, rotarod, and tail suspension reflex tests. Additionally, the characterization of neuromuscular junctions (NMJ) revealed structural defects in the morphology, complexity and branching of NMJs in the H304R/+ and H304R/HR mice. Immunohistochemistry characterization of the brains of wild-type, H304R/+ and H304R/R HR mice at early postnatal time points also revealed differences in the brain architecture. In order to understand the effects of the mutant DHC allele on development, mice of all three genotypes are being examined for neurodevelopmental milestones from postnatal day 1 (P1) through postnatal day 21 (P21). Finally, we are characterizing dynein-dependent intracellular motility in neurons from the wild-type, H304R/+, and H304R/R mice embryos.

CLASP1 is Required for CLASP2 Localization and Function at Microtubules in Interphase Cells.

R. J. Thoppil¹, A. A. Sanders¹, E. J. Lawrence¹, K. Chang¹, S. Narasimhan¹, M. Zanic¹, I. Kaverina¹;
¹Cell and Developmental Biology, Vanderbilt University, Nashville, TN

CLIP-associated proteins (CLASPs) are highly conserved microtubule (MT) plus-end tracking proteins (+TIPS) that are involved in regulating MT dynamics; specifically, CLASPs were shown to promote MT rescue and enhance MT stability. Human CLASPs consists of two paralogs: CLASP1 and CLASP2, which have been found associated with the cell cortex, kinetochores, the Golgi and at the ends of growing MTs. Although both CLASPs have been structurally and functionally characterized in depth, mutual regulatory interactions between these two proteins have not been explored. In the present study, we use a variety of human cell lines to show that while CLASP2 depletion does not interfere with cellular CLASP1 localization, the loss of CLASP1 dramatically influences CLASP2 localization in interphase. In
particular, CLASP2 is no longer associated with MT plus ends, while other MT +TIPs were not affected, and CLASP2 still retained at the Golgi. This effect suggests that CLASP1 specifically facilitates CLASP2 localization at the MT plus ends. Addressing potential underlying mechanisms, we tested if CLASP1 was involved in regulating CLASP2 phosphorylation by GSK3β, which is known to abolish CLASP2 binding to MTs. Here, we found that CLASP1 did not modify CLASP2 phosphorylation levels. Moreover, when GSK3β was inhibited in CLASP1-depleted cells, CLASP2 localization to MTs was restored, indicating that CLASP1 is capable to localize CLASP2 to MTs despite its physiological phosphorylation level. Moreover, our co-immunoprecipitation assays show that CLASP1 forms a complex with CLASP2 in cells. Since prior evidence indicates that CLASP variants can homodimerize via a C-terminal coiled-coil region, we propose that CLASP1 heterodimerizes with CLASP2 in order to target it to MTs. Functionally, CLASPs play a prominent role in MT dynamics and stability, and are critical for nucleation of Golgi-derived microtubules (GDMTs). In our in vitro reconstitution assays, CLASP2 by itself strongly promotes MT nucleation. However, decrease of GDMT nucleation in cells depleted of CLASP1 alone was as prominent as the effect of depletion of both proteins. We conclude that CLASP1-dependent localization of CLASP2 to MT ends is necessary for CLASP2 function in cells, and thus CLASP1 is upstream of CLASP2 in regulating MT nucleation and dynamics.

Microtubule acetylation induced by α-tubulin acetyltransferase overexpression impairs hepatic protein trafficking and lipid droplet motility.

J.L. Groebner¹, M.M. Girón Bravo¹, M. Rothberg¹, D.J. Tuma², P.L. Tuma¹;

¹Department of Biology, The Catholic University of America, Washington, DC, ²Department of Internal Medicine, University of Nebraska, Omaha, NE

Tubulin post-translational modifications (PTMs) create a “code” on the microtubule cytoskeleton to differentially regulate molecular motor and microtubule associated protein (MAP) binding and activity to support innumerable cellular processes. The “tubulin code” is further complicated in the liver because alcohol metabolism produces highly reactive products (acetaldehyde and oxygen radicals) that form various protein adducts and indirectly induce acetylation. Our focus is to understand how alcohol metabolism-derived modifications contribute to liver damage in alcoholic liver disease (ALD). Our previous studies have shown that alcohol consumption leads to enhanced microtubule acetylation and stability that can explain alcohol-induced defects in motor-mediated protein trafficking (e.g., secretion, transcytosis, and nuclear translocation) and lipid droplet motility. To directly assess the relationship between microtubule acetylation and defects in hepatic microtubule motor-mediated motility, we overexpressed α-tubulin acetyltransferase (α-TAT1) to promote acetylation in the absence of alcohol. Using a recombinant adenovirus expressing α-TAT1, we were able to induce acetylation in a dose-dependent manner and replicate similar levels of acetylation (2-3 fold increase) seen during alcohol metabolism in polarized, hepatic WIF-B cells and in livers from alcohol-fed rats. To examine the effects microtubule acetylation has on motor-mediated trafficking and motility, we monitored basolateral secretion, transcytosis and lipid droplet motility. In cells overexpressing α-TAT1, albumin secretion was impaired to a similar extent as observed in alcohol-treated cells. Transcytosis of polymeric IgA receptor (“professional transcytosing protein”) and aminopeptidase N (single spanning membrane protein) from the basolateral-to-apical membrane was impaired to a lesser extent than in alcohol-treated cells. Live cell imaging of BODIPY-labeled droplets also revealed significantly decreased droplet motility. Immotile, enlarged lipid droplets colocalized with dynactin/dynein to suggest that droplet binding properties may be impaired. Together these results demonstrate that microtubule acetylation alone can explain defects...
in microtubule motor-dependent processes that can alter cellular functions. We are currently performing microtubule binding assays and isolating lipid droplets to assess defects in dynein/dynactin binding in cells with a hyperacetylated microtubule environment. Currently there are no treatments available to relieve or reverse the disease state in the progression of ALD, therefore modulating the cellular protein acetylation state could provide a novel therapeutic target.

γ-Tubulins are highly conserved members of the tubulin superfamily essential for microtubule nucleation. Humans possess two γ-tubulin genes. It is thought that γ-tubulin-1 represents ubiquitous isotype, whereas γ-tubulin-2 is found predominantly in the brain, where it may be endowed with divergent functions beyond microtubule nucleation. The molecular basis of the purported functional differences between γ-tubulins is unknown. Previously we have reported that human γ-tubulin-2 nucleates microtubules and rescues mitotic progression in γ-tubulin-1 depleted cells (PLoS ONE 7: e29919, 2012). Here we report discrimination of human γ-tubulins according to their electrophoretic and immunochemical properties depending on C-terminal regions of the γ-tubulins. Using epitope mapping, we discovered mouse monoclonal antibodies that can discriminate between human γ-tubulin isotypes. Real time quantitative RT-PCR and 2D-PAGE showed that γ-tubulin-1 is the dominant isotype in fetal neurons. Although γ-tubulin-2 accumulates in the adult brain, γ-tubulin-1 remains the major isotype in various brain regions. Localization of γ-tubulin-1 in mature neurons was confirmed by immunohistochemistry and immunofluorescence microscopy on clinical samples and tissue microarrays. Differentiation of SH-SY5Y human neuroblastoma cells by all-trans retinoic acid, or oxidative stress induced by mitochondrial inhibitors, resulted in upregulation of γ-tubulin-2, whereas the expression of γ-tubulin-1 was unchanged. Fractionation experiments and immunoelectron microscopy revealed an association of γ-tubulins with mitochondrial membranes. These data indicate that in the face of predominant γ-tubulin-1 expression, the accumulation of γ-tubulin-2 in mature neurons and neuroblastoma cells during oxidative stress may denote a prosurvival role of γ-tubulin-2 in neurons.

Microtubules, dynamic polymers of αβ-tubulin heterodimers, carry out diverse cellular functions in eukaryotes. Microtubule-associated proteins (MAPs), including microtubule polymerases/depolymerases, regulate the organization and dynamics of these filaments in cells. The α-
and β-tubulin gene families expanded substantially in higher eukaryotes. In particular, the human genome encodes at least seven α- and eight β-tubulin isoforms that differ in amino acid sequences and show cell type-specific expression. In vivo studies have suggested the non-interchangeable roles of tubulin isoforms during development. Recent experiments using recombinant human tubulins or chimeric tubulins have begun to reveal how differences in the primary sequences of human tubulin isoforms impact MAP interactions and assembly dynamics of microtubules. However, it has been difficult to analyze the interactions of MAPs with microtubules of different human tubulin isoforms as generating affinity-tag free recombinant human tubulins is challenging. Here, we develop a strategy to generate isotypically pure recombinant human tubulin heterodimers that lack affinity tags. We generate human α-tubulin isoform 1B in combination with either human β-tubulin isoform B2B (A1B/B2B) or B3 (A1B/B3). We then use total internal reflection fluorescence (TIRF)-based assays to quantitatively examine the direct binding of MAPs to human microtubules. We find that MCAK, a kinesin-13 family microtubule depolymerase, disassembles taxol-stabilized A1B/B2B and A1B/B3 microtubules at rates between 0.2 μm/min and 7.5 μm/min. Further, related to the co-existence of different tubulin isoforms in cells, we find that varying the ratio of B3 and B2B tubulin in microtubules can tune the rate of MAP-stimulated depolymerization up to 10-fold. Together, our data reveal that the compositions of human tubulin isoforms in microtubules modulate MAP-mediated polymer dynamics.

Elucidating the Role of a Human β-tubulin, TUBB4B: Functional Analysis of a Novel Patient-Derived Mutation.

S.M. Schreiner¹, D.L. Sackett², J.K. Moore¹;

¹Cell and Developmental Biology, University of Colorado Anschutz Medical Center, Aurora, CO,
²Cytoskeletal Dynamics Unit, Eunice Kennedy Shriver NICHD, National Institutes of Health, Bethesda, MD

Humans specifically express at least six genes encoding α-tubulin and seven encoding β-tubulin, known as tubulin isoforms. While expression of some isoforms is developmentally regulated and cell-type specific, it is not fully understood why humans have so many tubulin genes and how isoforms might contribute to different microtubule function in different cellular contexts. Mutations in human isoforms that are associated with human diseases provide a powerful window into isoform function. Here we report a novel, heterozygous mutation in TUBB4B, the human βIVb isoform, identified by whole genome sequencing of a patient enrolled in the NIH Undiagnosed Diseases Program (UDP) identified. The mutation causes a glutamine to arginine substitution in the GTP binding domain of TUBB4B. The βIVb isoform has been implicated in axonemal function in model organisms; therefore, we hypothesize that disrupting the function of TUBB4B may ultimately be detrimental to cilia. Interestingly, we find that a higher fraction of UDP patient fibroblasts possess cilia than control cells, indicating that TUBB4B may play a specific role in ciliary function in mammalian cells. In contrast, the overall microtubule network in UDP patient fibroblasts does not exhibit a microtubule stability defect when exposed to cold treatment and does not have increased acetylated tubulin levels. To determine how the Q11R mutation impacts β-tubulin function, we generated an analogous mutation in budding yeast β-tubulin, TUB2. We find that tub2-Q11R fails to rescue a tub2Δ null mutant, indicating that the mutation is sufficient to disrupt β-tubulin function. Heterozygous diploids expressing one copy of tub2-Q11R are viable, resistant to microtubule destabilizing drugs, and exhibit hyper-stable microtubules. To further characterize this mutation, we examined alternative substitutions at Q11, including -Q11E and -Q11S, and tested how they affect GTP-dependent microtubule properties including GTP hydrolysis and its associated conformational changes. Both tub2 -Q11E or -Q11S mutants are sufficient to rescue a tub2Δ null

Monday-84
mutant. Additionally, these mutants exhibit sensitivity to microtubule depolymerizing drugs and have a microtubule instability phenotype indicating that the substitution of a large, positively charged arginine into the exchangeable GTP binding site of β-tubulin specifically impacts microtubule functions. Based on these results, we speculate that the Q11R mutation may alter cilia formation by increasing microtubule stability in the axoneme. Further work on this project will help further elucidate both the mechanism of how the Q11 residue contributes to β-tubulin function and the role of TUBB4B in ciliary function.

**Targeted localization of microtubule severing enzymes in vivo.**

S.R. Advani¹,², J.L. Ross², T.J. Maresca³;
¹Molecular and Cellular Biology Program, University of Massachusetts Amherst, Amherst, MA,
²Department of Physics, University of Massachusetts Amherst, Amherst, MA, ³Department of Biology, University of Massachusetts Amherst, Amherst, MA

Microtubule-severing enzymes recognize defects in microtubules and are capable of remodeling microtubule networks. They are ubiquitous and function during mitosis, meiosis, and cell migration. There has been effort to control microtubule dynamics in specific cellular compartments, in order to develop therapies that help us overcome the pathologies of Alzheimer’s disease, accelerate wound healing, and regenerate spinal neurons (Matamoros and Baas, 2016; Dent, 2017; Charafeddine, 2015). Severing enzymes have proven to be challenging to study in vivo and in vitro, since they have a tendency to aggregate when overexpressed and drastically affect microtubule network homeostasis. Given that severing enzymes function at many locations in the cell, molecular tools must be built to control their activity at specific locations. Here, we describe the development of tools to target microtubule-severing enzymes to different cellular compartments. As a proof of concept, we have successfully targeted human katanin p60 to the kinetochore in Drosophila S2 cells. The human katanin p60 is active and severs interphase Drosophila microtubules when expressed ubiquitously. While at the kinetochores, human katanin p60 had a subtle effect on kinetochore fibers, chromosomal misalignment, interkinetochore distance and mitotic duration. Future directions of the work include targeting katanin to the cellular periphery and the Golgi.

**TACC3 regulates the dynamic microtubule plus-end in an in-vitro environment.**

G. Cammarata¹, B. Erdogan¹, B. Pratt¹, H. Nazarenko⁵, Q. Coughlin⁵, P. Ebbert⁵, L.A. Lowery¹;
¹Biology, Boston College, Chestnut Hill, MA

The Transforming Acidic Coiled-Coil (TACC) family of proteins plays an integral role in the regulation of the plus-end of microtubules. It is at this plus-end that the characteristic dynamic nature of microtubules allows for constant tubulin heterodimer addition and removal, thereby affecting the overall extent of microtubule growth. In addition to affecting the dynamicity of microtubules, the TACC family of proteins is known to interact discretely with other +TIPs (plus end tracking proteins), such as the microtubule polymerase, XMAP215. Although such protein interactions have been described before, the knowledge of the TACC family’s complete mechanism affecting the plus-end is not known. Recent in-vitro evidence as well as live cell data from our lab supports the idea that one such member, TACC3, may possess a role in directly affecting the polymerization of microtubules. In addition, data shows variation in physical binding and localization patterns of TACC members on the ends of microtubules. We have
employed high resolution time lapse imaging, in-vitro reconstitution assays, and biochemical techniques to look further into how these TACC proteins differentially regulate the overall dynamic nature of the microtubule.

Inhibitory effects of eucalyptol on diabetes-associated loss of glomerular slit junctions and podocyte foot process effacement.

D. Kim¹;
¹Food Science and Nutrition, Hallym University, Chuncheon, South Korea

Kidney podocytes, highly differentiated epithelial cells, establish an interdigitating foot processes and participate in the assembly of the foot processes and the slit diaphragm. The maintenance of the slit diaphragm complex is critical in the sieving function of the glomerular filter. Hyperglycemia-induced damage to podocytes is thought to be a critical early event in diabetic nephropathy. Eucalyptol is a natural organic essential oil which is a monoterpenoid present in eucalyptus oil with antiinflammatory and antioxidant properties. This study investigated renoprotective effects of eucalyptol on loss of glomerular slit junctions and foot process effacement caused by glucose stimulation. Mouse podocytes were incubated in media containing 33 mM glucose for 4 d in the presence of 1-20 µM eucalyptol. The expression of the slit diaphragm proteins of nephrin and podocin were diminished in glucose-exposed podocytes, which was dampened by eucalyptol. The expression of the slit diaphragm-associated proteins of α-actinin-4 and CD2AP, and the podocyte adhesion molecule integrin β1 were reduced in podocytes damaged to glucose. In contrast, the eucalyptol treatment enhanced the expression of these proteins responsible for the maintenance of the foot process organization. The in vivo animal model employed db/db mice orally administrated with 10 mg/kg of eucalyptol. Electronic microscopical observations found that podocyte foot process effacement occurred in diabetic mouse glomeruli. On the contrary, oral administration of eucalyptol encumbered foot process effacement of diabetic podocytes through inhibiting loss of glomerular slit junctions-associated proteins of α-actinin-4 and CD2AP. These results demonstrated that eucalyptol maintained normal structures of podocyte foot process and slit diaphragm. Therefore, eucalyptol may be a potent renoprotective agent combating diabetes-associated damage to podocytes in relation to the maintenance of the glomerular filtration barrier.

SUMO interacts non-covalently with tubulin and the TOG protein Stu2/XMAP215.

M. Greenlee¹, A. Alonso¹, M. Rahman¹, T. Tabb¹, N. Meednu², S. Morris¹, R.K. Miller¹;
¹Biochemistry and Molecular Biology, Oklahoma State University, Stillwater, OK, ²Biology, University of Rochester, Rochester, NY

The Small Ubiquitin-like Modifier, SUMO, can interact with target proteins two ways, covalently or non-covalently. Covalent conjugation of SUMO occurs on the target protein through an isopeptide bond formed between the carboxyl group of the terminal glycine of SUMO and the epsilon amino group of the conjugated lysine residue. A non-covalent interaction occurs thorough the hydrophobic and ionic interactions of a “SUMO-Interacting Motif” within the interacting protein. Stu2 is the yeast homologue of CKAP5/XMAP215, a TOG protein that promotes microtubule dynamics by facilitating the loading of tubulin dimers onto microtubule ends. Although Stu2p plays a vital role in microtubule function, little is known about how it is regulated. We analyzed Stu2 for both covalent and
non-covalent interactions with SUMO. Two-hybrid analysis showed that Stu2 interacts with Smt3/SUMO and several key members of the sumoylation system including the E2 conjugating enzyme, Ubc9p. Domain mapping of amino- and carboxyl- terminal truncations shows that the dimerization region of Stu2 is important for its interaction with SUMO. Using an in vitro sumoylation assay, four shifted bands of Stu2 can be observed. Inactivation of the Ulp1 SUMO protease with a temperature sensitive mutant results in Stu2 displaying a higher molecular weight band in vivo. Pull-down assays in denaturing buffer containing urea demonstrate that an anti-SUMO reactive band co-migrates with Stu2. Stu2 also interacts with a sumo-targeted ubiquitin ligase, or STUbL enzyme. Together, these results indicate that Stu2 can be conjugated by SUMO. To test whether Stu2 could interact non-covalently with SUMO, we analyzed Stu2p for an interaction with a non-conjugatable form of SUMO fused to GST. Stu2p bound to the non-conjugatable SUMO but not to GST alone. Phenotypic analysis of mutants within the SUMO interacting motif in Stu2p that is responsible for the interaction is in progress. As tubulin is a major binding partner of Stu2p, we also tested tubulin. Tubulin also bound to the non-conjugatable form of SUMO, but not GST. This binding was independent of the presence of full-length Stu2p. Two-hybrid analysis suggests that the beta-tubulin Tub2p is the major SUMO-interacting tubulin. In contrast, the SUMO targeted ubiquitin ligase, Ris1p, bound to both alpha and beta tubulins. Together our work suggests that Stu2p can interact with SUMO by multiple mechanisms, covalent and non-covalent. This has implications for its interaction with its other partner-MAPs that are also sumoylated.

Montréal, QC

Microtubules of the model organism C. elegans differ from the textbook eukaryotic microtubule both in their structure and dynamics. For example, microtubules in somatic cells do not contain the canonical 13 protofilament (pf) lattice seen in most eukaryotes; rather, most cells have 11 pfs. Furthermore, microtubules in various C. elegans tissues grow extremely fast (up to 60 um/min) - almost an order of magnitude higher than other model organisms. To determine the origin of these phenomena, we purified tubulin from whole C. elegans lysates. Interestingly, we observed a shift to smaller pf numbers for spontaneously nucleated microtubules relative to bovine microtubules. Furthermore, C. elegans microtubules grew much faster in vitro, with an apparent on-rate constant ~3-fold higher than for bovine tubulin, and underwent more frequent catastrophes, indicating that C. elegans tubulin is the most dynamic to date. To determine how C. elegans achieves these differences, we solved the structure of C. elegans microtubules at 4.8 A resolution. We found that C. elegans microtubules have retained the helical parameters of other eukaryotes, suggesting 11 pf microtubules found in vivo are super-twisted. We confirmed this result with negative stain electron tomography of the C. elegans embryo. When we mapped sequence conservation onto our structure, we found that the lateral bond interfaces has many divergent residues. Monte-carlo simulations of microtubule growth revealed that a modest increase in lateral bond energies is sufficient to recapitulate the growth rates observed in vitro. Together, these data provide insight into tubulin evolution by characterizing divergent dynamic and structural properties in a higher eukaryote.

TACC3 mitigates Nocodazole-induced growth cone effects and is required for proper embryonic neural development.
E. Lee¹, B. Erdogan¹, L.A. Lowery¹;
¹Biology, Boston College, Chestnut Hill, MA

Proper navigation of the developing axon necessitates the complex interactions between the microtubules (MTs) of the growth cone, associated proteins, and extracellular cues. Specifically, plus-end tracking proteins (+TIPs), proteins that reside at the plus-end of microtubules, play a crucial role in the development of embryonic neurites. We have previously demonstrated that TACC3 functions as one of these +TIPs and binds plus-ends of MTs in Xenopus laevis embryonic growth cones. Here, using quantitative analysis of high-resolution live imaging, we also show that TACC3 mitigates reduction in MT dynamics parameters -growth speed, length and lifetime- in response to Nocodazole exposure at low concentrations, and that TACC3 also limits neurite retraction under low concentrations of Slit2. Furthermore, we have observed that the impairment of proper axon navigation and growth may lead to neural morphological differences between the telencephalic hemispheres in Xenopus laevis embryos. In conclusion, our results illustrate that TACC3 may play a role in altering a developing axon’s response to external guidance cues and in facilitating proper neural morphological development.

Sequence-encoded charge patterning of the intrinsically disordered tail of FtsZ impacts polymerization and bacterial cell division.
M.C. Cohan¹, A.E. Posey¹, A. Mittal¹, S.J. Grigsby², A.S. Holehouse¹, P.J. Buske², P.A. Levin², R.V. Pappu¹;
¹Biomedical Engineering, Washington University in Saint Louis, Saint Louis, MO, ²Biology, Washington University in Saint Louis, Saint Louis, MO

Polymerization of FtsZ, a bacterial homolog of tubulin, is an essential step in the assembly of the divisome (Z-ring) and the regulation of cell division in rod-shaped bacteria. The modular architecture of FtsZ includes a highly conserved GTPase domain and an intrinsically disordered C-terminal tail (CTT) that encompasses a poorly conserved polyampholytic linker (CTL) that is essential for Z-ring formation. Being a polyampholyte, the conformational properties of the CTL are determined by the patterning of oppositely charged residues quantified using a parameter. Although the sequences of CTLs are poorly conserved, is bounded within a narrow range of 0.2 ≤ ≤ 0.4. This suggests that sequence-encoded conformational properties and interactions mediated by the CTL must be conserved. We tested this hypothesis by scrambling the CTL of B. subtilis FtsZ to generate CTT variants with values that are within and beyond the observed bounds. FtsZ variants that lie within the bounds support ring-formation through a GTP-dependent mechanism. However, as increases beyond the bounds, ring formation is impaired and the CTTs promote an alternative tail-mediated assembly. Sequence features within CTLs modulate the subtle interplay amongst tail- and core-driven FtsZ assembly, high and low GTPase activity, and strong and weak lateral associations of FtsZ polymers. Our findings suggest that a “Goldilocks precept” i.e., the tail-mediated interactions must not be too strong or too weak, might govern the evolution of FtsZ-CTTs. Sequence selection in accord with the Goldilocks precept requires tail sequences with appropriately complex amino acid composition and optimal -values. Interestingly, the principles we have uncovered for FtsZ appear to be relevant for understanding the evolution of a larger class of tailed or “bristled” NTPases.

UNC-45A is a novel spindle-associated microtubule destabilizing protein that antagonizes the effect of paclitaxel in cancer cells.

A. Mooneyham1,2, Q. Yang3, Y. Iizuka1,2, C. Coombes3, M. McClellan3, V. Shridhar4, J. Meints5, M.K. Lee5, M.K. Gardner3, M. Bazzaro1,2;
1 Obstetrics, Gynecology and Women’s Health, University of Minnesota, Minneapolis, MN, 2 Masonic Cancer Center, University of Minnesota, Minneapolis, MN, 3 Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, 4 Experimental Pathology, Mayo Clinic College of Medicine, Rochester, MN, 5 Neuroscience, University of Minnesota, Minneapolis, MN

UNC-45A is a highly conserved member of the UCS (UNC-45/CRO1/She4p) protein family. Genetic studies in lower organisms (S. cerevisiae, C. elegans and Drosophila) have shown an evolutionarily conserved role for UNC-45A in regulating cytoskeletal dynamics1-5. We are interested in understanding the role of UNC-45A with respect to its cytoskeletal-associated functions in mammalian cells. In our laboratory we have shown that UNC-45A is required for cytokinesis and motility in cancer cells6, for exocytosis in immune cells7 and for neurite outgrowth in cortical neurons8. Strikingly, new evidence from our laboratory shows that UNC-45A strongly co-localizes with interphase microtubules (MTs) and mitotic spindles throughout the cell cycle. Knockdown of UNC-45A in dividing cells results in multiple mitotic defects including increased mitotic index, increased spindle length, misaligned chromosomes, lagging chromosomes, and multipolar spindles. Moreover, acetylated tubulin levels in mitotic spindles are markedly increased upon loss of UNC-45A, suggesting that UNC-45A has microtubule destabilizing activity. This was confirmed in an in vitro Total Internal Reflection Fluorescent (TIRF) microscopy system, where UNC-45A was found to directly bind and destabilize MTs in absence of any other cellular factors. MT-destabilizing proteins have an important role in drug resistance to paclitaxel, a microtubule stabilizing agent commonly used in the treatment of breast and ovarian cancer. In an ovarian cancer cell system, loss of UNC-45A sensitizes cells to paclitaxel treatment. Conversely, cells that acquire paclitaxel resistance show increased expression of UNC-45A. Finally, immunohistochemical (IHC) analysis of ovarian cancer clinical specimens revealed a statistically significant correlation between UNC-45A expression and likelihood of resistance. These studies suggest UNC-45A is a novel microtubule-associated protein (MAP) with MT-destabilizing activity that antagonizes the effect of paclitaxel in cancer cells. Uncovering mechanistic details behind these novel UNC-45A functions has the potential to impact multiple fields of study, from translational research to basic cytoskeletal cell biology.

A Microtubule Organizing Center Directing Intracellular Transport in the Early Mouse Embryo.

J. Zenker¹, M.D. White¹, R.M. Templin¹, R.G. Parton², O. Thorn-Seshold³, S. Bissiere⁴, N. Plachta¹;
¹IMCB, A*STAR, Singapore, Singapore, ²IMB, University of Queensland, Brisbane, Australia, ³Department of Pharmacy, Ludwig-Maximilians-University, Munich, Germany

The centrosome is the primary microtubule organizing center (MTOC) of most animal cells. However, preimplantation mouse embryos only establish centrosomes at the late blastocyst stage. Therefore, the mechanism by which the early mammalian embryo organizes its microtubules (MTs) is unclear. By imaging fluorescently labeled MTs in live mouse embryos using four-dimensional confocal (4D) microscopy, we recently discovered a non-centrosomal form of MT organization in the early embryo. We find that contrary to most animal cells, the cytokinetic bridge does not undergo stereotypical abscission after cell division in the developing mouse embryo. Instead, it serves as a scaffold for the accumulation of proteins that stabilize MT minus ends and promote MT outgrowth throughout interphase, thereby transforming this structure into a non-centrosomal MTOC. Moreover, we show that this MTOC directs the transport of proteins such as E-cadherin to the cell membrane, which are essential to establish the first forms of tissue architecture during development. Together, our findings reveal how MTs are organized and function during the early stages of mammalian embryogenesis.

Tissue-specific degradation of essential centrosome components in vivo reveals distinct microtubule populations at noncentrosomal MTOCs.

M.D. Sallee¹, J.C. Zonka¹, B. Raftrey¹, J.L. Feldman¹;
¹Biology, Stanford University, Stanford, CA

Microtubule organization is critical for cell function. Nearly all dividing animal cells use the centrosome as a microtubule organizing center (MTOC) to tether chromosomes to the spindle poles to facilitate the correct segregation of DNA between daughter cells. By contrast, differentiated cells organize their microtubules in a wide variety of patterns, and establish specific noncentrosomal locations as MTOCs to achieve their microtubule arrangements. While centrosomes redundantly require AIR-1/Aurora A and γ-TuRC for microtubule nucleation and organization, it is unknown how these tasks are accomplished at noncentrosomal MTOCs (ncMTOCs). A simple hypothesis is that ncMTOCs use these essential centrosomal proteins, tethering them to noncentrosomal sites with site-specific adapters. The C. elegans embryonic intestine is a simple epithelial model in which to test this hypothesis in vivo; the apical surfaces of these cells become specified as ncMTOCs during polarization and MTOC components such as γ-TuRC and AIR-1 localize to the apical membrane. Using tissue-specific degradation of endogenous AIR-1 and γ-TuRC components GIP-1/GCP3 and MZT-1/MOZART, we have tested the role of these proteins in ncMTOC function. Consistent with their known role at the centrosome, GIP-1, MZT-1, and/or AIR-1 depletion results in strong mitotic defects in intestinal cells prior to polarization and results in fewer intestinal nuclei. Futhermore, AIR-1 depletion perturbs TAC-1/TACC and γ-TuRC recruitment to intestinal centrosomes. Like at the centrosome, γ-TuRC recruitment to the apical ncMTOC requires GIP-1. Intriguingly, although localization of GIP-1 to the centrosome in dividing intestinal cells requires MZT-1, localization of GIP-1 to the apical ncMTOC does not, suggesting that MZT-1 specifically links γ-TuRCs to the centrosome and not to MTOCs in general. Further distinguishing MTOC function at the centrosome, the recruitment of γ-TuRC or TAC-1/TACC to the apical MTOC does not require AIR-1. Surprisingly,
degradation of AIR-1, GIP-1, or MZT-1, and even the depletion of both AIR-1 and GIP-1, has no overt effect on the localization of microtubules to the apical ncMTOC. GIP-1 degradation results in reduced apical localization of EBP-2/EB1 and fewer comets, though comets are still observed, indicating that only a subset of apical microtubules is dependent on γ-TuRC function. Together, these results suggest that centrosomal and noncentrosomal MTOCs require different proteins to function and that the apical ncMTOC is composed of distinct populations of microtubules.

1Department of Systems Biology, Harvard Medical School, Boston, MA, 2Marine Biological Laboratory, Woods Hole, MA, 3Department of Physics, Massachusetts Institute of Technology, Cambridge, MA, 4Department of Chemical Engineering, University of Wyoming, Laramie, WY, 5Department of Molecular Biology, University of Wyoming, Laramie, WY

During early embryogenesis in *Xenopus laevis*, each cell division plane bisects the boundary between a pair of large microtubule asters that propagate from the poles of the mitotic spindle. The asters are a network of short, dynamic microtubules oriented radially outward from the microtubule organizing center (MTOC). Before cleavage, asters grow and move so that the cell divides approximately at its midplane and perpendicular to its long axis. Aster movement is thought to depend on length-dependent forces from cytoplasmic dynein opposed by hydrodynamic drag; however, it remains unclear how these forces propagate through the network of short, and short-lived, microtubules, resulting in aster movement. We reconstituted aster movement in *Xenopus* egg extract, and imaged the growth and interaction of asters under slit-like confinement. Aster boundaries stopped growing when they interacted with neighboring asters. The boundaries between asters formed dynamic, tessellated polygonal patches that resembled 2D foams. MTOCs moved relative to aster centroids and boundaries, and this movement was partially inhibited by the CC1 fragment of dynactin, which inhibits dynein-dependent forces. We measured the dynamic geometries of MTOCs and aster boundaries at different MTOC densities, and will use numerical and analytical modeling to investigate whether known forces can explain the results. Within the egg, microtubule asters must navigate abundant obstacles including lipid droplets and yolk platelets, which are removed during preparation of the extract. To simulate them, we added agarose spheres to the extract, and asters were able to grow around these obstacles. The global organization of microtubules remained radial, and the boundaries between asters remained approximately straight and equidistant between pairs of MTOCs. We also imaged the response of asters to controlled flows. We conclude that the short, dynamic nature of microtubules in large asters facilitates aster growth and movement through a cytoplasm containing abundant obstacles.

Spindle morphology tailoring through time: Interplay between spindle architecture and morphogenesis of the mammalian brain.
D.C. Vargas-Hurtado1, V. Marthiens1, C. Pennetier1; R. Basto1;
1UMR144, Subcellular structure and cellular dynamics, Institut Curie, Paris, France

Accurate chromosome segregation is essential for genome stability. Chromosome number deviations (or aneuploidy) influence cellular fitness and performance. During mitosis, a highly dynamic microtubule-
based structure, the mitotic spindle, is assembled to connect sister chromatids to the spindle poles providing the forces to segregate the chromosomes. Centrosomes, the main microtubule-organizing centres (MTOCs) of animal cells, organize the spindle poles contributing to spindle orientation and bipolarity. Interplay between centrosomes, spindle microtubules and associated proteins influence the fidelity of each cell division.

From all the organs in the human body the brain is particularly vulnerable to centrosome defects. Aneuploidy generated by centrosome dysfunction impairs embryonic neural progenitor survival, which culminates in severe brain size reduction at birth, a pathological condition known as microcephaly. Intriguingly, aneuploidy has also been reported in physiological conditions. Thus, there seems to be an intrinsic susceptibility of embryonic neural progenitors to mitotic errors. The origin of this susceptibility is not known. In order to unravel the mechanisms of error-prone mitosis in the neuroepithelium, we characterized mitotic spindle assembly during mouse neurogenesis in the WT brains.

Strikingly, we found that the morphology of the spindle changes during neurogenesis. While at early stages, the spindles of neural progenitors contain longer astral microtubules (MTs) that interact with the cell cortex, spindles at later stages gain in central spindle robustness at the expense of astral microtubule abundance. This change is followed by significant differences in the levels/distribution of key spindle associated factors along the spindle. Moreover, we identified Tpx2, a microtubule nucleating, organizing and stabilizing factor, as one of the key factors involved in the switch of spindle morphology.

Overall, our results indicate unexpected modifications in the pathways used by neural progenitors to build a bipolar spindle during neurogenesis, which confer a different chromosome segregation capacity. Indeed, by challenging the spindle formation with the presence of extra centrosomes, we observed an improvement of mitotic accuracy during the course of neurogenesis. We thus propose that during mammalian neurogenesis not all the progenitors are equally competent to segregate chromosomes correctly.

CENP-E-PRC1 interaction provides a temporal cue for central spindle assembly.
Y. Liu1,2, W. Wang1,2, P.Y. Yao2, D. Li1, X. Wang1,2, h. wang1, Y. Li1, X. Liu1,2, X. Yao1,2;
1Cellular Dynamics, Anhui Key Laboratory for Cellular Dynamics Chemical Biology, Hefei, China, 2Keck Center for Molecular Imaging, Morehouse School of Medicine, Atlanta, GA

Mitotic kinesin CENP-E plays key roles in chromosome congression and spindle checkpoint satisfaction. We have recently identified and characterized syntelin, a novel allostERIC inhibitor selective for CENP-E (Ding et al., 2010. Cell Res. 20, 1386-1389; Mo et al., 2016. Nat. Chem. Biol. 12,226-232; Liu et al., 2016. J Mol Cell Biol. 8,144-156). Cells treated with syntelin progress through interphase, enter mitosis normally with a bipolar spindle and lagging chromosomes around the poles. Our optical trap analyses show that syntelin is an allostERIC inhibitor which tightens CENP-E-microtubule interaction by slowing inorganic phosphate release. To delineate the role of CENP-E in reorganization of interpolar microtubules into an organized central spindle, metaphase synchronized cells were exposed to syntelin and other mitotic motor inhibitors. Syntelin does not perturb inter-polar microtubule assembly but abrogates the anti-parallel microtubule bundle formation. Real-time image shows that CENP-E inhibited cells undergo central spindle splitting which is confirmed by transmission electron microscopic analyses. Using a syntelin affinity matrix, we identified a novel CENP-E complex containing PRC1. Interestingly, inhibition of CENP-E did not alter the interaction between CENP-E and PRC1 but perturbed temporal assembly of PRC1 to the midzone. These findings reveal a previously uncharacterized role of CENP-E motor in temporal control of central spindle assembly. Currently, we are reconstituting the central
spindle sliding assay in vitro and delineate how CENP-E-PRC1 interactions establish the central spindle and promote spindle elongation using super-resolution imaging analyses.

Structures of growing and shortening microtubules suggest that anaphase forces act in part on bending protofilaments.

J.R. McIntosh¹, E.T. O'Toole¹, E.V. Ulyanov², F. Ataullakhanov³, N.B. Gudimchuk⁴; ¹M.C.D. Biology, Univ. Colorado, Boulder, CO, ²Physics, Lomonosov Moscow State University, Moscow, Russia, ³Physiochem. Pharmacol, Cntr Theoret. Problems, Moscow, Russia

We have used electron tomography to examine the tips of microtubules (MTs) growing or shortening in vivo and in vitro. The plus ends of MTs in the interzone of cells in anaphase B and kinetochore-associated MTs in metaphase are polymerizing in vivo. All these MTs are capped by PFs that show curvatures ranging from ~20 deg/dimer near their tips to ~10 deg/dimer near the MT wall. All PFs bend within a plane that contains the MT axis, so they are clearly separated from their neighbors. Since tubulin polymerization in vivo is facilitated by numerous tip-associated proteins, we have also examined the polymerization of pure tubulin in vitro, nucleated by axonemes from Chlamydomonas (kindness of M.E. Porter, Univ. MN). These growing MTs also display curving PFs at their tips, even when examined by rapid freezing and electron cryo-tomography. Again, PF curvature is greatest at the PF tip and decreases linearly with approach to the MT wall. The PFs of these MTs begin to curve away from the MT wall at a range of positions along the MT axis, so growing MT ends are “ragged.” The distribution of standard deviations of the mean positions of curvature onsets from many MTs peaks at 25 nm for growth at 1.2, and 4 mg/ml tubulin, but the frequency of outliers with high deviations increases with tubulin concentration. We compared these PF curvatures with those found on MTs induced to shorten in vitro by 25-fold isothermal dilution of MTs grown at 2 mg/ml and found curvatures that were slightly higher than those on growing MTs. The raggedness of ends on shortening MTs was, however, significantly less. The plus ends of kinetochore-MTs in anaphase A are shortening in vivo. Their PFs are longer than other PFs, and the linear decrease in PF curvature is not seen. These results suggest that MT growth occurs by the addition of bent tubulin to the tips of existing PFs, not to some niche where it can make bonds with multiple neighbors. Depolymerization is the reverse of the polymerization process. The fact that the PFs on anaphase kinetochore-MTs do not increase in curvature near their tips implies the action of cellular factors acting on these PFs, inducing them to straighten. This could be due to some of the force that these MTs exert on kinetochores during anaphase A.

Cdk1 phosphorylation of Nde1 and CENP-F contributes to G2-M Nuclear Envelope and Kinetochore dynein recruitment.

C. L. Wynne¹, C. Bertipaglia¹, D. Doobin¹, R.B. Vallee¹; ¹Pathology and Cell Biology, Columbia University Medical Center, New York, NY

Cytoplasmic dynein exhibits marked redistribution during the cell cycle, but the mechanisms responsible for this behavior remain incompletely understood. Dynein is recruited to the G2 nuclear envelope (NE) by early and late mechanisms involving, respectively, links to the nucleoporin RanBP2 through BicD2, and to the nucleoporin Nup133 through CENP-F and Nde1 (Baffet et al., 2015; Bolhy et al., 2011; Hu et al., 2013; Splinter et al., 2010). The late pathway is initiated by Cdk1-mediated exit of CENP-F from the
nucleus. Additionally, in mitosis, Nde1 and CENP-F subsequently co-localize to mitotic kinetochores from prophase until anaphase. To determine the mechanisms responsible for Nde1 and CENP-F co-redistribution and dynein recruitment we have examined their phosphorylation by Cdk1. Using a Cdk1 phosphorylation site-specific antibody and GFP-tagged wt and triple phosphomimetic and phosphomutant cDNAs, we have defined the role of Cdk1 in Nde1 behavior in HeLa cells. We find that Cdk1 phosphorylation of Nde1 is required for Nde1 recruitment to the G2 NE and mitotic kinetochore well into anaphase, a pattern comparable to the distribution of CENP-F. Phosphomutant Nde1 is very weak at the G2 NE. However, it is present at prometaphase kinetochores, but is completely lost upon chromosome alignment and MT attachment. Cdk1 phosphorylation of Nde1 increases its binding to CENP-F in vitro by ~ 2.5-fold, suggesting a mechanism for regulating the Nde1 and dynein recruitment from G2 through much of mitosis. To test the over-all importance of this mechanism in dynein recruitment to kinetochore, we rescued Nde1 knockdown with a dynein binding-deficient Nde1 mutant, which reduced the kinetochore dynein level by 50%. We also tested the role of Cdk1 phosphorylation in brain development using in utero electroporation of embryonic rat brain. We find that double phosphomutant Nde1 cDNA blocks G2-specific apical nuclear migration in radial glial progenitor cells (RGP). In contrast, a single site phosphomutant permits apical nuclear migration to the ventricular surface of the brain, but blocks mitotic entry. Finally, we have identified 9 Cdk1 sites in CENP-F, which may be responsible for its Cdk1-dependent nuclear export (Baffet et al., 2015). Together, these results indicate that Cdk1-phosphorylation of Nde1 and, possibly, CENP-F play critical roles in G2/M dynein regulation.

Loss of Fodrin Gives Mitotic Defects.
R.K. Nellika1, J.S. Sreeja1, S. Sengupta1;
1Division of Cancer Research, Rajiv Gandhi Centre for Biotechnology, Trivandrum, India

Fodrin, a cytoskeletal protein of non-erythroid origin, plays a pivotal role in the maintenance of cytoskeletal structure integrity of plasma membrane. It is also involved in axonal transport and movement of organelles. Recent studies, however, showed its role in apoptosis and TGF-β signaling pathway. We have earlier shown that fodrin disappears from centrosomes in brain derived cells as the cells enter the prometaphase stage and comes back after cytokinesis. To check more of its functional involvement in mitosis, we have downregulated fodrin by shRNA treatment in neuronal and glial cells where it is found in large amounts. Downregulation of fodrin gave mitotic defects, like multipolar and broken spindles were observed. In these cells, chromosomes were un congressed. Further a high percentage of cells displayed mitotic delay. Compared to control cells that were showing mean mitotic duration of 30 min, fodrin downregulated cells showed mean mitotic duration of 52 min and some cells were even blocked in metaphase during a 150 min follow-up after fodrin downregulation for 96 h. The mitotic defects and mitotic delay indicate increase in the checkpoint protein functions. Among the checkpoint proteins, BubR1 was found to be increased during metaphase stage upon fodrin downregulation as compared to control downregulation. Besides, fodrin downregulation gave a smaller spindle size as compared to the control shRNA treated spindles. About 25% decrease in the pole to pole distance of spindles was observed in fodrin downregulated cells. These results show that fodrin has much more functional importance than earlier thought.

Structural Basis for Katanin Self Assembly.
S. Nithianantham¹, F.J. McNally¹, J. Al-Bassam¹;
¹Molecular and Cellular Biology, University of California, Davis, CA

The reorganization of microtubules in mitosis, meiosis and development requires the microtubule-severing activity of katanin. Katanin is composed of a AAA ATPase subunit and a regulatory subunit. Whereas other AAA ATPases form stable hexamers, we show that wild-type katanin only forms heterodimers and heterotetramers. Heterododecamers were only observed for an ATP hydrolysis deficient mutant in the presence of ATP, suggesting an auto-inhibition mechanism that prevents oligomerization. X-ray structures of katanin’s AAA ATPase in monomeric nucleotide-free and pseudo-oligomeric ADP-bound states reveal conformational changes in AAA subdomains and N and C-terminal expansion segments that explain this auto-inhibition of assembly. These data lead to a model in which self-inhibited heterodimers bind to a microtubule, then transition into an assembly-competent conformation upon ATP binding. Microtubule-bound heterododecamers then promote tubulin extraction from the microtubule prior to oligomer dissociation.

Dynamic Instability of Microtubule Minus Ends.
C. Strothman¹, M. Podolski¹, A. Rahman², I. Richardson², M. Zanic¹,²;
¹Department of Cell and Developmental Biology, Vanderbilt University Medical School, Nashville, TN,
²Department of Chemical and Biomolecular Engineering, Vanderbilt University, Nashville, TN

Dynamic organization of microtubule minus ends is essential for the formation and maintenance of acentrosomal microtubule arrays, such as those found in epithelial cells, neurons, or cells undergoing meiosis. In vitro, both microtubule ends switch between phases of assembly and disassembly, behavior known as microtubule dynamic instability. However, while the minus ends have characteristically slower growth rates, the frequency at which they transition from the growing to the shrinking state (known as ‘catastrophe frequency’) is similar to that observed at the plus ends. The mechanisms underlying this difference between the two ends are not known. While kinetic parameters measured at the microtubule plus ends have informed numerous mechanistic models to describe the plus end, whether these existing models can adequately explain minus end dynamics remains to be determined. Here, we use an in vitro reconstitution approach with total internal reflection fluorescence (TIRF) microscopy to determine the parameters characterizing minus-end dynamics. Using these minus end data, we evaluate several models of dynamic instability, previously developed to describe dynamics of microtubule plus ends. The present study aims to elucidate the fundamental nature of the microtubule minus end, which is imperative for understanding the minus end in the context of cellular regulation by external factors.

Autocatalytic microtubule nucleation determines the size and mass of spindles.
F. Decker\textsuperscript{1,2,3}, D. Oriola\textsuperscript{1,2,3}, B. Dalton\textsuperscript{1,2,3}, J. Brugués\textsuperscript{1,2,3},
\textsuperscript{1}Center for Systems Biology Dresden, Dresden, Germany, \textsuperscript{2}Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, \textsuperscript{3}Max Planck Institute for the Physics of Complex Systems, Dresden, Germany

The mitotic spindle is a complex self-organized structure that distributes the DNA between daughter cells during cell division. Interestingly, the main building blocks of the spindle, the microtubules, only have a lifetime of about 20 s while the entire structure remains for minutes up to hours. This requires constant creation of new microtubules, which is called nucleation. How microtubules, however, are nucleated in spindles and how spindles obtain their defined size despite the rapid turnover of their components is largely unknown. Here, we developed a new method based on laser ablation to measure the nucleation profile of transport-inhibited spindles in \textit{Xenopus laevis} egg extract and found that microtubule nucleation is spatially regulated. In combination with theory and quantitative microscopy, we show that new microtubules grow in an autocatalytic way and in direct physical contact to pre-existing microtubules. The autocatalytic activity of this nucleation system is spatially regulated by the limiting amounts of active microtubule nucleators, which decrease with distance from the chromosomes. This mechanism provides an upper limit to spindle size even when resources are not limiting.

\textsuperscript{1}molecular, cellular and life sciences, University of Wyoming, Laramie, WY, \textsuperscript{2}Systems biology, Harvard medical school, Boston, MA, \textsuperscript{3}Chemical engineering, University of Wyoming, Laramie, WY, \textsuperscript{4}Chemical and bio molecular engineering, University of Delaware, Newark, DE

The cytoplasm of a eukaryotic cell is a complex and dynamic microenvironment that requires proper organization to insure cell function. The microtubule (MT) cytoskeletal network plays a fundamental role in this organization. During interphase, it serves as both a supportive scaffold for organelles and as an arborized system of tracks for intracellular transport. Whereas during mitosis, the position of the interphase aster, which often coincides with the geometric center of the cell, determines the eventual location of the spindle apparatus and ultimately the cytokinetic furrow. The ability of the aster to find the cell center is particularly impressive in large blastomeres, where scale dictates aster movement over long distances. These movements require the generation of positioning forces and in this context there are thought to be three primary forces to generate this force balance: (i) pushing forces generated by the interaction between growing MT plus ends and the cell cortex, (ii) cortical pulling forces produced by MT dependent motors anchored in the cell cortex, and (iii) cytoplasmic pulling forces generated by motor mediated transport along aster MTs and interaction with organelles in the cytoplasm. How these different forces are integrated to position asters within cells of varied sizes and geometries remains an open question. To address it, we have developed the use of photolabile hydrogels to capture and release artificial microtubule organizing centers (aMTOCs) in defined geometric hydrogel microenvironments. Combined with cell-free extracts, we used this system to visualize the effects of such geometries on aster MT dynamics, MT density and aster positioning. Our current data suggests that
constraining an aster decreases the MT density without affecting nucleation rate. Using this approach, we hope to elucidate how the cellular microenvironment impacts aster growth, especially aster positioning through experimentally defined spatial patterns of MT density and extent.

Distal appendages (DAPs) are nanoscale, pinwheel-like structures protruding from the centriole distal end. DAPs mediate membrane docking for ciliogenesis, marking the cilia base around the ciliary gate. Here, through a superresolved multiplex of thirteen centriole-distal-end components, we surprisingly found that, instead of pinwheels, intact DAPs exhibit a “cone-shaped” architecture with components filling the space between each pinwheel blade, a new structural element we termed the distal appendage matrix (DAM). Specifically, CEP83, CEP89, SCLT1 and CEP164 form the backbone of pinwheel blades, with CEP83 confined at the root, and CEP164 extended to the tip near the membrane-docking site. In contrast, FBF1 marks the distal end of the DAM toward the ciliary membrane. Strikingly, unlike CEP164 essential for ciliogenesis, FBF1 is required for ciliary gating of transmembrane proteins, revealing DAPs as the essential part of the ciliary gate. Our results thus redefine both the structure and function of DAPs.

Myosin-Va is required for preciliary vesicle transportation to the mother centriole during ciliogenesis.
C. Wu1,2, H. Chen2, T.K. Tang1,2;
1Taiwan International Graduate Program in Interdisciplinary Neuroscience, National Yang-Ming University and Academia Sinica, Taipei, Taiwan, 2Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan

Primary cilia are microtubule-based organelles protruding from the apical cell surface to sense different chemical signals. Defects in ciliogenesis can lead to a number of genetic disorders collectively known as ciliopathies. Pre-ciliary vesicle accumulation at the distal appendages of mother centrioles to form a larger ciliary vesicle is critical in early step of ciliogenesis. What is the marker protein for the preciliary and ciliary vesicle? Where do the ciliary vesicles come from? How do the ciliary vesicles transport to the distal appendages of centrioles? The above questions remain largely unknown. Here, using three-dimensional structured illumination microscopy and correlative light and electron microscopy we first demonstrate that the actin-based motor protein Myosin-Va localizes to pre-ciliary vesicles, ciliary
vesicles, and ciliary sheath. Moreover, the myosin-Va-associated ciliary vesicle is not only detected in the intracellular pathway-based ciliogenesis like RPE1 cells but also the extracellular pathway based ciliogenesis like IMCD3 cells. CRISPR/Cas9-mediated Myosin-Va gene knockout in cells dramatically inhibits not only the attachment of the pre-ciliary vesicles to the distal appendages of mother centriole but also cilia assembly, implying that Myosin-Va is required for regulating the ciliary vesicle trafficking. By comparing with other early ciliary membrane protein, we found that Myosin-Va functions upstream of EHD1-Smo- and Rab11-mediated ciliary vesicle formation. Importantly, through disrupting the function of microtubules and dynein, we further demonstrate that, Myosin-Va-associated ciliary vesicles are derived from the post-Golgi membrane, and transported to the pericentrosomal region by dynein-mediated transportation along microtubules. Finally, disturbing the centrosome-based branched actin filament by Arp2/3 inhibitor, CK-666 or siRNA-mediated knockdown of Arp2 dramatically inhibits the formation of large ciliary vesicle at the distal appendages but does not affect the transportation of the pre-ciliary vesicle from the post-Golgi to the pericentrosomal region. These results indicate that Myosin-Va takes over and transports pre-ciliary vesicles from pericentrosomal region to the mother centriole along the centrosomal branched-actin network. Together, our results indicate that Myosin-Va is the first marker to identify the preciliary and ciliary vesicle and Myosin-Va-regulated preciliary vesicle transportation from the post-Golgi to the distal appendages of mother centriole is the earliest step of ciliogenesis.

Defects in cilia are linked to human genetic diseases, called ciliopathies, and cancer. Ciliogenesis is thought to occur via two distinct processes. In the extracellular pathway, the mother centriole (MC) docks with the plasma membrane prior to ciliary growth. In contrast, the intracellular pathway involves the trafficking, fusion and reorganization of vesicular membranes at the MC prior to ciliary extension followed by emergence of the cilium at the cell surface. Here, we demonstrate that the F-BAR domain containing proteins PACSIN1 and -2 play an essential role in intracellular ciliogenesis in human and zebrafish cells. PACSINs are required for the shaping of smaller MC associated vesicles into the larger ciliary vesicle (CV). Membrane rearrangement at the CV step depends on the initial recruitment of EHD1/3 proteins, two known PACSIN1/2 binding partners linked to the Rab11-Rab8 pathway as well as SNAP29. Using Correlative Light and Electron microscopy (CLEM) combined with a Focused Ion Beam-Scanning Electron microscope (FIB-SEM), we observed membrane tubules connected to the developing intracellular cilia and the ciliary pocket in mature cilia in three-dimensions. Remarkably, during ciliogenesis these tubular membranes connect the developing cilium and the plasma membrane, forming a membrane channel to the outside of the cell. Using three color live cell imaging, we found that tubule channels originate from the intracellular cillum and require PACSINs. Together, our work uncovers a novel role for F-BAR containing proteins and membrane tubulation in ciliogenesis and explains how the developing intracellular cillum emerges from the cell.

A Bioactive Peptide Amidating Enzyme Is Required for Ciliogenesis.  
D. Kumar1, D. Strenkert2, R.S. Patel-King3, S.S. Merchant3, R.E. Mains3, B.A. Eipper1,3, S.M. King1;  
1Department of Molecular Biology and Biophysics, University of Connecticut Health Center, Farmington, CT, 2Department of Chemistry and Biochemistry, University of California Los Angeles, Los Angeles, CA, 3Department of Neuroscience, University of Connecticut Health Center, Farmington, CT  

We recently identified peptidylglycine α-amidating monooxygenase (PAM), a cuproenzyme required for generating amidated bioactive signaling peptides, in Chlamydomonas and mammalian cilia. PAM consists of two catalytic cores (monooxygenase and lyase) located in the secretory pathway lumen, followed by a transmembrane domain and small cytosolic region important for trafficking. Chlamydomonas PAM knockdown lines exhibit normal growth rates under both photoautotrophic and photoheterotrophic conditions, and their contractile vacuole cycle time is similar to controls. However, these strains fail to assemble normal cilia beyond the transition zone (TZ), which has missing Y linkers, and upregulate levels of two TZ components, CEP290 and NPHP4. In addition, singlet microtubules oriented orthogonal to the normal ciliary long axis and amorphous material including IFT proteins were present in the ciliary stubs distal to the TZ. The knockdown strains also have altered levels of IFT subcomplex A components, abnormal Golgi architecture, enlarged starch granules without a concomitant increase in total starch (likely due to defective trafficking of Golgi-derived starch metabolic enzymes), and exhibit selective defects in protein secretion. A line expressing a mutant PAM lacking most of its cytosolic C-terminal domain assembles cilia and is motile, suggesting that the PAM catalytic cores are important for ciliogenesis. Indeed, when deciliated wildtype Chlamydomonas cells were treated with either a mechanism-based monooxygenase inhibitor or a copper-specific chelator, the rate of reciliation was significantly retarded, indicating that amidating activity is a key ciliogenic parameter. RNAi-mediated reduction of PAM gene expression in planaria reduced cilia-mediated organismal gliding velocity and motile ciliary density on the ventral surface. The remaining cilia were aberrant with dyskinetic motion, decreased beat frequency and defects in axonemal architecture. In addition, numerous cytosolic axonemes lacking a ciliary membrane were present in the ventral epithelial cell cytoplasm, suggesting that lack of PAM leads to basal body docking and ciliary membrane trafficking defects, but does not affect axonemal assembly per se. Pam−/− mouse embryos die at embryonic day ~14.5 with massive edema. At this early developmental stage, the embryos lack multiciliated cells. However, primary cilia in neuroepithelial cells of the brain ventricles were significantly shorter than controls. Our data suggest that PAM activity and alterations in post-Golgi trafficking contribute to the observed ciliogenesis defects and provide an unanticipated, highly conserved link between PAM, amidation and ciliary assembly. Supported by DK032949, GM042143 and GM051293 (NIH).

A mechanistic study of how O-GlcNAcylation levels regulates cilia lengths in mammalian cells.  
J. Tian1, H. Qin1;  
1Biology department, Texas AM University, College Station, TX  

Primary cilia are microtubule (MT) based hair-like structures that extend from the surface of many types of cells. Dysfunctional primary cilia is involved in a large number of human diseases and disorders, such as polycystic kidney disease (PKD) and Bardet-Biedl syndrome (BBS), obesity and diabetes, collectively termed ciliopathies. The ciliary functions rely on defined ciliary lengths. Besides the cell types, the
nutritional environment has been shown to regulate the ciliary length. However, the cellular internal mechanism of ciliary length regulation involved in responding to external environment condition is unclear. We recently uncovered a negative correlation between the nutrient sensing O-GlcNAcylation levels and cilia lengths in mammalian cells. Increased O-GlcNAcylation correlates with shorter cilia lengths, while decreased O-GlcNAcylation correlates with longer cilia. Previous studies have shown that HDAC6 (histone deacetylase 6), acting through axoneme microtubule deacetylation, governs ciliary disassembly. We showed that HDAC6 is O-GlcNAcylated and its modification related to HDAC6 protein stability. Future work is centered on addressing the hypothesis that O-GlcNAc of HDAC6 increases its deacetylase activity, thus shortening cilia lengths.

The role of IFT54 in tubulin transport and cilia stability.
J. Wingfield¹, K.F. Lechtreck¹;
¹Cellular Biology, University of Georgia, Athens, GA

Intraflagellar transport (IFT) shuttles tubulin, the major structural protein of cilia and flagella, from the cell body into cilia to promote elongation. The IFT proteins IFT81 and IFT74 form a tubulin binding module: IFT81 binds the dimers via its calponin homology (CH) domain and the basic N-terminal domain of IFT74 interacts with the acidic C-terminus of β-tubulin.1 In vivo studies in Chlamydomonas reinhardtii revealed that strains lacking either the N-terminal domain of IFT74 (ΔN-IFT74) or carrying mutations incapacitating the CH-domain of IFT81 (CH5E-IFT81) build near full-length flagella albeit at a slower rate. ift81 CH5E-IFT81 ift74 ΔN-IFT74 double mutants, however, fail to assemble cilia with a subset of cells possessing stumpy flagella with a normal axonemal structure.2 Thus, IFT81/74 appear to form the major tubulin binding site on IFT trains. However, several other IFT proteins possess CH-domains and the N-terminal CH of IFT54 has been shown to bind tubulin in vitro.3 To address the question whether IFT54 contributes to tubulin transport, we characterized an insertional mutant in the IFT54 gene. The mutant expresses a C-terminally truncated non-functional IFT54 protein and completely lacks flagella. The mutant phenotype is rescued by both full-length and truncated CH-less IFT54 (ΔCH-IFT54). Specifically, the ift54 ΔCH-IFT54 strain assembles full-length, motile cilia at a normal rate, arguing against an essential role of IFT54 CH in tubulin transport. However, ift54 ΔCH-IFT54 interfered with cilia assembly in combination with the above described mutations in the IFT81 or the IFT74 genes: An ift54 ΔCH-IFT54 ift74 ΔN-IFT74 double mutant is entirely flagella-less similar to other IFT loss of function mutants. Only about 20% of the cells of the ift54 ΔCH-IFT54 ift54 CH5E-IFT81 double mutant possess near full-length flagella, and flagellar regeneration is slower than in the parental strains. Double mutant cells often remain entrapped in the mother cell wall despite the presence of flagella. Electron microscopy revealed that the mutant flagella are prone to abscission and fragmentation. Thus, the CH domain of IFT54 is required for normal cilia assembly when the tubulin binding sites of either IFT74 or IFT81 are impaired. To determine if this phenotype is the result of decreased tubulin transport or a more general defect in IFT, we are investigating the transport of GFP-tagged tubulin and tubulin derivates in ift54 ΔCH-IFT54 and suitable double mutants. 1. The flagellar associating protein FAP85 of *Chlamydomonas* is one of the microtubule inner proteins.
J. Kirima, H. Kojima, K. Oiwa,
1Graduate School of Life Science, University of Hyogo, Harima, Japan, 2Advanced ICT Research Institute, Kobe, Japan

*Chlamydomonas* flagellar axonemes are composed of 200-600 types of proteins. Despite of extensive studies, many proteins have remained un-characterized. Among these un-characterized flagellar associating proteins (FAPs), we focused on the protein with an EF-hand motif, FAP85 which is specific for *Chlamydomonas*. We have identified the protein with molecular weight of 22kDa in the high salt extract of *Chlamydomonas* flagella with using peptide mass fingerprinting, which was previously named FAP85. We then cloned cDNA encoding FAP85 and expressed it in *E. coli* cells as a ProS2-conjugated form. The polyclonal antibody against the expressed protein was prepared and was confirmed to interact with native FAP85. The western blot analyses demonstrated that the anti-FAP85 antibody recognizes a prominent band of 20-kDa in every isolated axonemes from mutants lacking major axonemal components (the outer arm-lacking mutants, *oda1* and *oda2*; the inner arm dynein I1-lacking mutant *ida1*; inner-arm dynein (subspecies, a c d and e) lacking mutant, *ida5*; DRC-defect mutants, *pf2* and *pf3*; radial spoke-lacking mutants, *pf14*, the central pair lacking mutant, *pf18*; beak-like structure-lacking mutants, *mbo1*). N-Lauroylsarcosine (Sarkosyl) treatment solubilized the FAP85 from the axonemes, concomitantly with the solubilization of the A tubule. Immuno-gold electron microscopy on Sarkosyl-treated axonemes showed that gold-particles were observed only on the inner wall of A tubules of the doublet exposed with Sarkosyl treatment and had the structural repeat of ca. 50 nm. Furthermore, FAP85 had effects on tubulin kinetics, in which the critical concentration of tubulin decreased and the rate of tubulin polymerization slightly became faster in the presence of FAP85. According to these results, we conclude that FAP85 is a novel component of microtubule binding proteins localized on the inner wall of the A tubule.

The growing motile cilium tip undergoes a time-dependent development process.
M. Reynolds, T. Phetruen, R. Fisher, K. Chen, Y. Wu, B. Pentecost, G. Gomez, P. Ounjai, H. Sui,
1Wadsworth Center, New York State Department of Health, Albany, NY, 2Biology, The University of Scranton, Scranton, PA, 3Biology, Mahidol University, Bangkok, Thailand

Eukaryotic motile cilia are microtubule-based structures responsible for cellular locomotion and movement of extracellular fluids. While motile cilium regeneration and the structure of the motile cilium axoneme have been well described, the development of the distal tip region and its structure during ciliogenesis remain poorly characterized. We studied tip region development during cilium regrowth and discovered that the tips of motile cilia display dynamic morphology as the cilium develops. In these investigations, we sought to investigate the factors that control ciliary tip region lengths, and determine whether these different morphologies are conserved across species. The motile cilia of deciliated *Chlamydomonas reinhardtii* and *Tetrahymena thermophila* were observed during their regrowth using scanning electron microscopy, negative staining transmission electron microscopy, and cryo-electron tomography. The investigation revealed that the ciliary tip region is subject to a time-dependent
development process that is independent of species. Furthermore, the cillum tip continues to develop after the regrowing cillum reach their stable, full lengths.

Phosphatidylinositol 4,5-bisphosphate (PIP2) is Essential for Cillum Assembly and Function in *Drosophila melanogaster*.  
A. Gupta1,2, J.A. Brill1,2;  
1Cell biology, Hospital for Sick Children, Toronto, ON, 2Molecular Genetics, University of Toronto, Toronto, ON  

Cilia are antenna-like sensory organelles whose malfunction underlies many genetic disorders in humans. Recent studies have found that dephosphorylation of phosphatidylinositol 4,5-bisphosphate (PIP2) by inositol 5-phosphatase (INPP5E) is necessary for cillum assembly and function. We present evidence against a simplistic model for the PIP2 code of cilia. Specifically, we show that PIP2 is essential for both formation and proper function of chordotonal cilia in *Drosophila melanogaster*. We report the presence of a tightly localized pool of relatively high PIP2 levels within the chordotonal cillum, suggesting that the notion of cillum as organelles devoid of PIP2 should be reconsidered. We also observe that neuronal clones mutant for the type I phosphatidylinositol 4-phosphate 5-kinase A/B ortholog Skittles (sktl) do not assemble cilia. Furthermore, in contrast to overexpression of Sktl in chordotonal neurons [1], RNAi-mediated sktl knockdown does not affect the localization of the Tubby domain protein Tulp. Instead, sktl RNAi induces defects in intraflagellar transport, which is unaffected in inpp5e mutants that contain high intraciliary levels of PIP2 [1]. We also report a novel role for PIP2 in transition zone length control – sktl RNAi induces aberrant elongation of transition zone-associated Cep290. This phenotype is mimicked by loss of PIP2 in the ciliated male germline of *Drosophila*. Our observations reveal unappreciated complexity in the functional relationship between PIP2 and cilia.

Identification and characterization of cillum proteins in *Caenorhabditis elegans*.  
T.Y. Su1, A. Dammermann1;  
1Max F. Perutz Laboratories, University of Vienna, Vienna, Austria  

In addition to forming centrosomes in dividing cells, centrioles have an evolutionarily conserved role as basal bodies templating the formation of cilia. While numerous centriolar and ciliary components have been identified, key aspects of ciliogenesis, including basal body membrane docking and initiation of axoneme elongation remain poorly understood. In addition, previous studies of cilia in *Drosophila* and *Plasmodium* revealed an intraflagellar transport-independent biogenesis pathway, for which few molecular components are currently known. Finally, the genes linked to many human ciliopathy cases have not been determined. Together, these results indicate that additional cilia proteins and regulators remain to be identified.  
We have been undertaking a phylogenetic profiling approach to identify novel genes whose conservation pattern across eukaryotes suggests a potential role in cillum assembly or motility, which we are characterizing using *Drosophila* and *C. elegans* as experimental models. The nematode *C. elegans*
has proven to be a particularly powerful system to dissect the function of novel cilia genes because cilia are exclusively found in post-mitotic neurons, which are dispensable for viability and fertility. The availability of a wide range of ciliary markers, together with the stereotypical pattern of nematode development, makes it easy to characterize the role of novel proteins involved in cilia biogenesis. Of the 386 human genes whose inheritance pattern is characteristic of cilia, 135 are conserved in C. elegans including a set of 60 novel genes. Preliminary characterization of available mutants revealed a number of additional cilia genes. This poster will present the primary data from our screen, as well as more detailed characterization by light and electron microscopy of several of these novel proteins, including an apparent regulator of cilia biogenesis conserved across eukaryotes.

TrypTag.org – Genome wide protein localisation reveals organelle sub-domains, with functional consequences in the flagellum.
J.D. Sunter¹, R.J. Wheeler², S. Dean², B. Edwards², K. Gull²;
¹Department of Biological and Medical Sciences, Oxford Brookes University, Oxford, United Kingdom,
²Sir William Dunn School of Pathology, University of Oxford, Oxford, United Kingdom

Organelles have highly organised, complex internal structures that enable them to perform a diverse set of biological functions. Analysing this complex structural organisation on a genome-wide scale, using methods like mass spectrometry is typically extremely challenging and often loses fine-scale structural resolution. To address this, we are determining the localisation of every protein encoded in the Trypanosoma brucei genome using our high-throughput tagging methodology and automated quantitative image analysis of cell ultrastructure. Trypanosomes are ideal for this study as they combine an exquisitely ordered cellular architecture with conserved core eukaryotic biology. Trypanosome organelles have precisely defined positions/distributions in the cell, and inter-organelle contact occurs at specific positions; crucially they have greater internal order than yeast cells or typical human cell lines. To date we have localised over 80% of the 8129 proteins encoded in the genome and the data we are generating is made freely available on our website http://tryptag.org. We have shown many proteins localise to specific organelle sub-domains and this organelle asymmetry/inhomogeneity applies to all organelles, including the flagellum, endoplasmic reticulum and mitochondrion. Here, as one example, we concentrate on our comprehensive molecular cartography of the flagellum and the role of protein asymmetry within the flagellum. So far, we have found 43 proteins that localised to the proximal region of the flagellum only, 29 to the distal region only, 62 flagellar tip proteins and 289 proteins in the basal body or transition zone. Comparable asymmetry of protein localisation was also observed for flagellar membrane proteins. The cohort of distal flagellum proteins included orthologs of the docking complex proteins DC1 and DC2, required for attaching the outer dynein arms to the microtubule doublets of the axoneme. We showed there are also proximal flagellum DC1-like and DC2-like orthologs. This proximal/distal asymmetry is important for flagellum beat control in trypanosomes, and predicts tissue-specific control of flagellum beat by DC1 and DC2 orthologs in humans. This one example of exploiting the TrypTag dataset has identified a new candidate ciliopathy gene and produced a map at molecular detail of the entire flagellum. TrypTag is a rich dataset that will help define organelle sub-domains and therefore refine overall organelle function with implications for the entire eukaryotic cell biology field.

Mammalian primary cilia disassembly is heterogeneous but primarily occurs via rapid whole cilium shedding.
M. Mirvis\(^1\), W.J. Nelson\(^{1,2}\);
\(^1\)Molecular and Cellular Physiology, Stanford University, Stanford, CA, \(^2\)Biology, Stanford University, Stanford, CA

The regulated cycle of assembly and disassembly of primary cilia is critical for correct ciliary signaling function and cell cycle control. While assembly and maintenance of the primary cilium are well studied, much less is known about the mechanism(s) of ciliary disassembly. Based on studies of the single celled biflagellate algae Chlamydomonas reinhardtii in which anterograde and retrograde intraflagellar transport (IFT) control ciliary assembly and maintenance, it is thought that a change in the balance of IFT could lead to ciliary disassembly. Here we tested this, and other hypotheses for ciliary disassembly in mouse epithelial IMCD3 cells expressing fluorescent markers of the ciliary membrane (SSTR3) and basal body (pericentrin PACT domain). Confocal time lapse imaging at high spatiotemporal resolution revealed a striking diversity of cilia disassembly behaviors that included gradual reabsorption into the cell and direct shedding from the cell surface, and ranged from seconds to hours. Inhibition of retrograde IFT with ciliobrevin D had no effect on overall loss of cilia or disassembly dynamics, indicating that IFT is not the principal regulator of cilia disassembly in these cells. The most prevalent method of cilia disassembly (~70\% of cases) was super-fast cell shedding, which occurred in seconds (2.8 ± 1.3 um cilia length/min). Immunofluorescence and Western blot analysis of material concentrated from the medium confirmed the presence of ciliary material detached from cells following induction of cilia disassembly. Ciliary shedding was preceded by a calcium influx within cilia, and was disrupted by depolymerization of actin with cytochalasin D or latrunculin A. This work reveals unexpected diversity in mechanisms of ciliary disassembly, and points to new potential regulators of this highly dynamic and heterogeneous process.

How cells control the size of their organelles: Flagellar length control in Chlamydomonas.
D. Bauer\(^3\), W.F. Marshall\(^1\);
\(^1\)Biophysics, University of California - San Francisco, San Francisco, CA

How cells control the size of their organelles is an unanswered question in Biology. Flagella are an ideal organelle to study this question because of their simplistic structure; they are essentially one dimensional structures, only changing in length, which offers an advantage in simplicity over more complicated organelles like the endoplasmic reticulum. To study flagellar length control, we have built a microfluidic device capable of trapping Chlamydomonas cells for periods of time much longer than flagellar regeneration. With this device, we are able to measure length scale fluctuations predicted by theory that have not been measured before, enabling us to identify likely length control models.

THE ROLE OF SMALL GTPASE ARL3 IN THE FORMATION AND FUNCTION OF THE CHLAMYDOMONAS FLAGELLA.
H. Qin1, X. Jiang1;
1Department of Biology, Texas AM University, College Station, TX

ARL3 is a cilia-related protein expanding from single-cell protozoans to mammalians. ARL3 has been shown to be involved in the ciliogenesis and serve as a displacement factor for the lipid-modified proteins. Functions of ARL3 other than ciliogenesis may be caused by the misdistribution of a subset of lipid-modified peripheral membrane proteins. These proteins depend on ARL3 in order to be properly released to the cilia. Currently, questions remain unclear about the function of ARL3 in ciliogenesis, and the relative extent that this arl3-dependent displacement pathway contributes. In this study, we characterized a Chlamydomonas arl3 mutant, which presents various subtle flagellar defects. We found that cells rescued with ARL3-GTP assemble significantly shortened flagella than others, confirming that overexpression of ARL3-GTP leads to ciliogenesis defects. Moreover, we compared the protein composition of isolated flagella between the mutant arl3 and the wild-type cc125. As we expected, the axonemal composition did not show significant change whereas the protein bands with altered intensity were detected in the detergent-rich partition, which contains membrane proteins. This study provides insights into possible mechanisms of ciliary dysfunction caused by the depletion of ARL3. Moreover, the isolated arl3 mutant can be a valuable tool in further function analysis of ARL3.

The contraction of Centrin filaments initiates assembly of the cilium by pumping IFT and flagellar precursors from the Zone of Exclusion (ZOE) into the ciliary/flagellar stubs.
C. Wood1, J. Salisbury2, J.L. Rosenbaum3;
1Dept Cell Biology, Harvard University, Boston, MA, 2Cell Biology, Mayo Clinic Medical School, Rochester, MN, 3Dept MCDB, Yale University, New Haven, CT

The Zone of Exclusion (ZOE) is an area of cell organelle exclusion located between the ciliary basal bodies and the nucleus, and bounded by bundles of centrin filaments connecting the basal bodies to the nucleus. We now show by TEM and fluorescence microscopy that the ZOE area is a flattened disc. Upon removal of the flagella of Chlamydomonas, calcium enters the cytosol, the centrin filaments rapidly contract, and pull the nucleus up underneath the basal bodies. This pushes the contents of the ZOE into the ciliary stubs. We now show that the ZOE contains IFT proteins and flagellar precursors. Earlier work had shown that IFT quickly appears, after flagellar detachment, in the flagellar stubs (Marshall and Rosenbaum, JCB 2001). Upon completion of flagellar assembly, the ZOE re-appears in the cytoplasm, following the kinetics of flagellar precursor utilization and re-synthesis (Lefebvre and Rosenbaum, JCB, 1978). Centrin contraction requires calcium (Salisbury et al, JCB (1987) as does the initiation of flagellar assembly (Lefebvre and Rosenbaum, JCB, 1978). The flagella will not assemble without centrin contraction. These results are consistent with the kinetics of flagellar regeneration in Chlamydomonas which have no lag phase (Rosenbaum, Moulder and Ringo, JCB, 1968) and the kinetics of flagellar precursor pool utilization during flagellar assembly in Chlamydomonas (Lefebvre and Rosenbaum, JCB, 1978). The results suggest that IFT and its associated flagellar precursors are associated with the centrin filaments in the ZOE, and are moved into the forming ciliary stubs by centrin contraction on deciliation. The IFT is initially moved into the stubs as a "bolus" which contains all the iFT the flagellum will ever
have as it elongates (Marshall and Rosenbaum, et al MBoC 2005). Future studies will probably show the molecular association of IFT, flagellar precursors, and centrin in the cytoplasm.

Biochemical and Structural Insights into the Interaction of Myristoylated Cargo with Unc119 Protein and Their Release by Arl2/3.

M. Jaiswal1, E.K. Fansa2, A. Wittinghofer3, S.K. Köslng2;
1Department of Cellular Logistics, Max-Planck Institute for Biophysical Chemistry, Göttingen, Germany,
2Max-Planck Institute for Molecular Physiology, Dortmund, Germany

Primary cilia are highly specialized small antenna-like cellular protrusions that extend from the cell surface of many eukaryotic cell types. The protein content inside cilia and cytoplasm is very different, but details of the sorting process are not understood for most ciliary proteins. Here we address the question whether the binding affinity has an impact on the transport of myristoylated cargo by the carrier proteins Unc119a and Unc119b like prenylated cago and their carried protein PDE6β. We thus analyzed the binding strength of N-terminal myristoylated cargo peptides (GNAT1, NPHP3, Cystin1, RP2, and Src) to Unc119a and Unc119b proteins. The affinity between myristoylated cargo and carrier protein, Unc119, varies between subnanomolar and micromolar. Peptides derived from ciliary localizing proteins (GNAT1, NPHP3, and Cystin1) bind with high affinity to Unc119 proteins, whereas a peptide derived from a non-ciliary localizing protein (Src) has low affinity. The peptide with intermediate affinity (RP2) is localized at the ciliary transition zone as a gate keeper. We show that the low affinity peptides are released by both Arl2-GppNHp and Arl3-GppNHP, whereas the high affinity peptides are exclusively released by only Arl3-GppNHP. Determination of the x-ray structure of myristoylated NPHP3 peptide in complex with Unc119a reveals the molecular details of high affinity binding and suggests the importance of the residues at the +2 and +3 positions relative to the myristoylated glycine for high and low affinities. The mutational analysis of swapping the residues at the +2 and +3 positions between high and low affinity peptides results in reversing their affinities for Unc119a and leads to a partial mislocalization of a low affinity mutant of NPHP3.

Photoreceptors rely on intracellular trafficking mechanisms to ensure proper delivery of specialized membrane proteins to their ciliary, light-sensitive outer segment. Unfortunately, very little is known about the mechanisms sorting cargos at the Golgi complex for transport to the ciliary membrane. Previously, the small GTPase, Arf4, emerged as a key molecule driving the selection of membrane proteins for delivery to the cilia. Specifically, Arf4 was thought to be critical for sorting the visual pigment, rhodopsin, from trans-Golgi network into transport vesicles destined for the outer

Monday-106
segment. Experiments performed in cell culture similarly suggested that Arf4 may be involved in the sorting of kidney-specific ciliary proteins as well. We now deleted Arf4 specifically in either rod photoreceptor cells, kidney, or globally during the early postnatal period. Arf4 deletion in photoreceptors did not cause rhodopsin mislocalization or retinal degeneration, as would be expected if Arf4 played a critical role in outer segment protein transport. Likewise, Arf4 deletion in kidney did not cause cystic disease, as would be expected if Arf4 were involved in general ciliary trafficking. In contrast, global Arf4 deletion in the early postnatal period resulted in growth restriction, severe pancreatic degeneration and premature death. Thus, while our data support a role for Arf4 in endomembrane trafficking and reveals its essential role in exocrine pancreatic function, it demonstrates that Arf4 is not the key molecule for sorting ciliary cargo. This work is critically important to the photoreceptor field as it will drive the search for alternative ciliary pathways and players.

An uncharacterized transport pathway for membrane proteins in primary cilia revealed by high-speed super-resolution microscopy.
A. Ruba\(^1\), W. Luo\(^1\), W. Yang\(^1\);
\(^1\)Department of Biology, Temple University, Philadelphia, PA

The primary cilium is a microtubule-based protrusion on the surface of many eukaryotic cells. It houses essential components of the Hedgehog, planar cell polarity, and many other signaling pathways, all of which require efficient protein trafficking between cytosol and primary cilium for transmitting signals and recycling receptors. It is believed that vesicular trafficking is employed for the intracellular protein transport from the Golgi to the primary cilia, while membrane diffusion and intraflagellar transport (IFT) are the major transport mechanisms for the intraciliary transport of transmembrane proteins. However, where post-Golgi vesicles fuse to and how membrane proteins are delivered into primary cilia remain in dispute. Using a high-speed super-resolution microscopy approach, we mapped the three-dimensional (3D) spatial locations of transport routes for transmembrane proteins translocating between the cytoplasm and primary cilia in live cells with an unprecedented spatiotemporal resolution of 2 ms and 10-20 nm. Remarkably, our high-resolution 3D data reveal that a previously uncharacterized transport pathway exists for vesicles loaded with transmembrane proteins inside the axonemal lumen through the transition zone and into the ciliary shaft. The distinct spatial locations of this new transport pathway and the IFT train route suggest a more precise and complete model for the cytoplasm-cilium transport of membrane proteins.

Ciliary GPCRs are required for adipogenesis.
K.I. Hilgendorf\(^1\), P.K. Jackson\(^1\);
\(^1\)Microbiology and Immunology, Stanford University, School of Medicine, Stanford, CA

The primary cilium, a small antenna-like cellular projection, is localized on the surface of all mesenchymal progenitor cells. Moreover, the primary cilium is required for differentiation of mesenchymal cells. However, how the primary cilium functions in these processes remains poorly understood. Here, I will present a novel ciliary G protein-coupled receptor that regulates adipogenesis of both a murine cell line model of adipogenesis and primary isolated murine and human pre-adipocytes. Activation of this novel ciliary pathway by its natural ligand or a pharmacological agonist acutely raises
cyclic AMP levels in the primary cilium, resulting in entry into mitotic differentiative expansion, activation of the master adipogenic transcription factor Ppar,y and terminal differentiation. Conversely, a pharmacological antagonist inhibits adipogenesis. We will provide genetic evidence further detailing the signaling mechanisms that couple this GPCR to differentiation and ciliary signaling. Moreover, we show that this study has uncovered the physiologically relevant ligand to replace IBMX, a phosphodiesterase inhibitor commonly used to initiate adipogenesis in vitro by raising cellular cyclic AMP. This places the primary cilium at the crossroad of whether or not to initiate adipogenesis. Since adipocytes turnover regularly and excess nutrient uptake drives an increase in both the size and number of adipocytes, we strongly believe that our findings have significant impact on our understanding of what marks a pre-adipocyte and how its cell fate is regulated.

Isolation of ciliary proteins from the transient primary cilium of differentiating 3T3-L1 pre-adipocytes.  
T.N. Browne1, B. Henderson1, L.B. Cook1;  
1Biology, The College at Brockport, State University of New York, Brockport, NY

Obesity has become a leading health crisis in Western society. One biomedical approach to a cure is to target how the body manages energy storage and expenditure such that intentional pharmaceutical design can be used to manage signaling pathways. Our work focuses on the development of adipose tissue, specifically the expansion and differentiation of pre-adipocytes using murine 3T3-L1 cells as a model system. 3T3-L1 cells form a transient primary cilium during differentiation that is absolutely required for adipocyte formation. These cilia can be labeled for fluorescence microscopy or Western Blot using antibody to acetylated tubulin. Our goal is to better understand why proteins migrate to the primary cilium, the molecular interactions they participate in and the cellular processes they regulate. The specific aim of this project is to develop a ciliary protein isolation procedure for differentiating 3T3-L1 cells that would ultimately be useful for performing mass spectrometry, so that we can identify the pool of proteins in primary cilia. To date there is no established protocol for ciliary isolation from 3T3-L1 cells. Most ciliary isolation methods target model cells with lengthy cilia that aren’t dependent upon developmental stage, and initial attempts to isolate 3T3-L1 cell cilia were particularly challenging. Both shear force and calcium shock methods were attempted on large pools of ciliated pre-adipocytes. Calcium shock followed by successive discontinuous and continuous sucrose gradient fractionations was deemed most successful with acetylated tubulin detected in just 4 of 58 fractions. Furthermore, fractions are being probed via Western Blot with antibodies against other ciliary marker proteins such as IFTs and BBS proteins as well as general plasma membrane markers to confirm maximal separation of ciliary proteins prior to scale-up procedures.

Use of a new inducible Mchr1-CreER mouse model to study the role of primary cilia in obesity.  
S.E. Engle1, T.L. Masters1, P.J. Antonelli1, R. Bansal1, L.S. Whitehouse1, N.F. Berbari1;  
1Biology, Indiana University Purdue University Indianapolis, Indianapolis, IN

Studies of rare genetic disorders such as Bardet-Biedl Syndrome (BBS) and Alström Syndrome (ALMS) have continued to reveal the importance of genetics in the biology of appetite and satiety. Both BBS and ALMS are classified as ciliopathies because they result from dysfunctional primary cilia. Primary cilia are...
small, microtubule based cellular protrusions that function as specialized signaling centers. Several G-protein coupled receptors (GPCRs) preferentially localize to the primary cilium, including melanin concentrating hormone receptor 1 (Mchr1). While the melanin concentrating hormone (MCH) pathway plays a recognized role in feeding behavior, the importance of the localization of Mchr1 within the cilium remains unclear. To better understand the impact of ciliary Mchr1 localization on obesity phenotypes, we generated a novel transgenic mouse model (Mchr1-CreER) that uses the Mchr1 promoter to drive the expression of the inducible CreER. This model allows us to study terminally differentiated Mchr1 expressing cells. We first studied the expression pattern of Mchr1 in adult mice by crossing Mchr1-CreER mice with mice expressing a RosaLacZ Cre reporter allele. We observed robust Mchr1-CreER activity in the hypothalamus, hippocampus, and cerebellum. Two Mchr1-CreER founder lines showed similar expression patterns. We are currently comparing the expression pattern of Mchr1 in a constitutive Mchr1-Cre line with our inducible Mchr1-CreER line. Ongoing studies of the Mchr1-CreER mice include assessing the effect of conditional loss of primary cilia in terminally differentiated Mchr1 expressing cells on feeding behavior and energy homeostasis. Following cilia loss in Mchr1-expressing cells we will track body weight and feeding behavior in vivo and changes in electrical activity in vitro. These studies will further our understanding of ciliary GPCR signaling and may reveal unrecognized roles for cilia that can impact feeding behavior and obesity in adults.

Deficiency of IFT-A protein, THM1, sensitizes pre-adipocytes to insulin signaling and differentiation, and heightens adipose insulin sensitivity in a pre-obese state.
D.T. Jacobs¹, B.A. Allard¹, L.M. Silva¹, A. Al-Namaani¹, E. Agborbesong¹, T. Wang¹, P.V. Tran¹; ¹Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS

The growing prevalence of obesity and associated insulin resistance and metabolic disease worldwide presents a significant negative impact on human health. Adipose tissue plays a critical role in insulin sensitivity. Hypertrophy or the enlargement of adipocytes is associated with metabolic dysfunction, while hyperplasia or formation of new adipocytes from pre-adipocytes may promote healthy metabolism. Ciliopathies link obesity to dysfunction of the primary cilium, an antenna-like sensory organelle that mediates signaling pathways. Mutations in THM1, an intraflagellar transport complex A (IFT-A) component which mediates ciliary protein transport, have been reported in patients with Bardet-Biedl Syndrome, which manifests obesity as a cardinal clinical feature. We have reported that global deletion of Thm1 in adult mice causes obesity. Here we examine the role of THM1 deficiency in adipogenesis. shRNA-mediated THM1 knock-down (kd) of 3T3-L1 mouse pre-adipocytes caused shortened primary cilia with bulbous distal tips. Following differentiation and Oil Red O-staining of lipid droplets, THM1 kd cells showed markedly enhanced adipogenesis, which was accompanied by earlier activation of AKT and ERK signaling and earlier nuclear expression of adipogenesis transcriptional regulators, C/EBP and PPAR. Additionally, THM1 kd pre-adipocytes showed greater AKT and ERK activation in response to insulin than control cells. White adipose tissue of pre-obese Thm1 conditional knock-out mice had higher levels of insulin sensitivity markers, PPAR and adiponectin, than control mice. Moreover, mesenteric white adipose tissue of pre-obese Thm1 conditional knock-out mice showed higher AKT activation than control littermates in response to intraperitoneal administration of insulin. Interestingly, we observed that the timing of peak insulin response was sex-dependent, and male and female mice showed maximal responses 15 and 30 minutes following insulin injection, respectively. Together, these data indicate that THM1 deficiency in pre-adipocytes promotes insulin
signaling and differentiation, and enhances adipose insulin sensitivity in a pre-obese state. This is the first demonstration of the role of an IFT-A component in regulating adipogenesis.

Primary hypothalamic neuronal culture for assessing primary cilia associated signaling.
R. Bansal\textsuperscript{1}, S.E. Engle\textsuperscript{1}, P.J. Antonellis\textsuperscript{1}, T.L. Masters\textsuperscript{1}, L.S. Whitehouse\textsuperscript{1}, K. Stickel\textsuperscript{1}, A.J. Baicum II\textsuperscript{1}, T.R. Cummins\textsuperscript{1}, N.F. Berbari\textsuperscript{1};
\textsuperscript{1}Biology, Indiana University Purdue University Indianapolis, Indianapolis, IN

Primary cilia are microtubule based cellular appendages that function as sensory and signaling centers for cells in both mammalian development and adult tissue homeostasis. Interestingly, conditional loss of primary cilia from neurons in the hypothalamus leads to hyperphagia and obesity in mouse models of ciliopathies. Though \textit{in vivo} studies have helped elucidate the role of hypothalamic cilia in feeding behavior, their precise roles in signaling associated with the obesity phenotype remain unclear. Here we have developed a system for primary neuronal cultures to assess cell and neurobiology questions that affect hypothalamic neuronal populations involved in regulating feeding behavior. Specifically, we cultured neurons from wildtype C57BL/6J mice on the day of birth and evaluated the hypothalamic neuronal populations and cilia signaling proteins. Similar to our previous work with hippocampal neurons, nearly half of cultured hypothalamic neurons possess primary cilia. To determine if cilia mediated signaling can directly impact neuronal electrical activity, we cultured neurons from ciliopathy models and controls on multi-electrode arrays. Initial data show that these cultured hypothalamic neurons in our system alter their action potential activity upon addition of leptin or melanin-concentrating hormone (MCH) as predicted based on published \textit{in vivo} data. Current studies are also aimed at utilizing this system to assess the impact of specific cilia mediated signaling pathways such as Mchr1 and hedgehog on neuronal activity and morphology. This system provides a rapid and higher throughput approach to help elucidate cellular mechanisms through which cilia may influence behavior and energy homeostasis. Ultimately, a better understanding of mechanisms of centrally mediated feeding behavior will lead to new therapeutic targets for obesity.

Unusual elemental composition of the statoliths of Mnemiopsis leidyi and Beroë ovata.
A.G. Moss\textsuperscript{1};
\textsuperscript{1}Biological Sciences, Auburn University, Auburn, AL

Ctenophores are the subject of much research effort in light of recent studies that have shown that the Ctenophora are the sister group to all other animals (Science 342:1242592). Tamm and coworkers (Curr Biol 24:R951; Biol Bull 227:7; Biol Bull 229:173) revealed unexpected architectural and functional details of the ctenophore statocyst, statolith and component lithocytes, which are supported on the tips of balancer cilia. Here, I describe yet another extraordinary feature of these ancient gravity sensors: namely that the lithocyte concretions of \textit{Mnemiopsis leidyi} and \textit{Beroë ovata} entirely lack calcium. In the fall of 2014, specimens of \textit{M. leidyi} and \textit{B. ovata} were collected by dipping from the docks of Woods Hole, Massachusetts. Statocysts were excised using microsurgical technique and subjected to several treatments: some were not fixed; some were fixed in 4% paraformaldehyde in sea water; some were fixed in 4% paraformaldehyde/2.5% glutaraldehyde in sea water. A total of >200 preparations were prepared. Fixation eased the fine dissection process and improved integrity of the samples but had no
impact on the composition. Individual ~10 μm diameter lithocytes were released from the preparations by further fine manual microdissection, allowed to separate from statocyst tissue by gravity and concentrated in a deep well dish. Lithocytes were refractile and easily observed in the dissection microscope. All preparations were rinsed extensively with ultrapure water. Samples for scanning electron microscopy and electron dispersion spectroscopy (SEM/EDS) were examined with a Zeiss Supra40VP equipped with an Oxford Instruments/INCA Synergy 350 Energy Dispersive X-ray and EDS microanalysis system. SEM and EDS samples were air-dried and mounted on aluminum stubs with carbon conductive tape (PELCO Tabs™), and coated with 4 nm carbon (Leica MED 020 Coating Station) to stabilize the preparations. Examination of lithocytes by differential interference microscopy revealed a lumpy botryoidal shape; many appeared to be made of several fused structures. This was confirmed by SEM. Lithocytes examined by polarization microscopy displayed no birefringence. Most of the lithocytes broke open upon contact with the carbon tabs and revealed stellate crystals. EDS analysis of the crystals and intact lithocytes, whether fixed or not, in all EDS modes, revealed the presence of only sodium, oxygen and sulfur. Known biominerals and purified reagents were used as controls; all displayed appropriate, expected composition. Acknowledgements: Louie Kerr/MLBL CMF, Drs. Oldenbourg, Tamm and Ameral-Zettler for indispensable aid and lively discussion. Funding: Sabbatical award, Office of the Vice President for Research and the Office of the Provost. Investigating the Biological Role of the Voltage Sensitive Phosphatase.
W. Ratzan1; S.C. Kohout1;
1Cell Biology and Neuroscience, Montana State University, Bozeman, MT

Our research is focused on elucidating the biological role of the voltage sensitive phosphatase (VSP). VSP is an intriguing protein in that it is one of the only examples of an enzyme regulated by the electrical state of the cell. Specifically, VSP couples a voltage sensing domain, normally found in voltage-gated ion channels, to a phosphatase capable of dephosphorylating phosphatidylinositol phosphates (PIPs). Since its discovery in Ciona intestinalis 2005, VSPs from several vertebrate model species have been characterized. Heterologously-expressed VSPs display depolarization dependent PIP phosphatase activity and endogenous VSPs are expressed in the embryos, kidneys and nervous systems of humans, mice, Xenopus frogs and chickens. Despite years of research, the biological role of VSP remains unclear. Our data suggest that VSP plays a role in cilia biogenesis or function. Primary cilia are considered sensory and signaling organelles that respond to the extracellular environment of the cell, whereas the beating of motile cilia in highly specialized cells creates extracellular fluid flow. Proper cilia function is crucial during embryonic development and during normal kidney and neuronal function. Many ciliopathic syndromes manifest with developmental defects, cognition disorders and renal cysts. Furthermore, cilia have a depolarized electrical environment distinct from the main cell body and are regulated by PIP signaling. Based on morpholino knockdown, immunocytochemistry and immunoprecipitation data, we propose that VSPs are integral ciliary proteins that mediate an unrecognized link between membrane potential and ciliary PIP signaling. Furthermore, we believe that future studies on VSP’s biological role will provide crucial insights toward the development of therapies for several poorly-understood ciliopathies.
Adenylyl cyclases (ACs) are enzymes responsible for the conversion of ATP into the second messenger cyclic adenosine monophosphate, cAMP. cAMP signaling is highly compartmentalized and differential expression and organization of the nine membrane-bound AC isoforms is important for the varied effect of cAMP signaling. ACs are involved in chemo- and mechanosensing in the brain and olfactory systems wherein the localization of key isoforms to the primary cilium, a solitary antenna-like organelle, is critical. The primary cilium is a key mechanosensor in bone and kidney tissues. We have previously shown that AC6 is critical to bone cell fluid-flow response and load-induced bone adaptation. In this work we examine the contribution of type 3 adenylyl cyclase (AC3) to osteocyte primary cilia mechanosensing.

Previously, it was only known that AC6 localized to the osteocyte primary cilium. Double immunocytochemistry for acetylated alpha-tubulin, a marker of the primary cilium, and AC3 showed that AC3 localization is enriched in the cilium of MLO-Y4 osteocyte-like cells. We assessed gene expression of Adcy3, encoding for the AC3 protein, and Adcy6, encoding for the AC6 protein, by RT-qPCR (data shown as mean ± SE, n = 8, Adcy3 and Adcy6 normalized to GAPDH). In IMCD cells, AC6 was highly expressed (3.33 ± 0.18), while AC3 was not detectable. In osteocyte-like cells, AC3 (0.92 ± 0.04) and AC6 (0.95 ± 0.13) were expressed equally, but at a significantly lower level than that of AC6 in kidney epithelial cells (p < 0.001). To investigate if AC3 is involved in mechanotransduction, we performed an siRNA-mediated knockdown of Adcy3 and applied fluid flow for one hour. We have previously shown that Cox-2 gene expression is significantly increased after fluid flow. The scramble siRNA control group had 2.3 ± 0.9 fold increase of flow/no-flow expression of COX-2 normalized to GAPDH (n = 8), while the AC3-knockdown group had a significantly (p = 0.015) greater flow/no-flow increase of 3.8 ± 1.3 (n = 12). There was no significant difference in COX-2 expression between the static control groups, indicating the knockdown alone did not alter COX-2 gene expression. Due to the differential expression pattern of adenylyl cyclases in mechanosensitive cells and the contribution of AC3 and AC6 to osteocyte mechanosensing, the adenylyl cyclase pool in the osteocyte cilium provides a novel target for new therapeutics.

Three dimensional architecture of primary cilia in kidney cells.
S. Sun1,2, R. Fisher1, S. Bowser1, B. Pentecost1, H. Sui1,2; 1Division of Translational Medicine, Wadsworth Center, Albany, NY, 2Department of Biomedical Sciences, University at Albany, School of Public Health, Albany, NY

Primary cilia are microtubule based structures that protrude into extracellular space as environmental sensors. In the kidney collecting duct, primary cilia are flow sensors for cell proliferation control and can deflect elastically under liquid flow. The elastic bending property relies on the framework structure of primary cilia (axoneme). It is widely accepted that the main structure of the axoneme of primary cilia has a cylindrical architecture with nine peripheral microtubule doublets (the 9+0 configuration). There are no central microtubule singlets in contrast to motile cilia. However, there are some published electron
micrographs showing structural features deviating from the 9+0 configuration. In this work, we obtained the first three dimensional (3D) architecture of a whole primary cilium from kidney cells by combining dozens of electron tomograms of serial plastic sections. In the 3D structural maps, nine microtubule doublets extend from the nine triplets of the basal body to the distal tip of the primary cilium with different lengths, and only several of them reach the ciliary tip by their A-tubes. There are electron dense networks connecting the microtubules one with another and with the ciliary membrane. The 3D architecture is anticipated to provide structural insight into the elastic bending property of primary cilia and contribute to our understanding about their mechanosensory functions.

Multiple clinical, targeted kinase inhibitors influence ciliary dynamics.
A.A. Kiseleva1,2, V.A. Korobeinikov3, A.S. Nikonova1, M.B. Einarson1, E. Nicolas4, P. Zhang1, J.R. Peterson4, E.A. Golemis1; 1Molecular Therapeutics Program, Fox Chase Cancer Center, Philadelphia, United States, 2Biochemistry and Biotechnology, Kazan Federal University, Kazan, Russia, 3Department of Pathology and Cell Biology, Columbia University, New York, United States, 4Cancer Biology Program, Fox Chase Cancer Center, Philadelphia, United States

The primary cilium is an antenna-like organelle extended from the cell surface which provides a platform for receptors for signaling pathways including PDGFα, Hedgehog, and Wnt. Mutations in genes encoding ciliary proteins can lead to the development of severe disorders called ciliopathies, such as polycystic kidney disease (PKD), and complete loss of cilia is often associated with cancerous transformation of epithelial cells. Intriguingly, in some solid tumors, the unciliated cancer cells secrete Hedgehog to activate ciliated stromal cells, allowing stromal cells to provide vital growth signals to the cancer cells. Understanding and manipulating such asymmetric ciliary signaling in tumors versus stromal cells can potentially improve therapeutic response. In previous work, we unexpectedly identified two targeted, clinical anti-cancer agents - the Aurora-A inhibitor alisertib, and HSP90 inhibitor ganetespib - as controlling ciliary dynamics. To determine if additional drugs affect cilia and cilia-dependent signaling, we analyzed the activity of 180 kinase inhibitors of known specificity for action in controlling ciliary assembly or disassembly. For this, we developed a stable hTERT-RPE1 cell line model with an integrated Arl13b-GFP reporter to visualize cilia, and performed a mid-throughput screen to identify 1) ciliary resorption in G0 phase, or 2) cilia disassembly in cells induced to cycle by serum treatment. This identified 17 compounds specifically affecting ciliary dynamics, which had never previously been linked to cilia. These include the multi-targeted receptor tyrosine kinase (RTK) inhibitor sunitinib, the EGFR inhibitor erlotinib, and additional agents targeting other RTKs and, surprisingly, specific pro-inflammatory kinases. Mechanistically, brief treatment with sunitinib and some agents inducing ciliary resorption promoted transient cell cycle independent activation of Aurora-A at the ciliary basal body to promote disassembly. Sunitinib and other pro-disassembly agents caused both rapid and durable loss of cilia in vitro and in vivo, in models for cancer and PKD, and in normal tissue. RNAi experiments assigned specific kinases as mediating ciliary effects of multi-targeted kinases: for example, sunitinib triggers cilia disassembly through inhibition of PDGFRα. In some cases, these effects on control of the primary cilium caused apparent “off-target” activity of specific drugs in modulating signaling by Hedgehog, based on control of functionality of the ciliary Hedgehog receptors. These findings suggest new mechanisms by which some cancer drugs may affect heterocellular tumor signaling, and contribute to a better understanding of mechanisms underlying the dynamics of the resorption and protrusion of the primary cilium, and cilia-related p

**Roles of Primary Cilia in the Oligodendrocyte Lineage.**

A. Subediak\(^1\), J.L. Fuchs\(^2\);

\(^1\)Biological Sciences, University of North Texas, Denton, TX

Primary cilia are non-motile organelles that stem from the basal body and protrude from the cell surface. They are present in most vertebrate cell types. During ontogeny, cilia-associated pathways such as sonic hedgehog (Shh), Wnt/β-catenin and Notch, are vital for generating and specifying cells of the oligodendrocyte lineage. However, cilia have not been reported in mature oligodendrocytes. Thus, cilia may be lost at some point. Here we investigate the timing and function of cilia loss in vivo. In mice of postnatal ages P4 through adult, cilia immunoreactive for Arl13b or ACIII were common in oligodendrocyte progenitor cells (OPCs), but were absent in myelinating, APC/CC1(+) oligodendrocytes. Thus, primary cilia may be lost as cells give up their proliferative capacity and prepare to myelinate axons. The expression of myelin genes depends upon enhanced Wnt/β-catenin signaling. Because primary cilia sequester β-catenin, cilia loss should promote activity in this pathway. We proposed that cilia loss may lead to upregulation of Wnt/β-catenin activity, which in turn permits myelination. In support of this hypothesis, we found that only those Olig1(+) cells without cilia expressed β-catenin and TCF3. We also examined Axin2-lacz mice, in which lacz is a reporter of Wnt/β-catenin activity. In these mice, cilia were absent in Olig2(+)lacz(+) cells, but were not uncommon in the Olig2(+)lacz(-) population. We further tested the importance of cilia by examining Tg737orpk mice, which are deficient in the intraflagellar transport protein IFT88. In the mutant brain, cilia number and length decline during postnatal development. Mutant and wildtype brains were compared on P31. The Tg737orpk brain showed marked decreases in the numbers of APC/CC1(+) oligodendrocytes, and smaller declines in NG2(+) and Olig2(+) OPC populations. This result suggests that cilia loss interferes with the generation and maturation of cells in the oligodendrocyte lineage.

**A Bioactive Peptide Amidating Enzyme is Specifically Released in Ciliary Ectosomes during Mating in Chlamydomonas.**

D. Kumar\(^1\), R. Luxmi\(^2\), M. Bartolotta\(^1,3\), R.E. Mains\(^2\), S.M. King\(^1\), B.A. Eipper\(^1,2\);

\(^1\)Department of Molecular Biology and Biophysics, University of Connecticut Health Center, Farmington, CT, \(^2\)Department of Neuroscience, University of Connecticut Health Center, Farmington, CT, \(^3\)Wheaton College, Norwood, MA

In both rodents and Chlamydomonas, peptidylglycine α-amidating monooxygenase (PAM), which converts C-terminal glycine residues into α-amides, is present in the secretory and endocytic pathways and in motile and non-motile cilia. A Type I integral membrane protein, the catalytic cores of PAM function in the lumen of the secretory pathway and on the external surface of cilia. PAM is required for the assembly of cilia in Chlamydomonas, planaria, zebrafish and mice. Cilia not only sense signals from the extracellular environment, but also transmit information in the form of vesicles (ectosomes) budded from the ciliary membrane (Wood et al., Curr. Biol. [2013]; Wang et al., Curr. Biol. [2014]; Cao et al., eLIFE [2015]). Topologically, ectosome formation is similar to intraluminal vesicle (ILV) formation; ILVs are released as exosomes upon multivesicular body/plasma membrane fusion. As PAM is present in ILVs in mammalian cells and in salivary and urinary exosomes, we hypothesized that CrPAM might be
released in ciliary ectosomes. *Chlamydomonas* ectosomes have a protein composition distinct from that of the ciliary membrane, implying that their content is regulated (Long et al., Curr. Biol. [2016]). Ciliary CrPAM associates with the axoneme and is only solubilized by treatment with both detergent and high salt, as are dynein arms; this axonemal attachment may be mediated directly by the cytosolic PAM C-terminal domain or via some other axoneme-tethered component. During vegetative growth, CrPAM levels are highest during the light phase, peaking towards the end of G1 just prior to mitotic entry. CrPAM protein is also increased in both gametes and early zygotes. Intriguingly, PAM mRNA levels are elevated in both resting gametes and those treated with the cell wall-degrading lysozyme, but decrease precipitously following gamete activation with dibutylryl cAMP (data from Ning et al., Genes Dev. [2013]). In ectosomes prepared from wildtype (cc124 and cc125) vegetative cells, PAM activity and PAM protein were barely detectable. In contrast, ectosomes prepared from mating gametes (cc125×Hap2 and cc124×cc125) had greatly enhanced levels of both PAM protein and activity; approximately one cilium-equivalent of PAM was released/cell/hour. Thus, the PAM-axoneme association is regulated, and PAM is specifically trafficked into ectosomes during mating. Ectosomal CrPAM may amidate secreted peptides, or ectosomal release may represent a cellular mechanism to remove CrPAM from the cilia either because it is now unnecessary or, possibly, because it is inhibitory to further progress in gamete fusion. We are currently examining the mechanisms involved in this regulated release process and testing whether ectosomal CrPAM is bioactive. Supported by DK032949 and GM051293 (NIH).

*Chlamydomonas* Secretes Amidated Peptides during Mating.  
R. Luxmi¹, D. Kumar², C.E. Blaby-Haas³, R.E. Mains¹, S.M. King², B.A. Eipper¹²;  
¹Department of Neuroscience, University of Connecticut Health Center, Farmington, CT, ²Department of Molecular Biology and Biophysics, University of Connecticut Health Center, Farmington, CT, ³Brookhaven National Laboratory, Upton, NY

Peptidylglycine α-amidating monoxygenase (PAM) plays an essential role in the biosynthesis of many neuroendocrine peptides. We recently demonstrated that active PAM (CrPAM) is expressed in *Chlamydomonas reinhardtii*; strikingly, knockdown of CrPAM results in failure of ciliogenesis, while inhibition of its monoxygenase activity slows reciliation. Bioinformatic analysis of the *C. reinhardtii* genome identified multiple genes that encode secreted proteins whose features resemble those of neuroendocrine peptide precursors. The secretory pathway in this unicellular green alga shares much in common with other eukaryotes; orthologs of many of the enzymes associated with classical propeptide processing (endopeptidases, carboxypeptidases) have been identified in *C. reinhardtii*. In addition to the classical signal peptide pathway, bioactive ectosomes are released from *C. reinhardtii* cilia. Controlled secretion and activation of endoproteases play an essential role in the vegetative and sexual life cycles of *C. reinhardtii* and nutrient deprivation triggers the secretion of compensatory enzymes (e.g., alkaline phosphatase and arylsulfatase). Since published RNASeq studies reveal changes in CrPAM expression during sexual reproduction, we prepared cc124(-) and cc125(+) gametes. One hour after mixing the gametes, cells, debris and mating ectosomes were removed by differential centrifugation, leaving the mating secretome. PAM activity was recovered in the cell and ectosome pellets, but was undetectable in the mating secretome. Biological triplicates of the mating secretome were fractionated by SDS-PAGE; after visualization with colloidal Coomassie, proteins were separated into 10 fractions by molecular weight. Following in-gel trypsin digestion and LC-MS/MS analysis, 1232 proteins were identified. Using PredAlgo, a signal peptide was identified in 118 proteins; subcellular localization was not assigned for 77 proteins. Of the annotated signal peptide-containing proteins, 18% were pherophorins, 13% proteases and 8% Ser/Thr kinases. Protein prevalence in each gel slice was assessed using normalized spectral
counts; in this way, proteins subjected to proteolytic cleavage could be identified. Signal peptide-containing proteins and unassigned proteins were more likely to undergo proteolytic cleavage than proteins assigned to the Chloroplast, Mitochondria or Other categories. A screen for amidated products identified a signal peptide containing protein with an amidated C-terminus. Mating secretome constituents that passed through a 10 kDa cutoff filter are being analyzed to identify additional amidated products. Our data suggest a role for peptide/protein amidation in sexual reproduction in C. reinhardtii. Supported by DK032949 and GM051293 (NIH).

Characterization of the role of Diaphanous-related formin (DIAPH) in cilia.
O. Palander1,2, W.S. Trimble1,2;
1Biochemistry, University of Toronto, Toronto, ON, 2Cell Biology, The hospital for sick children, Toronto, ON

The primary cilium works as sensory structure by localizing receptors of various signaling pathways such as Sonic Hedgehog, Wnt and PDGF. Genetic defects that compromise cilia formation (ciliogenesis) or cilia maintenance cause a spectrum of disorders referred to as ciliopathies. Previous research had implicated RhoA signaling in ciliogenesis, but the pathways downstream of RhoA involved in promoting cilia growth are poorly understood. One class of RhoA effectors are the DIAPH (Diaphanous-related formin) family of formins that promote actin polymerization and also promote microtubule (MT) stability in an adenomatous polyposis coli (APC) and EB1-dependent manner. EB1 and EB3 have previously been shown to localize at the base of cilia and are implicated in cilia biogenesis by centrosome-related mechanisms. Intriguingly, APC mutations in Gardner’s syndrome also result in cilia defects, suggesting that in some circumstances APC might also have a role in ciliogenesis. However, the role of DIAPH proteins had not been examined. We therefore localized individual DIAPH family members by immunofluorescence microscopy and found that they localized to the base of cilia, but in non-identical patterns. Chemical inhibition of the DIAPH family, or siRNA-mediated depletion of individual family members (DIAPH1, DIAPH2 of DIAPH3) resulted in reduced cilia length and decreased ciliogenesis. In addition, we found that targeted overexpression of DIAPH proteins to the base of cilia causes cilia elongation and the formation of bulb at the distal tip of axoneme. These bulbs contain accumulations of IFT88 and membrane protein polycystin-2 (PC2), consistent with previous studies showing that an imbalance of anterograde and retrograde trafficking caused by defects in retrograde traffic causes bulbous distal ends in primary cilia. Finally, we expressed mutant forms of DIAPH that possess only the actin nucleating, or microtubule-stabilizing properties of DIAPH and found that both activities are important for efficient bulb formation. Together, our results suggest that activation of formins by RhoA promotes ciliogenesis through their actin nucleation and microtubule stabilization activities and likely do so in collaboration with +TIP proteins.
INPP5E is a ciliary phosphoinositide 5-phosphatase whose mutations are the cause of two human ciliopathies, Joubert (JBTS) and MORM syndromes, and whose activity supports Hedgehog-dependent tumor progression. We previously showed that INPP5E is a critical regulator of ciliary phosphoinositide levels, which in turn control ciliary protein composition and Hedgehog signaling (Garcia-Gonzalo et al. 2015 Dev Cell). However, how INPP5E activity and ciliary localization are controlled remains unclear. Here, we have studied whether protein kinase A (PKA) and tyrosine kinases (TKs) regulate INPP5E function. After noticing that both PKA consensus sites in INPP5E are disrupted by known JBTS mutations, we used site-directed mutagenesis to generate non-phosphorylatable and phosphomimetic mutants of the putative PKA target serines. Likewise, given that INPP5E is known to undergo tyrosine phosphorylation, we mutated several candidate tyrosines in a similar way. Our results suggest that INPP5E ciliary localization can be regulated by phosphorylation.

Cells release extracellular vesicles (EVs) that are nano-sized packages allowing for the exchange of protein and genetic content. Cilia release bioactive EVs that contain cargoes including proteases, agglutinins, and polycystins (Wood and Rosenbaum. Trends Cell Biol. 2015). Cilia may also receive EVs. Altered cilium-EV interactions are observed in ciliopathies such as polycystic kidney disease, suggesting a role for EVs in cilia function. The mechanisms that regulate ciliary EV biogenesis, release, and bioactivity, and the contributions of EVs to ciliary signaling are only beginning to be identified. In C.elegans, cilia are present at dendritic tips of sensory neurons. Only a subset of C. elegans ciliated neurons are EV releasing neurons (EVNs): 21 male-specific EVNs and six non-sex specific IL2 neurons (Wang and Barr. Cell Mol Neurobiol. 2016). The six IL2 neurons are four quadrant IL2, and two lateral IL2 neurons. Using transmission electron microscopy (TEM) and tomography, we found that all EVN cilia do not share the same axonemal architecture and that there are ultrastructural differences at the periciliary region between quadrant and lateral IL2s suggesting specialization between EVN subtypes. We hypothesize that EVN specific mechanisms impart cilia with the ability to make and release EVs. Using transcriptional profiling, we identified 335 genes that are overrepresented in the EVNs (Wang et al. Curr Biol 2015). This list includes EVN specific genes such as an alpha tubulin that establishes a specialized axonemal architecture important for releasing EVs (Silva et al. Curr Biol 2017), and pan-ciliary genes that may have specialized roles in the EVNs. rab-28 is pan-ciliary GTPase gene that is overrepresented in the EVN transcriptome and that is important for the maintenance of cilia ultrastructure, and function of amphid neurons that do not make and release EVs (Jensen, Carter et al.,
Using live imaging, we found that rab-28 mutants mislocalize EVN ciliary proteins and display hyperactive EV release of select cargo. TEM on rab-28 mutants revealed increased number of microtubule doublets in the IL2 axoneme and an accumulation of EVs in the extracellular space surrounding IL2 cilia. We are determining whether RAB-28 regulates EV release via effects on the axoneme or membrane events at the IL2 cilia base. Our identification of RAB-28 as an EV regulator is expected to identify mechanisms that generate ciliary functional diversity by modulating axonemal arrangement, ciliary membrane events, or both.

Disruption of primary cilia components leads to reduced proliferation in myoblasts.
C. Boyle1, V. Zora1, S. Dornbush1, Z. Gromley1, S. Gromley1;
1DeBusk College of Osteopathic Medicine, Lincoln Memorial University, Harrogate, TN

The primary cilia is thought to play a critical role in the regulation of myogenesis, as the presence of primary cilia in myoblasts is associated with their proliferation, and disassembly of primary cilia correlates with myogenic differentiation. In an attempt to identify proteins that may be involved with this regulation, a yeast two hybrid screen was carried out using centriolin, a known component of primary cilia, as bait. This screen revealed a member of the HECT family of E3 ligases as a binding partner to centriolin. In cultured cells, disruption of centriolin using the CRISPR/Cas9 system resulted in loss of this interaction and subsequent cell cycle arrest, followed by apoptotic death of the cells. Interestingly, there was also a marked increase in cells exhibiting morphologies consistent with a recently described cell type known as telocytes. These results suggest that centriolin and its interaction with HECT E3 ligases may play important roles in the maintenance of the proliferative state of myoblasts as disruption of this interaction leads to a cessation of the cell cycle and induction of cell death.

Loss of neuronal cilia alters olfactory bulb morphology.
J.C. McIntyre1;
1Neuroscience, University of Florida, Gainesville, FL

Olfactory sensory neurons (OSNs) project axons into the olfactory bulb (OB), where they form synapses with mitral cell dendrites in glomeruli. The activation pattern of glomeruli, and associated mitral cells underlie odor coding in the OB. Within this network are interneurons that shape synaptic input from OSNs as well as activity of mitral cells. Glomerular activity also depends on innervation from higher brain regions that supply modulation to the synaptic circuits. For example, neurons in the OB can be modulated by neural hormones associated with hunger and satiety. An unexplored mechanism of neural modulation involves primary cilia, evolutionarily conserved organelles, the function as signaling centers for numerous extracellular cues and several neuromodulatory G-protein coupled receptors (GPCRs) are localized to neuronal primary cilia. The role of neuronal cilia, and the GPCRs enriched in them, however remains unclear. Recent data suggests neuronal cilia regulate dendritic growth and branching patterns as well as agonist induced activity. The goal of this study is to investigate the neuromodulatory role of cilia of neurons in the OB. mRNAs for several GPCRs including GPR161, somatostatin receptor type 3 (SSTR3), and melanin-concentrating hormone receptor (MCHR1) are abundant in neurons in the OB. IHC for MCHR1 showed the receptor localized to a subset of periglomerular interneurons and granule cells, but not mitral cells. The localization of MCHR1 to largely interneurons suggests a role for their regulation.
of granules cells in response to neuromodulators in order to shape olfactory processing. Moreover, MCH positive fibers are detected in the OB, in close approximation to granule cell cilia. To investigate cilia on mature granule neurons, we used Gad2iresCre mice to selectively knockout the ciliary gene Ift88. Loss of Ift88 resulted in widespread loss of cilia on granule cells. At 6 weeks of age, the OB of knockout mice was noticeably disorganized and glomeruli were significantly smaller. Additionally, innervation by OSN axons and dopaminergic neurons was decreased. These results indicate that cilia on mature interneurons are important for their function and the maintenance of the OB.

1Genetics and Biochemistry, Clemson University, Clemson, SC, 2Molecular Genetics and Microbiology, Duke University, Durham, NC, 3Biology, Furman University, Greenville, SC

Cryptococcus neoformans, a basidiomycete yeast, causes lethal meningitis in immunocompromised individuals. One of the major virulence factors of C. neoformans is its ability to proliferate at host temperature of 37°C. Uniquely in C. neoformans, septin proteins are not essential for viability at 24°C but are necessary for cytokinesis and survival at 37°C. While the role of septins in cytokinesis is conserved in all eukaryotes except plants, their exact contribution to this process remains elusive. Moreover, mechanisms of cytokinesis in C. neoformans are largely unknown. Through a deletion screen we identified a homologue of anillin as essential for survival of C. neoformans at 37°C. A strain deleted for the anillin encoding gene exhibited a similar phenotype to that of the septin deletion mutants. The anillin homologue localized to the site of cell division during cytokinesis in a septin-dependent manner, and the assembly of the septin complex, specifically during cytokinesis, depended on the presence of anillin. Our data are consistent with a similar role for anillin in C. neoformans to that described for the anillin homologue, Bud4, in the ascomycete yeast, Saccharomyces cerevisiae. Interestingly, while septins are essential in S. cerevisiae under all growth conditions, presumably due to their essential role in cytokinesis, Bud4 is not essential. Thus, our data suggest that the contributions of septins to cytokinesis are not conserved between the two main fungal phyla Basidiomycota and Ascomycota.

Role of Aurora Kinases in Single-Cell Regeneration of Stentor.
A. Lin1, W.F. Marshall1;
1Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

Single cells are capable of developing complex patterns and shapes, but the mechanism by which cells develop shape is largely unknown. Stentor coeruleus is a classical model system to study the development and regeneration of cell shape due to the large size (1mm cubed), the presence of distinct cortical features that define body axes, and most importantly due to the fact that we can surgically manipulate the cells and visualize their regeneration. When the oral apparatus is regenerated in Stentor, the macronucleus undergoes shape changes identical to those that occur during cell division at the point in division when a new oral apparatus is formed. This observation has suggested that the
timing of distinct steps of oral apparatus formation might be regulated by the same molecules that regulate the timing of division, possibly suggesting that mitosis mechanisms are integral to the processes of regeneration. To study whether there is a connection between regeneration and mitosis, we looked at the role of Aurora kinases in regeneration. Aurora kinase A (AurkA) is a kinase known to regulate spindle assembly. Aurora kinase B (AurkB) is known to guide kinetochore attachment to the spindle. We studied the role of AurkA and AurkB in single-cell regeneration using Aurora kinase inhibitors. We have observed that AurkA inhibitor, MLN8237, accelerates regeneration. Surprisingly, AurkA and AurkB inhibitor, PF03814735, suppresses regeneration entirely. Thus, we show that Aurora kinases are involved in single cell-regeneration and there is a link between regeneration and mitosis, which has implications in health.

The role of mitotic cell-substrate adhesion remodelling in animal cell division.
C.L. Dix¹, H.K. Matthews¹, S. McLaren², L. Wolf³, P. Almada¹, R. Henriques¹, M. Boutros², B. Baum¹;
¹Medical Research Council Laboratory for Molecular Cell Biology, University College London, London, United Kingdom, ²Division of Signalling and Functional Genomics, German Cancer Research Center (DKFZ), and Department for Cell and Molecular Biology, Medical Faculty Mannheim, Heidelberg University, Heidelberg, Germany

Animal cells undergo a dramatic series of shape changes as they divide which depend on remodelling of the contractile actomyosin cortex and on release of cell-substrate adhesions. Here, we show that while focal adhesion complexes are disassembled during mitotic rounding integrins remain in place. These integrin-rich contacts connect mitotic cells to the underlying substrate throughout mitosis, guide polar cell migration following mitotic exit, and are functionally important, since adherent cells undergo division failure when removed from the substrate. Further, the ability of cells to re-spread along pre-existing adhesive contacts is essential for division in cells compromised in their ability to construct an actomyosin ring. Thus, Ect2 siRNA cells fail to divide on small adhesive islands, but successfully divide on larger patterns, as the connection between daughter cells narrows and severs as they migrate away from one another. Together these results reveal the importance of coupling adhesion remodelling to mitotic progression.

Aurora A kinase restricts contractile ring components to a narrow equatorial zone during cytokinesis in human cells.
S. Mangal¹, E. Zanin¹;
¹Center for Integrated Protein Science CIPSM, Department Biology II, Ludwig-Maximilians University, Munich (Planegg-Martinsried), Germany

Cytokinesis is the final event of cell division in which the mother cell splits into two daughter cells. During cytokinesis, the contractile ring is carefully positioned between the separating chromosomes by anaphase spindle. While the spindle midzone, located between segregating chromosomes, promotes the accumulation of contractile ring components at the equator, the centrosomal microtubule asters prevent the accumulation of contractile ring proteins at the cell poles. Recently, we have identified TPXL-1, a potent Aurora A kinase activator, as the first molecular component of the aster-based inhibitory signal in C. elegans. We have shown that Aurora A kinase activation by TPXL-1 is required for...
removing the contractile ring component anillin from the polar cortex in the one-cell C. elegans embryo. To determine if Aurora A inhibits the polar accumulation of anillin in human cells, we treated HeLa cells expressing anillin::GFP with the small molecule inhibitor MK5108 for 30-60 minutes and filmed them during anaphase. We found that inhibition of Aurora A resulted in a significant increase in the amount of anillin::GFP on polar cortex and a wider anillin zone at cell equator. In addition to Aurora A, metazoans have also the closely related Aurora B kinase which localizes to the spindle midzone and was previously described to have a role in cytokinesis. We confirmed that inhibition of Aurora A by MK5108 for 30-60 minutes does not inhibit Aurora B by analyzing Aurora A and B specific phospho-epitopes. Aurora A is involved in centrosome maturation and bipolar spindle assembly. Thus we tested whether short inhibition of Aurora A with MK5108 affects astral microtubules. Our preliminary results suggest that astral microtubules are not affected by Aurora A inhibition. We conclude that Aurora A inhibits the accumulation of contractile ring components at polar cortex in human cells and thereby promotes contractile ring formation at the cell equator during cytokinesis.

The midbody forms at the end of cytokinesis and facilitates abscission, the final separation of the daughter cells. The midbody has also been implicated in regulating additional cellular processes such as cell fate specification, cilia formation and apical polarity during epithelial lumen formation. To investigate developmental roles of the midbody, we examined cytokinesis and midbody fate in the invariant lineage of the C. elegans embryo. We show that unique patterns of cytokinesis and midbody inheritance occur in different parts of the lineage. In the first mitosis, symmetric furrowing positions a central midbody that is always internalized by the P1 daughter cell. In the next AB cell division, a highly asymmetric furrow positions a midbody in contact with and engulfed by EMS instead of either AB daughter cell. A dramatic shift in midbody behavior is observed in several tissues during morphogenesis. In two lumen-forming tissues, the intestine and the pharynx, midbodies form after symmetric furrowing and migrate across the cell to the future apical midline. This midbody migration event coincides with previously characterized polarization events in intestinal epithelia. Upon reaching the apical midline, the midbody ring is internalized and disappears; however, the Aurora B kinase, AIR-2, remains on the apical surface for over an hour after polarization. A similar apical localization pattern is observed for AIR-2 in the pharyngeal primordium. Finally, in cells that form amphid sensilla, we observe symmetrical cytokinesis and a midbody migration event that leads to a focal aggregation of AIR-2. AIR-2 persists along the leading edge of developing dendrites well after cytokinesis. Other midbody markers are either internalized and degraded or maintained with AIR-2 in a tissue-specific manner. We observe PAR-6 localization at the focal aggregation and tip of the sensilla, suggesting that it is apical. Therefore, the midbody migrates from its original position at the end of furrowing to the position of the apical surface in several developing tissues. Inactivating temperature sensitive cytokinesis mutants late in embryogenesis causes defects in positioning, continuity and shaping of the intestinal and pharyngeal lumen. Many animals fail to hatch, but among those that do, a high percentage show defects in neuronal DiI staining. These data suggest that the proper execution of cytokinesis, which shows surprising flexibility during development, and specific cytokinesis regulators such as AIR-2, may regulate the final interphase architecture of a terminally dividing cell.

Systematic analysis of atx-2 suppressors reveal novel regulators of PAR-5/14-3-3sigma function during mitosis in Caenorhabditis elegans.

M.F. Gnazzo¹, A.R. Skop¹, A.R. Villarreal¹;

¹Genetics, UW-Madison, Madison, WI

RNA regulation plays a critical role in mitosis, yet the mechanisms remain unclear. Our lab recently identified that the conserved RNA-Binding Protein(RBP), ATX-2, regulates cytokinesis by regulating targeting of ZEN-4 to the spindle midzone through a conserved translation regulator, PAR-5/14-3-3sigma (Gnazzo et al., 2016). While co-depletion of ATX-2 and PAR-5 restored ZEN-4 targeting to the spindle midzone, it did not rescue cell division. To identify factors that may work in concert with ATX-2 to regulate cell division, we conducted a two-part, candidate RNAi suppressor and visual screen to identify factors that are important for cell division and also target ATX-2 to the centrosomes and spindle midzone. Using this approach, ten genes suppress both the embryonic lethality and cytokinesis defects observed in atx-2 mutant embryos and their loss leads to a failure to target ATX-2 to the centrosomes and midzone. These ten genes (*act-2, cgh-1, cki-1, hum-6, par-2, rnp-4, vab-3, vhl-1, vps-24, and wve-1*), have a role in either RNA function or cell cycle regulation or both. The strongest suppressor, CGH-1/DDX6, is a DEAD-box RNA helicase with conserved roles in cell division, RNA processing, translation, and neuron function. Loss of CGH-1 rescued the cytokinesis defect and also restored ZEN-4 localization to the spindle midzone. ATX-2 and CGH-1 are mutually required for their localization to centrosomes and the spindle midzone. Our findings provide the first functional evidence that CGH-1/DDX6 regulates ATX-2 function during mitosis to target ZEN-4 to the spindle midzone and suggest that RNA machinery is necessary for the completion of cytokinesis.

¹Genetics, UW-Madison, Madison, WI, ²Molecular Biology and Genetics, Harvard University, Boston, MA, ³Leica Microsystems, Allendale, NJ

The midbody is a transient organelle derived from the spindle midzone and is essential for normal cell division. Long conceptualized as a simple structural component subject to degradation following cell division, recent studies suggest the midbody may play critical instructive roles in cell fate determination, stem cell maintenance, and oncogenesis (reviewed in Chen et al., 2013). In specific pluripotent and tumorigenic cell types, midbodies are preferentially inherited and escape autophagic degradation (Kuo et al., 2011). The correlation between midbody inheritance and cell fate specification is reminiscent of the differential inheritance of mRNAs or P granules in neurons and C. elegans embryos, respectively. Since mRNA localization to mitotic microtubules is required for cell cycle progression, we are exploring potential functional roles for specific midbody-associated mRNAs. We have identified 22 mRNAs specifically enriched in the midbodies of Chinese hamster ovary (CHO) cells, encoding proteins involved in regulating the cell cycle, cytokinesis, cell fate determination, alternative splicing, and transcription.
We are further characterizing the midbody transcriptome to determine the functional significance of these mRNAs, and will investigate the mechanisms that target them to the midbody.

\(^1\)Biology, Concordia University, Montreal, QC

Cytokinesis describes the separation of a cell into two daughters at the end of mitosis. This process is highly conserved and must be spatiotemporally coordinated to avoid aneuploidy and cell fate changes. A RhoA-dependent actomyosin contractile ring pinches in the cortex to divide the appropriate genetic and fate determinants into each daughter cell. The prevailing dogma in the field is that the mitotic spindle regulates the position of the contractile ring. However, studies have shown that microtubule-independent mechanisms also regulate cytokinesis. We found that Ran-GTP signaling from chromatin influences the localization of contractile proteins and cytokinesis in human cells. Our data supports that anillin, which is a scaffold protein that binds to and coordinates actin, myosin, RhoA and its upstream regulators, microtubules, and phospholipids, is the target of Ran-GTP signaling. Human anillin contains a C-terminal nuclear localization signal (NLS) that binds to Importin-β and is required for robust cytokinesis. The levels of free Importin-β, which are controlled by Ran-GTP, function as a molecular ruler to regulate the levels of cortical anillin. We recently discovered that the C-terminal NLS is conserved in *C. elegans* anillin, ANI-1, and binds to Importin-β. We hypothesize that Ran-GTP regulation of cytokinesis is conserved among metazoans and the strength of this pathway is proportional to ploidy, cell geometry and cell volume. To further test this, we are studying the regulation of cytokinesis by the Ran pathway in early *C. elegans* embryos. We found that Ran-GTP influences contractile proteins during early stages of cytokinesis, prior to ring ingression. Decreasing the levels of Ran-GTP by *ran-3* (RCC-1/RanGEF) RNAi decreased the time to ingression in the first cell division (P0), as well as in the next cell divisions (AB and P1). Interestingly, the decrease in rate was more dramatic in P1 vs. P0 or AB cells, and this change was independent of cell size. Imaging revealed that ANI-1 was more strongly recruited to the equatorial plane in P1 cells in comparison to P0 or AB cells, where ANI-1 levels are already quite high. Therefore, Ran signaling may be more strongly required in P1 by regulating ANI-1 localization. We are further testing this hypothesis by studying changes in cytokinesis in embryos with increased Ran-GTP levels, by *ran-2* (RanGAP) RNAi, as well as after perturbation of the importin complex.

Developing a Light-Induced Z-ring Disassembly (LiZRd) Assay to Probe FtsZ’s Role in E. coli Cell Division.
R.J. McQuillen\(^1\), C. Coltharp\(^1\), C.H. Bohrer\(^1\), J. Xiao\(^1\);
\(^1\)Biophysics Biophysical Chemistry, Johns Hopkins School of Medicine, Baltimore, MD

Bacterial cell division is an essential process mediated by the prokaryotic tubulin homolog FtsZ. Early in division, FtsZ forms a cytokinetic ring (the Z-ring) at midcell and recruits all other downstream factors which coordinate constriction and nucleoid segregation. While it is clear that FtsZ is required for successful cell division, its mechanistic role(s) represent an active area of investigation. Recent work in our lab shows that, FtsZ undergoes treadmilling at the midcell and that the dynamics of this motion are highly correlated to FtsZ’s intrinsic GTPase activity. We also observed that FtsI (PBP3) undergoes
directional movement and that its speed is correlated with that of FtsZ. We therefore hypothesize that the dynamic motion of FtsZ is required to regulate the spatiotemporal distributions of cell wall remodeling enzymes during constriction. However, how imperative the requirement for FtsZ is during constriction is still not well understood.

In an attempt to better understand FtsZ’s role during constriction, we are currently developing a method to rapidly disassemble the Z-ring at different time points over the course of the cell cycle and examine the consequences in the localization, function and dynamics of other divisome components. Our method uses variants of a pair of proteins, CRY2 and CIB1, isolated from Arabidopsis thaliana. This may represent an effective method to shed light on a number of questions: Is the presence of FtsZ required to initiate constriction? To what degree is membrane attachment of FtsZ essential? How long is FtsZ required at midcell to complete cell division? How does FtsZ delocalization affect the localizations of various cell wall synthesis enzymes?

Active Ran regulates anillin function during cytokinesis.
D. Beaudet¹, T. Akshi², C. Law¹, A.J. Piekny¹;
¹Biology, Concordia University, Montreal, QC, ²Biochemistry, University of Toronto, Toronto, ON

Several inputs spatially regulate cytokinesis to position and assemble an actomyosin contractile ring at a precise cortical location. Coupling ring positioning with the segregation of chromosomes is crucial to avoid aneuploidy, which is a precursor to genomic instability and cancer. The central dogma is that the mitotic spindle spatially controls the contractile ring, but we found that chromatin also spatially restricts cortical polarity for contractile ring positioning. A Ran-GTP gradient persists around chromosomes during mitosis and is crucial for mitotic spindle assembly. We hypothesize that this gradient also functions as a molecular ruler to regulate cortical contractility during cytokinesis. In support of this hypothesis, we found that Ran-GTP influences the localization of contractile proteins in mammalian cells. One of the molecular targets of Ran-GTP signaling is anillin, which binds to and coordinates F-actin, non-muscle myosin, active RhoA and its upstream regulators, microtubules and phospholipids. We found that a nuclear localization signal (NLS) within a C-terminal disordered loop of human anillin binds to importin-β and is required for cytokinesis. Point mutations within the NLS alter anillin’s localization, and the contractile ring oscillates and subsequently fails to ingress in a subset of cells in comparison to control cells. In addition, we found that this site is autoinhibited by the RhoA binding domain (RBD), and relieving this inhibition changes anillin’s affinity for importins and microtubules. Our current model is that the Ran pathway modulates cytokinesis by affecting anillin’s recruitment to the cortex. During mitosis, RhoA-GTP levels increase and bind to the RBD of anillin, causing a change in its conformation that makes the NLS and microtubule-binding domain more accessible. Importin-binding, which occurs in regions of the cell away from chromatin where Ran-GTP is high, may stabilize a conformation that further enhances anillin’s recruitment to the cortex. However, if importin levels are too high, this could negatively compete with anillin’s other interactions in the C-terminus. We believe that this pathway may be crucial for cells with asymmetrically displaced chromatin to help maintain polarity during division, or in cancer cells that have increased ploidy to ensure robust cytokinesis.

Accurate cytokinesis, the physical division of one cell into two, is essential for the development of all multicellular organisms. In animal cells, cytokinesis is driven by constriction of an actomyosin contractile ring. It has long been known that animal cells divide using a highly conserved molecular mechanism, but growing evidence suggests that the molecular requirements for, and regulation of, cytokinesis in individual cell types has more diversity than previously realized. Thus, to fully understand cytokinesis, we need to acknowledge this diversity and compare cytokinesis between different cell types. To address this question, we studied division in the 4-to-8 cell C. elegans embryo. At this early stage of development, each individual cell already has a distinct cell identity leading to a distinct cell lineage that is controlled by inherited factors, cell-cell contacts, cell polarity, and conserved cell fate-signaling molecules (e.g. Notch, Wnt, Src). Using fast-acting (<20 sec) temperature-sensitive mutants, we determined the level of activity and time of protein function required for successful cytokinesis in each of the 4 cells. We found reproducible, cell type specific variation in the cytokinetic requirement for the filamentous-actin (f-actin) nucleator formin\(^{Ctk-1}\), but not the motor myosin-II\(^{Myr-2}\). Specifically, in two of the four cells (EMS and P2), we found cell division was more robust and able to occur successfully with greatly reduced formin activity and contractile ring f-actin levels. To determine if this cell-type specific cytokinetic robustness was dependent on cell intrinsic or extrinsic regulation, we performed blastomere isolation experiments. We found in one cell (P2), this cytokinetic robustness is dependent on cell intrinsic regulation, whereas in another cell (EMS) this cytokinetic robustness is dependent on cell-fate signaling pathways and direct cell-contact with its neighbor cell, P2. Together, our results demonstrate both cell-intrinsic and cell-extrinsic mechanisms control cytokinetic diversity in individual cell types and can protect against division failure when the contractile ring is weakened.

Integrated cytoplasmic reorganization during human iPS cell mitosis.
S.M. Rafelski\(^1\), .. Allen Inst. for Cell Science\(^1\);
\(^1\)Allen Institute, for Cell Science, Seattle, WA

The Allen Institute for Cell Science is developing high-replicate, dynamic image data on cell organization and activities using endogenous fluorescently tagged human induced pluripotent stem cells (hiPSCs). To date, we have generated a collection of genome-edited hiPS cell lines (WTC line) with ~15 key GFP-tagged structures (www.allencell.org and other Institute poster abstracts). These include major organelles, like the nucleus, mitochondria, ER, and Golgi, as well as other key organizational structures, such as microtubules, centrioles, actin bundles, and cell-cell junctions. One of our goals is to quantify the relative location and dynamics of major cellular structures and activities as the stem cells traverse the cell cycle. As an internal positional reference, we label the cells with fluorescent dyes that localize to the plasma membrane (CellMask Deep Red) and nucleus (Hoechst DNA staining) as a proxy. We image the cells in 100s-1000s replicates using 3D live-cell spinning disk microscopy. The DNA dye also allows us to identify 8 stages of the cell cycle, using DNA morphology and texture attributes. The stages are: two stages of prophase, two stages of prometaphase, metaphase, anaphase, telophase/cytokinesis, and
interphase. We manually annotated a dataset of 50-100 cells in each mitotic stage. These cells were used as expert input to train a supervised machine learning-based classifier that enabled automated cell cycle staging, performant at >90% accuracy. We used a parallel approach to integrate and analyze intracellular localization of cellular organelles and structures over the 8 stages of the cell cycle, permitting us to identify and correlate localization patterns in time for all of the structures studied. For example, we observed very similar localization for both the ER (sec61beta) and the nuclear envelope (laminB1), contrasting an anti-localization pattern for the mitotic spindle (alpha-tubulin) and mitochondria (tom20p) throughout mitosis. We validate our single timepoint-derived observations with live-cell timelapse imaging, which permits us to directly observe transitions between intracellular structure localization patterns. As part of our workflow, we are performing 3D image processing and a statistical analysis of the variation of organelle position and morphology during mitosis.

Microtubule tips act as signaling hubs for positioning the cleavage furrow.
V. Verma¹, T.J. Maresca¹;
¹Biology, University of Massachusetts, Amherst, MA

Successful cell division yields two daughter cells each with a complete copy of the genome. Cell division culminates with the formation of an actin-myosin containing contractile ring, positioned midway between the segregated chromosomes. Constriction of the ring generates a cleavage furrow that physically divides the cytosol. A key step in cleavage furrow formation is the localized activation of cortical RhoA, which triggers signaling cascades that drive contractile ring assembly and constriction. Microtubules (MTs) are essential for furrow positioning, but the nature and molecular composition of MT-derived positioning signals are unresolved and controversial. To examine MT-based signaling in cleavage furrow positioning, live-cell TIRF microscopy was applied to Drosophila (Dm) S2 cells to quantitatively characterize the spatio-temporal properties of lynchpin cytokinesis regulators: Pavarotti (DmMKLP1), Aurora B, and Polo kinase. Interestingly, MKLP1, Aurora B, and Polo each uniformly tip-track on astral MT tips within minutes of anaphase onset before becoming patterned onto a subset of equatorial astral MTs. We deemed these specialized MT-based signaling hubs cytokinesis signaling (CS)-TIPS. TIRF-based visualization of active RhoA revealed that CS-TIPS activate RhoA within seconds of contacting the cortex. Myosin-regulatory light chain (MRLC) then becomes locally enriched in the vicinity of CS-TIPS when cortical contacts (even outside the equatorial region) persist for minutes. Localized RhoA activation and MRLC enrichment are lost concomitant with dis-assembly of the CS-TIP complexes. Interestingly, maintenance of CS-TIPS absolutely requires Aurora B kinase activity while polo kinase is required for CS-TIP signaling, but not assembly. We propose that CS-TIPS act as critical MT-based signaling hubs that activate RhoA via physical contact with the cortex to position the cleavage furrow during cytokinesis.

Vps4 Induces a Dynamic Subunit Turnover in ESCRT-III to Mediate Membrane Remodelling During Cytokinesis.
B.E. Mierzwa¹,2,3, N. Chiaruttini¹, L. Redondo-Morata⁵, J. Moser von Filseck⁴, J. König⁶,7, J. Larios⁴, I. Poser³, T. Müller-Reichert⁶, S. Scheuring⁵,9, A. Roux⁴,10, D.W. Gerlich¹;
¹Institute of Molecular Biotechnology of the Austrian Academy of Sciences (IMBA), Vienna, Austria, ²Present address: Ludwig Institute for Cancer Research, San Diego, CA, ³Present address: Department of
The Endosomal Sorting Complex Required for Transport (ESCRT)-III forms polymers that mediate membrane fission in many fundamental cellular processes, including cytokinetic abscission. To separate emerging daughter cells, ESCRT-III constricts the intercellular bridge until the membranes split. Prevailing models assume that persistent ESCRT-III filaments change their curvature to deform membranes for fission. However, it is not known whether ESCRT-III polymers exchange their subunits with soluble cytoplasmic pools, which is a common feature of many other force-generating filament systems like actin and tubulin.

Here, we investigated ESCRT-III polymer dynamics in live human cells and in vitro. Using photobleaching experiments, we found a rapid subunit turnover in growing ESCRT-III polymers at cytokinetic abscission sites. The ATPase Vps4, previously thought to primarily disassemble ESCRT-III, accumulated simultaneously with ESCRT-III, and was required for ESCRT-III dynamics and membrane constriction. To dissect the role of each component in polymer dynamics, we reconstituted polymerization of budding yeast ESCRT-III subunits on supported lipid membranes. The scaffold subunit Snf7 alone polymerized into a stable array of single-stranded filament spirals. Addition of ESCRT-III subunits Vps2 and Vps24 induced side-by-side filaments and suppressed further polymerization. Unexpectedly, this growth inhibition was alleviated upon addition of Vps4, resulting in growing ESCRT-III assemblies with turnover kinetics similar to those observed during cytokinetic abscission. High-speed atomic force microscopy revealed that Vps4 converts an immobile lattice of ESCRT-III filament spirals into a highly dynamic arrangement of growing and shrinking spirals.

Our study reveals a dynamic subunit turnover in ESCRT-III polymers, mediated by a constitutive activity of Vps4. This continuous ESCRT-III filament reorganization might increase the energy available for membrane deformation, and facilitates shape adaptation to variable membrane geometries - from nanometer-sized vesicles to micrometer-sized tubes as observed during abscission - thereby enabling ESCRT-III to function in diverse cellular processes.

Crosstalk between the Cdc42 GEFs Gef1 and Scd1 comprise a signaling network that coordinates sequential cytokinetic events.
B.S. Hercyk1, M. Das2;
1Biochemistry Cellular and Molecular Biology, University of Tennessee, Knoxville, TN

Cytokinesis is the process by which a cell physically separates, following mitotic chromosome segregation, to produce two daughter cells. In order for cell separation to occur, the plasma membrane must ingress and fuse to compartmentalize the daughter cells. In most eukaryotes, membrane ingression is accomplished by constriction of an actomyosin-based contractile ring. Little is known about the coordination of this multistep process, which involves ring assembly, ring constriction, and cell abscission. In the fission yeast S. pombe, cytokinesis has an additional layer of complexity due to the
presence of its cell wall. In organisms with a cell wall, the force provided by constriction of the actomyosin ring is not sufficient to promote membrane ingress due to the high turgor pressure within these cells. The cell overcomes this internal turgor pressure via the force generated by the synthesis a new cell wall at the division site, called the septum. How ring constriction and septum formation are coordinated to occur simultaneously is not understood. Our previous work demonstrates a role for the small Rho GTPase Cdc42 in this process. Cdc42 is spatiotemporally activated at the division site by its two GEFs (Guanine nucleotide Exchange Factors), Gef1 and Scd1. Gef1 localizes first and activates Cdc42 at the actomyosin ring to promote ring constriction. Scd1 then localizes to the ingressing membrane and regulates septum formation. Here we provide evidence of a novel crosstalk between these Cdc42 GEFs. Our data suggest that this novel crosstalk between the GEFs establishes a signaling network that monitors events to coordinate sequential progression through cytokinesis. We demonstrate that Gef1 localization is independent of the SIN (Septation Initiation Network) pathway kinases Plo1 and Sid2. However, disruption of the actomyosin ring results in loss of Gef1 localization at the division site. This indicates that Gef1 recruitment to the division site is independent of the SIN pathway, but requires an assembled actomyosin ring. Further, Gef1 promotes the recruitment of the other GEF Scd1 and its scaffold Scd2 to the division site. In return, Scd1 is required for Gef1 removal from the division site after completion of ring constriction. This is important because failure to remove Gef1 from the division site results in delayed cell abscission. Thus, crosstalk between the Cdc42 GEFs Gef1 and Scd1 gives rise to a gradient of active Cdc42 at the division site that coordinates the sequential events of ring constriction, septum formation, and cell abscission.

Binucleation fails to activate a tetraploidy checkpoint and instead causes chromosome segregation errors in the mouse preimplantation embryo.
L.G. Paim¹, G. FitzHarris¹²; ¹Centre de Recherche du CHUM, Montréal, QC, ²Department of Obstetrics and Gynaecology, Université de Montréal, Montréal, QC

Objective: The aim of this project is to understand the consequences of binucleation in mouse preimplantation development. Methods: To induce binucleation, mouse embryos were treated with Latrunculin at the 4-cell stage. Fixed and live cell imaging was performed to evaluate embryo development, cell cycle progression and chromosome segregation errors. For cell and micronuclei counts, embryos were stained with Alexa-Phalloidin (plasma membrane) and Hoechst (DNA). For microtubule-kinetochore attachment analysis, we performed a short cold shock treatment followed by CREST (kinetochores) and a-tubulin (microtubules) staining. For live cell imaging, embryos were microinjected with fluorescently tagged mRNAs labeling the histones (H2B:RFP), an S-phase marker (PCNA:EGFP), spindle poles (CDK5RAP2:GFP), microtubules (SiR Tubulin) and centromeric regions (TALE:mClover). Live and fixed images were acquired using either confocal or structured illumination microscopy. Results: The number of cells within binucleated embryos increased normally after 12h and 24h of culture, indicating that binucleation does not prevent embryonic cell divisions. Using live imaging of PCNA:EGFP, we observed that the cell cycle occurred with normal temporal dynamics in the binucleated embryo, however the subsequent tetraploid cell cycle showed an extended G1 and a shortened S-phase as compared to the diploid control. Regarding chromosome segregation errors, we observed that embryos that had been binucleated possessed substantially greater numbers of micronuclei than the control diploid group (P<0.05). Consistent with this, with live cell imaging, we observed higher rates of abnormal divisions as compared to the control group (P<0.05), including
regulated kinase defective may be reported the separation. T265D.

During cytokinesis, a contractile ring, composed of actin filaments and myosin II filaments, is formed at the cell equator allowing the cell to divide into two daughter cells. The motor activity of myosin II, regulated by phosphorylation of its regulatory light chains (MRLCs), is a driving force of the cleavage furrow ingestion through the actomyosin contraction. Several kinases, such as Rho-associated coiled-coil kinase (ROCK) and Zipper-interacting protein kinase (ZIP kinase, also known as DAPK3), has been reported to phosphorylate MRLC at the contractile ring. However, it remains unclear whether these kinases function independently of each other. It has been reported that ROCK phosphorylates ZIP kinase at Thr265 and Thr299 in vitro. Furthermore, previous report suggests that phosphorylation of ZIP kinase at Thr265 increases its kinase activity. Therefore, we hypothesize that phosphorylation of ZIP kinase at Thr265 by ROCK contributes to control cytokinesis. To address this, we expressed ZIP kinase wild type (ZIPK-WT), a non-phosphorylatable mutant (ZIPK-T265A) or a phosphomimic mutant (ZIPK-T265D) in HeLa cells and treated cells with a ROCK inhibitor, Y-27632. The decrease of phosphorylated MRLC and the delay of furrow ingestion by a ROCK inhibitor were rescued by the expression of ZIPK-T265D, but not ZIPK-WT or -T265A. This suggests that ROCK regulates MRLC phosphorylation followed by furrow ingestion, through ZIP kinase phosphorylation.

Disruption of the division-to-growth transition in fission yeast yields a novel phenotype of precocious cell growth without cell separation.
J. Rich1, M. Das1;
1Biochemistry Cellular and Molecular Biology, University of Tennessee, Knoxville, Knoxville, TN

In most eukaryotic cells, growth and cell division do not overlap temporally. The major regulator of polarized cell growth in eukaryotes is the conserved GTPase Cdc42. Cdc42 activation at the growing cell ends terminates during the onset of cell division and resumes immediately after cell separation. How Cdc42 is regulated during this division-to-growth transition is not well understood. Here we present that a disruption of this transition in fission yeast cells results in premature cell growth before cell separation. In such cells, Cdc42 is activated at the growing cell ends at the expense of the site of cell

Monday-129
separation. We achieve this disruption via Latrunculin A (LatA) treatment and subsequent recovery of wild-type cells. Quite remarkably, we find that a subset of these recovering cells resumes growth during or immediately after septum formation, and ultimately fails to separate. This subset consists of cells that are approximately 14µm and are likely in early-to-mid mitosis at the time of treatment. These PRESS cells (PRemature Elongation Sans Separation) exhibit rapid growth at a rate up to three times faster than untreated wild-type cells. To investigate why the PRESS cells fail to separate, we investigated the viability of the septum. We find that the septum forms normally, suggesting that it is competent for separation. Our previous studies in fission yeast cells show that the growing cell ends compete with each other. We propose that in PRESS cells, the growing ends out-compete the division site for cell delivery machinery. In support of this, we find that the type V myosin Myo52 localizes initially to the division site, but is recruited away to the growing cell ends. We also find that PRESS cells prematurely activate Cdc42 at the growing cell ends. To investigate the nature of Cdc42 activation at these ends, we observed mutants of Cdc42 regulators during LatA recovery. We find the PRESS phenotype is not predicated on the presence of Cdc42 activators Scd1 or Gef1. Further, loss of Cdc42 inhibitors Rga4 or Rga6 enhances the PRESS phenotype. Taken together, our data suggest that initiating cell growth after completion of division requires cell-cycle-dependent Cdc42 activation at the cell ends. Future work will investigate this cell-cycle-dependency and further characterize the higher order regulation of Cdc42 in order to define how a cell achieves its shape.

A novel role of Wee1 in regulating actomyosin ring constriction.
S.E. Dundon1, T.D. Pollard1,2,3;
1Molecular, Cellular, and Developmental Biology, Yale University, New Haven, CT, 2Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, 3Cell Biology, Yale University, New Haven, CT

Animal, fungal, and amoeboid cells assemble an actomyosin ring from conserved proteins that constricts the cleavage furrow during cytokinesis at the end of the cell cycle. Many studies have examined the physical forces during contractile ring constriction, but less is known about how cells ensure proper timing of ring assembly and constriction. Experiments on the fission yeast Schizosaccharomyces pombe have suggested that a checkpoint regulates constriction, but the molecular components and mechanisms of this checkpoint are unclear.

We hypothesize that this checkpoint includes a molecular “brake” to inhibit actomyosin ring constriction until all checkpoint requirements are satisfied. In S. pombe, complete assembly of the actomyosin ring as well as recruitment of cell wall synthesis enzymes is necessary to initiate constriction. S. pombe cells with the temperature-sensitive bgs1-191 mutation (the gene encoding one of the β-glucan synthases that synthesizes the primary septum) activate the constriction checkpoint and build rings that do not constrict at 36°C. Therefore, the brake is engaged in these cells. Using this background to activate the checkpoint reliably, we have evidence that the famous cell cycle kinase Wee1 (which inhibits CDK activity to regulate mitotic entry) has a role in this poorly understood checkpoint. In contrast with bgs1-191 alone, bgs1-191 wee1-50 double mutants successfully complete cytokinesis at 36°C. Therefore, loss of Wee1 function compromises the brake. Accordingly, Wee1 overexpression prolongs ring assembly, delays the onset of ring constriction, and slows ring constriction. These data support our hypothesis that a brake inhibits ring constriction in response to checkpoint activation, and indicate that Wee1 is a component of this brake. Additionally, ring disassembly is defective in wee1-50 cells at 36°C. These data are consistent with a model in which Wee1 inhibits myosin activity in the contractile ring, and reveal a novel role for this well-studied kinase in regulating the final steps of the cell cycle.

**Cleavage-furrow formation without myosin or F-actin in Chlamydomonas.**

M. Onishi, K. Pecanë, T. Jones IV, J.G. Umen, F.R. Cross, J.R. Pringle; ¹Genetics, Stanford University School of Medicine, Stanford, CA, ²The Rockefeller University, New York, NY, ³Donald Danforth Plant Science Center, St. Louis, MO

Like most other eukaryotes outside the unikont group, the green alga Chlamydomonas reinhardtii has no type-II myosin yet divides by forming cleavage furrows. We asked if any of its three myosins (one type-VIII and two type-XI) and two actins (the conventional IDA5 and divergent NAP1) is involved in cytokinesis. None of the myosins localized to the cleavage furrow when tagged with Venus, indicating that none of them acts as part of a novel (no myosin-II) type of contractile-actomyosin ring (CAR). We next attempted to eliminate F-actin using latrunculin B (LatB). However, this proved challenging because of the surprising mechanisms that Chlamydomonas possesses for defense against such toxins. In particular, although LatB treatment of wild-type cells caused rapid depolymerization of F-IDA5, it also induced a strong upregulation of NAP1, which then formed LatB-resistant F-NAP1 filaments. RNA-seq analyses showed that this upregulation of NAP1 reflects a broad transcriptional response, much of which depends on three newly identified "LAT" proteins. Many of the LAT-regulated genes contain an "LRE motif", which appears to function as a cis -acting regulatory site. Among the genes induced are those encoding multiple proteins of the ubiquitin-proteasome system, and this upregulation promotes rapid degradation of LatB-bound IDA5. This degradation appears to be functionally important, because these nonpolymerizable monomers can apparently interfere with the formation or function of F-NAP1. Also induced are the genes for the actin-interacting proteins coflin and profilin. Cofilin may further the clearance of IDA5 by assisting with F-IDA5 depolymerization, whereas profilin appears to function both in protecting monomeric IDA5 from degradation and in promoting the formin-mediated assembly of F-IDA5 and F-NAP1.

These analyses of the actin-homeostasis system also provided the means to examine the effects of a complete loss of F-actin, which could be achieved by LatB treatment of a nap1 null mutant. Surprisingly, such cells formed normal-looking cleavage furrows, although they failed in the final abscission step; these results indicate both that a basal, F-actin-independent mechanism drives furrow formation and that F-actin has a CAR-independent role in abscission. Further study of the mechanisms of cleavage-furrow formation and abscission in Chlamydomonas should bring new insights into the basal mechanisms and evolution of cytokinesis and a deeper and better understanding of the true role of the CAR that evolved in the unikont lineage.

**Anillin and Septin Colocalize with Myosin II in Nodes and Filamentous Assemblages within the Forming Cytokinetic Contractile Ring.**

C. Garno, B. Samasa, Z. Iorns, J.H. Henson, C.B. Shuster; ¹Department of Biology, New Mexico State University, Las Cruces, NM, ²Friday Harbor Laboratories, University of Washington, Friday Harbor, WA, ³Department of Biology, Dickinson College, Carlisle, PA

The sea urchin embryo has been a model system for studying cell division for over a century, and it was in sea urchin zygotes that the contractile ring (CR) was first described. However, despite nearly fifty years of research since that first discovery, our understanding of the precise ultrastructure of the CR...
remains elusive. We are using a combination of confocal, super resolution and electron microscopy to define the ultrastructural organization of CR cytokinetic factors by taking advantage of the ability to analyze the structure of the large scale CRs present in cortices isolated from dividing first division sea urchin embryos. By TEM and super resolution microscopy, we recently reported that in established CRs, myosin II minifilaments are organized into concatenated polymers that run parallel to the long axis of the ring. However, in early furrows, myosin II is organized into discrete nodes that appear to undergo a process of interconnection and coalescence coincident with the formation of the CR. Actin localizes to these nodes that initially define a broad stripe at the cell equator, within the zone of active Rho GTPase. In the present study we show that the nodes also contain anillin and septin2, two components thought to play central roles in linking actin, myosin II, RhoA and the membrane during cytokinesis. 3D SIM imaging suggests that within each node, anillin and septin2 both occupy a more central position relative to the myosin II regulatory light chain. As CR formation progresses, the septin2 and anillin staining focuses into a narrower, denser and faintly linear pattern coincident with a similar change in activated myosin II distribution. This alteration in septin2 pattern may represent the ability of short septin filaments to diffuse in the membrane and elongate into longer filaments via end-to-end associations. In late stage CRs the arrangement of septin2 staining appears similar to the gauze-like filamentous patterns reported for septin assemblages in other cell types and staining was strong in the midbody. In addition, the close association of septin2 with myosin II within the CR was preliminarily demonstrated by positive staining using the Proximity Ligation Assay. Furthermore the localization of septin2 to the CR region was not dependent on actin filaments given that it occurred in embryos in which actin filaments were depolymerized prior to cell division by treatment with Latrunculin B. Taken together these results underscore the critical scaffolding roles that anillin and septin play in the formation of the CR and highlight the usefulness of the sea urchin embryo isolated cortex model for analyzing CR structure.

Imaging of bacterial cell division components reveals subcomplexes with distinct dynamics.
M.J. Holmes1, E.C. Garner1;
1Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA

The mechanisms underlying cytokinesis in bacteria remain a mystery. Remodelling of cell wall at the division site creates a peptidoglycan septum separating daughter cells. Division protein dynamics are critical for directing this cell wall remodelling: treadmilling of tubulin-homologue FtsZ limits the rates of cell wall insertion at the division site and cytokinesis overall. However, FtsZ is only one member of a complex of at least a dozen proteins implicated in bacterial cytokinesis: the divisome. While protein dynamics in the divisome are crucial for division, they remain unelucidated for most complex members. We have obtained movies of single molecules of divisome components, including cytoplasmic proteins that directly bind FtsZ and periplasmic proteins that are recruited late in the cell cycle. Cytoplasmic components, that regulate FtsZ polymerization, are stationary, like FtsZ monomers within treadmilling filaments. Periplasmic proteins move directionally, similar to FtsZ filaments, while supporting cell wall remodelling. These results provide a model of a divisome consisting of multiple subcomplexes. Continuing this work, we will investigate the effect that these proteins have on FtsZ dynamics and cytokinesis rate. Furthermore, specific perturbations will elucidate the mechanism underlying motion for each component.
FLIRT: Fast local infrared thermoptogenetics for spatiotemporal control of ts protein function during cytokinesis.

S. Hirsch¹, S. Sundaramoorthy², Y. Zhuravlev¹, T. Davies², J.C. Waters³, M.M. Shirasu-Hiza¹, J. Dumont⁴, J.C. Canman²;

¹Genetics and Development, Columbia University Medical Center, New York, NY, ²Pathology and Cell Biology, Columbia University Medical Center, New York, NY, ³Cell Biology, Harvard Medical School, Boston, MA, ⁴Cell Division and Reproduction, Institut Jacques Monod, Paris, France

We developed FLIRT (Fast Local InfraRed Thermoptogenetics) to manipulate fast-acting temperature-sensitive (ts) protein function at precise times and locations during complex cellular processes. Molecular control of complex and transient cellular behavior such as cell motility or cell division involves a high degree of spatiotemporal regulation, which is difficult to study using traditional genetic approaches. Fast-acting (≤20 sec) ts mutants permit studies of the temporal regulation of protein function by simply shifting to the restrictive temperature to conditionally inactivate protein function during the complex cellular behavior of interest. To harness the power of fast-acting ts mutants for spatiotemporal studies, FLIRT works by focusing an infrared laser at distinct sub-cellular structure(s) or on specific cells to locally heat and inactivate ts proteins at precisely defined moments during a complex cellular behavior while simultaneously monitoring the kinetic effects on that process in vivo. Here we use FLIRT to probe the spatiotemporal regulation of the core cytokinesis machinery in worms; however, FLIRT is applicable to any cellular or developmental process in any model system accessible by light microscopy. Cytokinesis is the physical division of one cell into two that occurs at the end of the cell cycle. We use FLIRT in C. elegans to study the spatiotemporal regulation of cytokinesis using our growing collection of fast-acting and reversible ts cytokinesis-defective mutants. Cytokinesis is driven by constriction of a contractile ring composed of diaphanous formin-nucleated f-actin and the motor myosin-II. We found that FLIRT irradiation of half of the contractile ring in formin(ts) or myosin-II(ts) mutant embryos halts ring constriction on the irradiated side of the cell, but not on the non-irradiated side. This suggests the contractile ring is made up of individual contractile units that can function independently of a full contractile ring. FLIRT irradiation does not inhibit cytokinesis in control embryos lacking ts mutations, or in formin(ts) and myosin-II(ts) embryos irradiated outside of the division plane (in the polar cell cortex). Further, FLIRT is reversible and cytokinesis can complete when the IR laser is turned off mid-way through contractile ring constriction in myosin-II(ts) mutants. These results highlight the high degree of rapid and reversible spatial control that can be achieved with FLIRT. We are currently using FLIRT to test the contributions of subcellular regions of actomyosin contractility in cytokinesis and expanding our analysis to other fast-acting ts cytokinesis-defective mutants.

Human Replication Licensing Factor Cdt1 Serves as an Essential Link for Stabilizing Kinetochore Microtubule Attachments.
S. Agarwal1, K.P. Smith1, Y. Zhou2, A. Suzuki3, R.J. McKenney4, D. Varma1;
1Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL,
2Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC, 3Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 4Molecular and Cellular Biology, University of California - Davis, Davis, CA

Abstract: Robust kinetochore-microtubule (kMT) attachment is critical for accurate chromosome segregation. G2/M-specific depletion of human Cdt1, a protein that localizes to kinetochores in an Ndc80 complex-dependent manner, leads to abnormal kMT attachments and mitotic arrest indicating an independent mitotic role for Cdt1 in addition to its prototypic DNA replication origin licensing function. Our previous work demonstrates that the internal loop domain of the Hec1 subunit of the Ndc80 complex is required to recruit Cdt1 to kinetochores. Here, we show that Cdt1 directly binds to microtubules (MTs) and localizes to mitotic spindle MTs. Deletion mapping revealed that the C-terminus of Cdt1 carrying a winged-turn-helix domain is necessary but not sufficient for MT-binding. We find that Mitotic kinase Aurora B interacts with Cdt1 in mitotic extracts and phosphorylates Cdt1 in vitro. Aurora B-phosphomimetic Cdt1 exhibited attenuated MT-binding and its cellular expression induced defective kMT attachments and mitotic progression. Thus we provide evidence for a Cdt1-mediated MT-attachment site for the Ndc80 complex at kinetochores in addition to the well-established MT-binding sites at the N-terminal domain of the Hec1 subunit. We propose that Cdt1 links the loop domain of Ndc80 to MTs and enables an optimal MT-binding state for the complex.

Role of the human RZZ complex in coordinating the formation of stable kinetochore-microtubule attachments and proper chromosome alignment.
M.A. Amin1, R.J. McKenney2, D. Varma1;
1Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL,
2Molecular and Cellular Biology, University of California - Davis, Davis, CA

Chromosome alignment and segregation during mitosis depends critically on stable kinetochore-microtubule (kMT) attachment formation, mediated by the function of dynein and Ndc80 kinetochore modules. However, the mechanism by which kMT attachments are controlled by the coordinated function of both these modules to drive chromosome motility during early mitosis is still unclear. The RZZ (Rod-ZW10-Zwilch) complex is central to this coordination as it has an important role in dynein recruitment and has been shown to have a key function in the regulation of the Ndc80 complex for kMT attachments. Here, we show that severe chromosome alignment defects induced by dynein or Ndc80 depletion were rescued by codepletion of Rod, a component of the RZZ complex, independent of its function in the spindle assembly checkpoint. Interestingly, in the case of dynein, the rescue was accompanied by a remarkable restoration of stable kMT attachments. Moreover, the rescue of chromosome alignment was critically dependent on the plus-end-directed force mediated by CENP-E, as cells codepleted of Rod and CENP-E along with either dynein or Ndc80 were not able to maintain the
stability of kMT attachments. Our data suggests that the components of the dynein module directly controls the function of the Ndc80 module for stabilizing kMT attachments during early mitosis in human cells. The RZZ complex exerts an inhibitory effect on the function of the Ndc80 complex while dynein and its adaptor, Spindly, serve to modulate this effect and control kMT attachment strength to facilitate proper chromosome motility and alignment at the metaphase plate.

Nonsense-mediated mRNA decay regulates mRNA levels for kinetochore proteins in Saccharomyces cerevisiae.
S.I. Graves1, J.N. Dahlseed2;
1Biology Chemistry, Gustavus Adolphus College, Saint Peter, MN

Nonsense-mediated mRNA decay (NMD) is best known as a eukaryotic cell surveillance pathway that recognizes and targets aberrant mRNAs for accelerated decay. In a number of model systems, NMD also targets numerous wild-type mRNAs, thereby contributing to the regulation of gene expression. In Saccharomyces cerevisiae, we have identified three wild-type mRNAs seemingly affected by NMD. The CTF13, SKP1, and CEPI3 mRNAs encode proteins that bind centromere DNA to assemble the centromere-binding factor 3 (CBF3) complex of the kinetochore, which is essential for chromosome segregation during mitosis. Our lab has shown that the stability of CTF13 mRNA is directly affected by NMD. We aimed to determine if NMD similarly affects the stability of SKP1 and CEPI3 mRNAs. We engineered SKP1 and CEPI3 genes to express their wild-type mRNAs under the control of the carbon-source dependent regulator, Gal4p. As expected, both showed dextrose-dependent suppression and galactose-dependent induction. CEPI3 mRNA, but not SKP1 mRNA, accumulates in cells lacking NMD. Using carbon-source control, we are measuring rates of decay from steady-state for these mRNAs in yeast with and without NMD. Slower decay of either mRNA in yeast lacking NMD will indicate it is an NMD substrate. In future work, we aim to elucidate how any confirmed wild-type mRNA substrates of NMD are recognized for accelerated decay.

Regulation of PKA activity during Mitosis.
D.A. Parmiter1, J. Choy1, S.B. Shah1;
1Biology, Catholic University of America, Washington, DC

Accurate chromosome segregation is essential for normal function of cells and organisms. Disruptions in many of the cell cycle regulatory mechanisms ensuring proper chromosomal segregation lead to aneuploidy, an incorrect number of chromosomes, which causes congenital disorders, including Down’s Syndrome, and is pervasive in cancer. Previous work in multicellular and yeast systems have shown that Protein Kinase A (PKA) serves a critical function in glucose response and regulation of the cell cycle. PKA is a heterotetrameric enzyme, composed of regulatory and catalytic dimers. We have observed that PKA activity fluctuates at different points within the cell cycle, peaking during S Phase. We have previously reported that deregulated PKA can cause chromosomal instability, yet the mechanism remains unknown. Experiments measuring total PKA activity and split DHFR assays indicate that PKA is down-regulated when spindle-chromosome attachments are compromised. We hypothesize that PKA activity plays an important role in the spindle assembly checkpoint to minimize chromosome missegregation. Experiments will be presented that directly test this hypothesis. This work helps to elucidate a
mechanism that links PKA to chromosome stability, which has been elusive in the past, and suggests that nutrient signaling may directly impact chromosome segregation.

The molecular requirements for epigenetic establishment of centromeres depend on the type of underlying DNA.
G.A. Logsdon1, C.W. Gambogi1, E.J. Barrey2, P. Heun2, B.E. Black1;
1Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, 2Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

Human artificial chromosomes (HACs) are exciting tools for current and planned synthetic biology efforts and could have important future clinical applications. A key element in a HAC is the centromere because it directs the faithful segregation of the HAC to daughter cells in mitosis. Functional centromeres are defined by the presence of nucleosomes containing the histone variant, CENP-A. The acquisition of CENP-A nucleosomes on naked DNA HAC templates is the critical step for HAC formation because it initiates the self-propagating epigenetic pathway for centromere inheritance. We sought to artificially promote centromere formation by locally seeding CENP-A nucleosome assembly via its specific histone chaperone, HJURP. We reasoned that this would allow us to more efficiently form HACs to test whether or not it would relax the DNA sequence requirements reported for previous versions (i.e. a reported strict requirement for highly repetitive centromeric α-satellite DNA). Our epigenetic seeding approach successfully stimulated HAC formation on α-satellite DNA, providing an example in a mammalian system for epigenetic spreading of CENP-A-containing chromatin. Earlier studies had reported a strict requirement in HAC formation for the DNA binding protein, CENP-B, and the 17 bp element within α-satellite monomers to which it binds, the CENP-B box (Ohzeki et al., 2002. J. Cell Biol. 159, 765-775; and Okada et al., 2007. Cell 131, 1287-1300). We found that artificial epigenetic centromere seeding completely bypasses the requirement for CENP-B. We also found that HACs can form on complex DNA that lacks any detectable α-satellite DNA or CENP-B protein, both findings in stark contrast to the longstanding models of HAC formation. Surprisingly, targeting local HUURP recruitment did not stimulate HAC formation on complex DNA. Moreover, unlike their earlier α-satellite counterparts, complex DNA HACs allowed us to define the sequence composition, copy number, and precise location of CENP-A nucleosome assembly, providing important insight into HAC formation and stability. Complex DNA HACs also circumvent the cloning difficulties caused by highly repetitive α-satellite DNA that has limited the broader utility of the earlier generation of HACs. Together, our study innovates the HAC “toolbox” and reveals molecular requirements for centromere formation that unexpectedly vary depending on DNA sequence.

RbAp46/48 (Lin-53) - Hat-1 complex is crucial for de novo centromere formation in C. elegans.
Z. Lin1, K. Yuen1;
1School of Biological Sciences, The University of Hong Kong, Hong Kong, Hong Kong

After naked foreign DNA is injected into the C. elegans germline, artificial chromosomes (ACs) can be formed in its embryos and acquire segregation competency rapidly within a few cell cycles. The mechanisms underlying ACs segregation and de novo centromere formation are unknown. Here we show that de novo centromere formation occurs after oocyte fertilization. Immunofluorescent (IF)
staining following foreign DNA injection shows that centromeric protein CENP-A (Hcp-3) and Mis18BP1 (Knl-2) are both present on newly formed ACs in fertilized oocytes, although these ACs either do not segregate or lag at anaphase in the first round of mitosis. Furthermore, IF screening of histone modification marks on ACs in 1-cell embryos shows enrichment of H3K9ac, H4K5ac, H4K12ac, H4K20me, but lack H3K4me2, H3K4me3 and heterochromatin marks H3K9me2, H3K9me3 and H3K27me3. The H4K5 and H4K12 can be acetylated by Hat-1 in RbAp46/48-Hat-1 complex which is conserved in different species for depositing newly synthesized histone H3, H4 and CENP-A to the chromatin. The enriched H4K5ac and H4K12ac suggest that RbAp46/48-Hat-1 complex could be involved in the process of de novo centromere formation. We further show that inhibition of RbAp46/48 (Lin-53) and Hat-1 can totally abolish the H4K5ac, H4K12ac and CENP-A signal on newly formed ACs and disable the ACs’ segregation ability. These findings reveal that RbAp46/48(Lin-53)-Hat-1 complex is essential for initiating CENP-A deposition on naked DNA and facilitating de novo centromere formation in C. elegans.

A potential new error correction mechanism for chromosome segregation in anaphase.
D. Papini1, M. Levasseur1, J.M. Higgins1;
1Institute for Cell and Molecular Biosciences (ICaMB), Medical School, Framlington Place, Newcastle upon Tyne NE2 4HH, UK, Newcastle University, Newcastle upon Tyne, United Kingdom

The effective segregation of chromosomes is essential for genome integrity. Errors can lead to birth defects and may contribute to carcinogenesis. To prevent mis-segregation, the sister kinetochores must be attached to microtubules emanating from opposite spindle poles, and anaphase onset must be delayed until all chromosomes are correctly attached in this bi-oriented state. Even in normal cells, numerous attachment errors occur prior to bi-orientation. These errors are generally detected during prometaphase by surveillance mechanisms that allow their release and correction. To do this, the centromeric kinase Aurora B is required. However, some errors, such as merotelic attachments, can persist and lead to the formation of lagging chromosomes (LCs). These are observed at the midzone during anaphase and are a potential source of aneuploidy. To date, only formation of LCs has been well studied. It remains unclear how the cell deals with LCs once they are formed, and whether they are subject to any type of error correction that operates after anaphase onset to prevent aneuploidy.

Aurora B is the major regulator of error correction in early mitosis and destabilises incorrect microtubule attachments prior chromatin separation. At anaphase onset, Aurora B transfers from chromosomes to the central spindle, resulting in an activity gradient across the dividing cell, centred on the midzone. Because Aurora B is removed from centromeres in anaphase, it is commonly assumed that its role in error correction ends at this time.

Our recent data show that Aurora B substrates involved in error correction during early mitosis are also phosphorylated on lagging chromosomes in anaphase. We are therefore testing the hypothesis that the Aurora B gradient functions as a “measuring ruler”, allowing the cell to identify LCs and to correct their kinetochore-microtubule attachments after anaphase onset. Specifically, we are investigating whether Aurora B actively regulates chromosome attachment status by phosphorylation of kinetochore proteins on LCs and, in so doing, reduces the incidence of chromosome mis-segregation. This work may reveal a new error correction mechanism for chromosome segregation in anaphase.

Structural studies of the budding yeast kinetochore using single-molecule localization microscopy.
K. Cieslinski¹, J. Ries¹, S. Hoerner¹;
¹CBB, EMBL, Heidelberg, Germany

When a chromosome is erroneously attached during mitosis, the kinetochore undergoes structural changes which lead to checkpoint signalling, cell cycle arrest and chromosome reattachment. Thus, studies on the structural organization of the kinetochore is crucial to understand the function of this complex machinery. To understand the structural relation between the components at individual kinetochores we employed dual-color superresolution microscopy, specifically single-molecule localization microscopy, of the metaphase. We showed that the C-terminus of Cnn1 protein lies on a centromeric site of the metaphase kinetochore close to another centromere-binding protein Mif2. All C-termini of the MTW1 complex highly colocalize with each other as well as with C-terminus of Spc105 and Spc25. We developed a method for sub-unit counting based on the nuclear pore complex as a counting reference to measure the protein copy numbers of the kinetochore in metaphase and anaphase. In summary, we developed an experimental handle that allows structural studies of individual yeast kinetochores in situ at unprecedented detail, which will greatly further understanding of the kinetochore structure-function relationship.

Investigating the role of kinetochore dynein-dynactin in Spindle Assembly Checkpoint function.
A. Hodges¹, T. Biebighauser¹, L.R. Heasley¹, R. Wimbish¹, S.M. Markus¹, J.G. DeLuca¹;
¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Eukaryotic cells employ a fail-safe mechanism – the Spindle Assembly Checkpoint, or SAC – to ensure that mitotic cells do not enter anaphase until all chromosomes are properly attached to spindle microtubules. SAC proteins accumulate on unattached mitotic kinetochores and generate a “wait anaphase” signal to prevent activation of the Anaphase Promoting Complex/Cyclosome (APC/C) by inhibiting its activator, Cdc20. This “wait anaphase” signal is the MCC, or Mitotic Checkpoint Complex, and is comprised of Mad2, BubR1, Bub3, and Cdc20 itself. Bub3 and BubR1 are recruited to kinetochores through KNL1 “MELT” motifs, whose phosphorylation by Mps1 generates direct binding sites for Bub3 and its binding partners Bub1 and BubR1. Mad2 is thought to be recruited to kinetochores via two mechanisms: (1) direct binding to Bub1, and (2) a poorly-understood linkage to the RZZ complex (Rod, Zwilch, and ZW10), which also recruits the dynein adaptor, Spindly, which in turn recruits dynein and dynactin to kinetochores. Upon stable attachment to microtubules, SAC proteins are evicted from kinetochores, which results in reduced MCC complex assembly and activity, and the consequent activation of APC/C to initiate anaphase onset and mitotic exit. The molecular signal that results in SAC protein eviction from kinetochores upon stable attachment remains unclear; however, it is likely that two mechanism are involved: (1) a shift in the balance between kinetochore kinases and phosphatases to favor phosphatase activity, which reverses many of the SAC protein recruitment events, and (2) activation of kinetochore dynein, which results in the “stripping” of SAC proteins from kinetochores. The precise contributions of the dynein pathway to checkpoint function have been difficult to assess given its many functions in animal cells (and thus the pleotropic effects following cellular dynein disruption), and the current limitations in studying dynein function in vitro. Recent innovations have allowed for a
more precise dissection of kinetochore dynein function, specifically: development of a one-step procedure for isolation of motility-competent kinetochore dynein-dynactin complexes from cultured human cells, and the development of reagents that allow for specific disruption of kinetochore dynein function in cells. We have used these tools to determine the network of interactions that link SAC proteins to dynein and to investigate the molecular signals that initiate dynein-mediated SAC protein eviction from kinetochores upon stable microtubule attachment.

**Regulation of kinetochore plasticity during anaphase.**

K. Dhatcinamoorthy¹, B. Slaughter¹, J.J. Lange¹, J. Unruh¹, J.L. Gerton¹;²

¹Stowers Institute for Medical Research, Kansas city, MO, ²Department of Biochemistry Molecular Biology, The University of Kansas School of Medicine, Kansas City, KS

The kinetochore is a large evolutionarily conserved protein structure that connects chromosomes with microtubules. During chromosome segregation, outer kinetochore components track the depolymerizing end of a microtubule to facilitate separation of chromosomes into two cells. In budding yeast, each chromosome has a point centromere upon which a single kinetochore is built which attaches to a single microtubule. Studies from our lab have shown that the kinetochore structure is plastic during the cell cycle. The kinetochore submodule Dam1 is unchanged during anaphase whereas MIND and Ndc80 submodules add copies to form an 'anaphase-configuration' kinetochore. Using calibrated imaging we found that microtubule depolymerization and kinesin related motors contribute to copy number addition. Also, using temperature sensitive mutants we found that the Anaphase Promoting Complex (APC) is required for the Ndc80 complex addition during anaphase and Mitotic exit pathway mutants arrest the cell with the anaphase-configuration kinetochore. We speculate that the APC promotes the addition of Ndc80 complex subunits during anaphase and the Mitotic Exit Pathway partially disassembles the kinetochore in the next cell cycle. Our study provides insight into the regulation of kinetochore structural dynamics during chromosome segregation in living cells.

**Determining the Molecular Basis for Differences in Binding Affinity Between Human and Mouse Aurora Kinase B.**

S.S. Dipali¹, A.L. Nguyen¹, K. Schindler¹;²

¹Genetics, Rutgers University, New Brunswick, NJ

The Aurora kinases (AURK) are a family of serine/threonine kinases tasked with preventing aneuploidies from occurring in mitosis and meiosis, by regulating multiple processes critical for cellular division. Though the role of AURKB is well defined in somatic cells, where it acts as the catalytic subunit of the chromosomal passenger complex (CPC), work in mouse oocytes has identified that the germ-line specific paralog, AURKC, assumes many of AURKB's functions from mitosis in meiosis. These results leave the requirement for AURKB in mouse oocytes unknown. Work in the Schindler lab has demonstrated that while mouse AURKB is inefficient at competing with AURKC to bind the CPC even when overexpressed, ectopically expressed human AURKB robustly localizes to chromosome arms, efficiently out-competing AURKC for CPC binding. Surprisingly, human and mouse AURKB are 90% identical at the amino acid level. Here, we sought to determine what sequence differences between these two AURKs are important in CPC binding affinity, driving the disparity in competition between the homologs. By expressing deletion
and chimeric mutant versions of the kinases in mouse oocytes, we show that amino-terminal regions that differ do not dictate the localization differences between mouse and human AURKB. Understanding the way in which the localization of the Aurora kinases is regulated will be essential to uncovering the unique and complex functions regulated by these proteins in germ cells.

To ensure the correct segregation of sister chromatids during mitosis, the spindle assembly checkpoint (SAC) is a surveillance system that delays anaphase onset if one or more kinetochores are not properly attached to the spindle. Several kinetochore proteins, including MAD-1, MAD-2 and PCH-2, are necessary for generating the SAC response. MAD-2 is recruited at unattached kinetochore by MAD-1 and adopts two conformations: an open, inactive form, O-MAD-2, and a closed version, C-MAD-2, which acts as a SAC effector. MAD-1/MAD-2 dimers bind additional O-MAD-2, converting it to C-MAD-2 and facilitating the production of a soluble inhibitory signal. The concentration of this signal effectively tunes the SAC: the length of the cell cycle delay imposed by the SAC is governed by the ratio of the soluble checkpoint signal to cytoplasmic volume.

PCH-2 is required to localize MAD-2, but not MAD-1 at unattached kinetochore². We proposed that PCH-2’s role is to convert C-MAD-2 into O-MAD-2 to locally increase the concentration of O-MAD-2 at unattached kinetochores so that it can be converted to C-MAD-2 and generate the inhibitory signal. We hypothesize that this function ensures SAC strength, since mutants that abolish PCH-2’s localization at the kinetochores exhibit reduced SAC robustness.

To test this hypothesis, we investigated the SAC response in two scenarios in which SAC strength has been shown to increase: when cell volume decreases and in cells that take on specific developmental fates, specifically germline tissue. We perform these experiments in C. elegans, which gives us the opportunity to generate embryos of varying size in a context where cells take on specific developmental fates.

Our experiments indicate that PCH-2 function in the SAC becomes dispensable as the cell volume decreases: smaller pch-2Δ cells localize Mad-2 at unattached kinetochores and exhibit a functional SAC response. This role in SAC strength, however, is not limited to smaller cells, since we also found that PCH-2 is responsible for the stronger SAC in germline cells. These results suggest that the primary role of PCH-2 during the SAC response is to locally increase the concentration of O-MAD-2 to make the SAC stronger, a requirement that can be overcome in somatic tissue by decreasing cell volume. This may explain the requirement for PCH-2 in the SAC in some systems in which a large cell volume can present a challenge to a robust SAC response, such as mammalian cells and C. elegans embryos, as well as its dispensability in other systems characterized by small cell size, such as fission and budding yeast.

Accurate chromosome segregation relies on the ill-understood ability of kinetochores to convert their lateral microtubule attachment into the microtubule plus-end association, capable of the processive motion with tubulin dynamics. Here we report that this transition can be recapitulated in vitro using only two components: the plus-end-directed kinesin CENP-E and the microtubule wall-binding Ndc80 protein. CENP-E’s primary role is to establish the end configurations for Ndc80, while Ndc80 mediates the maintenance of end attachment. To gain insights into the molecular requirements for end-conversion, we paired CENP-E with other microtubule-binding proteins. Ska1, CENP-E Tail, EB1 and CLASP2 differed in their ability to retain the microtubule ends, and none performed as robustly as Ndc80. Likewise, a non-mitotic transporter Kinesin-1 failed to support the Ndc80-mediated end-conversion, implying that the pair of CENP-E kinesin and Ndc80 is optimally suited for this activity. To investigate the underlying mechanistic differences between these motors and MAPs, we developed a Brownian dynamics model for the molecular ensembles of proteins engaged stochastically in walking and diffusion on the microtubule wall. Modeling demonstrates that the observed differences in the end-retention by different MAPs can be largely attributed to their different residency times and rates of diffusion on the microtubule wall. The model also recapitulates the strikingly different behavior of Kinesin-1 and CENP-E, suggesting that it is rooted in their distinct force-detachment characteristics. Following a model prediction, we were able to achieve robust end-conversion with Kinesin-1 by amending its dynamic response via the reduced ATP concentration. Together, our results strongly argue that microtubule end-conversion is an emergent property of the ensemble of transporting motors and diffusing MAPs, limited by the microtubule end boundary. We propose that similar mechanism ensures microtubule end conversion at mitotic kinetochores.

Molecular mechanisms that prevent mislocalization of centromeric histone H3 variant CENP-A and chromosomal instability (CIN) in human cells.
R.L. Shrestha¹, J. Kim¹, G.S. Ahn¹, A. Rossi¹, L. Ozbun¹, G. Pegoraro¹, D.R. Foltz², M.A. Basrai¹;
¹National Cancer Institute, National institutes of health, Bethesda, MD, ²Department of biochemistry and molecular genetics, Northwestern University, Chicago, IL

Faithful chromosome segregation is a critical event for every cell. Defects in chromosome segregation contribute to chromosomal instability (CIN) and aneuploidy. Aneuploidy is a hallmark of cancers and may contribute to tumor heterogeneity and cancer progression. The centromeric histone H3 variant (CENP-A in humans, Cse4 in budding yeast) is evolutionarily conserved and essential for faithful chromosomal segregation. CENP-A overexpression has been reported in numerous types of cancer and correlates with poor prognosis. Recently, we showed that CENP-A overexpression in human cells (HeLa and RPE1) results in mislocalization to non-centromeric regions and contributes to CIN (Shrestha et al.,
Oncotarget 2017). However, the pathways that regulate CENP-A expression to prevent its mislocalization are not fully understood. Our research objective is to identify pathways that regulate cellular levels of CENP-A and prevent its mislocalization for faithful chromosome segregation. Using genome-wide screens with budding yeast we showed that mutants for the replication independent histone chaperones (HIR complex) and E3 ubiquitin ligase (SCF-Met30) are sensitive to overexpression of Cse4 and defined roles for the Hir2 and SCF-Met30 in preventing mislocalization of Cse4. In this study, we investigated whether HIRA and -TrCP, human homologues of HIR2 and SCF-Met30, respectively, have conserved roles in regulating cellular levels and localization of CENP-A. Here we show that similar to our findings in yeast, depletion of HIRA or -TrCP results in mislocalization of CENP-A and CIN phenotypes in human cells. Moreover, we observed reduced proliferation of CENP-A overexpressing cells and increased DNA damage upon HIRA depletion. In a second approach, we are performing high-throughput RNAi screens to identify regulators of CENP-A expression and localization. In summary, our results provide insights into pathways that regulate cellular levels of CENP-A and prevent its mislocalization for faithful chromosome segregation.

Centromere dysfunction impacts the centrosome causing PCM dispersion during mitosis and centriole loss in the following interphase.
S. Gamble1, D. Fachinetti1, R. Basto1;
1UMR144, Institut Curie, Paris, France

A balanced set of chromosomes is necessary to maintain genome stability. Defects in DNA repair, chromosome segregation or in the final step of cell division – cytokinesis – can all generate unbalanced genomes. In order to maintain a correct karyotype, DNA integrity and correct repartition of chromosomes are ensured by the activity of cell cycle checkpoints. These respond to various stimuli, like DNA damage or incorrect microtubule (MT)-kinetochore attachment, blocking cell cycle progression to allow repair or correction. Accurate chromosome segregation requires two important players: the centrosomes (1) and the centromeres (2). (1) Centrosomes are composed by two centrioles surrounded by PeriCentriolar Material (PCM) and act as dominant sites of MT nucleation in mitosis. Centrosomes are duplicated only once per cell cycle, so that two centrosomes contribute to the assembly of the bipolar mitotic spindle that segregates chromosomes to the two daughter cells during mitosis. (2) MTs from the mitotic spindle contact kinetochores, which are multiprotein complexes that assemble on a specialized region of each chromosome, the centromere. Centromere specification depends on recruitment and loading of centromere protein A (CENP-A), a centromere-specific histone H3 variant. We found that depletion of any of the centromere components CENP-A, CENP-C or CENP-N, compromises centromere integrity. The centrosome defects include (1) PCM dispersion during mitosis, (2) centriole mis-position at mitotic spindle poles and (3) centrosome loss in the following interphase. Interestingly, we observed that the loss of centrosome integrity in response to centromere dysfunction is MT-dependent and that abnormal MT dynamics contribute to any of the phenotypes mentioned above. Using several approaches that include drug treatment, siRNA, live imaging and super resolution microscopy we proposed a model in which centromere dysfunction leads to abnormal MT dynamics impacting in mitotic lengthening and culminating with PCM dispersion. Consequently, centrioles are mis-positioned at the spindle poles, leading to their subsequent loss in interphase. These results reveal an unexpected
functional relationship between centromeres and centrosomes during mitosis. Moreover, they suggest that defects in maintaining an optimal centromeric structure impacts the integrity of the mitotic spindle in more ways than initially predicted, not only affecting chromosome segregation, but also compromising centosome integrity.

Defining The Physical and Spatial Properties of the Spindle Assembly Checkpoint Across Species.
L.R. Heasley¹, J.G. DeLuca², S.M. Markus¹;
¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Accurate chromosome inheritance is necessary for the development and maintenance of all organisms. Thus, cells have developed a surveillance system called the Spindle Assembly Checkpoint (SAC), which suspends the onset of anaphase until all the chromosomes are positioned to be equally inherited. The SAC monitors attachment of spindle microtubules (MTs) to large protein complexes called kinetochores (KTs), which reside at the centromere of each chromosome. Unbound KTs facilitate the generation of a molecular ‘wait anaphase’ signal that manifests in the inhibition of anaphase onset. Recent phylogenetic analyses have revealed that the SAC is highly conserved across Eukarya. Intriguingly, the mechanisms by which cells carry out mitosis are quite variant across the kingdom (e.g., open vs. closed mitosis). How has the SAC adapted to function in these diverse mitotic contexts in order to achieve high-fidelity chromosome segregation? We are interested in understanding how the SAC functions in cells that undergo closed mitosis, in which the nuclear envelope (NE) remains intact during mitosis. We previously found that in cells which undergo open mitosis, ‘wait anaphase’ signals diffuse from the spindle into the cytoplasm. We hypothesized that in cells in which closed mitosis occurs, ‘wait anaphase’ signals could be confined to the nucleus. In an approach similar to our previous study, we have used binucleate budding yeast cells to define how SAC activation or anaphase onset in one nucleus impacts the mitotic progression of the other nucleus. We have found that unlike mammalian cells, anaphase onset is not coordinated between nuclei. Instead, nuclei progress into anaphase autonomously suggesting that ‘wait anaphase’ signals are not shared. We predicted that the restricted localization of SAC proteins could explain the nuclear autonomy we observe. We found that the proteins Mad1 and Bub1 remain localized within their parent nucleus whereas Mad2, Mad3 and Cdc20 localize to both nuclei. We investigated the possibility that once SAC proteins enter a nucleus, they are restricted from exiting back into the cytoplasm. This would provide individual nuclei discrete environments for SAC signaling and mitotic progression despite residing in a shared cytoplasm. Indeed, we have found that Cdc20, a primary component of the ‘wait anaphase’ signal, can enter both nuclei in the binucleate but then becomes ‘trapped’ within until mitotic exit, at which point it is degraded. Thus, these studies have revealed that in an organism which conducts closed mitosis, the NE restricts diffusion of ‘wait anaphase’ signals to the nucleus. The mechanism by which this restriction occurs and whether this is a conserved quality of all organisms which undergo closed mitosis remains unknown.

Kinetochore recruitment of the Ska complex is regulated by RSA-1 in C. elegans.
K.I. Lange1, A. Suleman2, M. Srayko3;
1Biological Sciences, University of Alberta, Edmonton, AB

During mitosis, the microtubule cytoskeleton is restructured to form the bipolar mitotic spindle. Dynamic microtubules interact with chromosomes via kinetochores to move and orient the chromosomes between the centrosomes. During anaphase, the sister chromatids are separated to ensure each daughter cell receives precisely one complement of the genome. Errors in chromosome segregation can cause aneuploidy, which is a driving force in tumour formation. RSA-1, a regulatory subunit for PP2A phosphatase in C. elegans, targets the enzyme to centrosomes and regulates microtubule outgrowth. We observed a genetic interaction between RSA-1 and the Ska complex. For example, increased levels of the Ska complex enhance the embryonic lethality associated with loss of rsa-1 function, and reduced levels of Ska restore embryonic viability. Furthermore, in rsa-1(or598) embryos, SKA-1 is prematurely and excessively recruited to kinetochores during spindle assembly. RSA-1 also affects the localization of Aurora A kinase on centrosomal microtubules, suggesting a functional link between RSA-1 activity at the centrosome and recruitment of Ska to the kinetochores. Additionally, using an RNAi-based screen, we identified several other components required for appropriate Ska localization in the embryo.

Outer kinetochore phosphatases - PP2A-B56 and PP1 – differently contribute to the establishment of chromosome-microtubule attachments.
D. Conti1,2, K.A. Cieslinski3, J. Ries3, V.M. Draviam3;
1Genetics, University of Cambridge, Cambridge, United Kingdom, 2London, Queen Mary University of London, London, United Kingdom, 3Cell Biology and Biophysics, EMBL, Heidelberg, Germany

Chromosome instability is a hallmark of malignant cancers but the underlying lesions are poorly understood. Chromosomal stability requires faithful chromosome segregation during cell division. It is ensured by a stable connection between the chromosome and microtubules (MTs) via a macromolecular structure called the kinetochore (KT). Immature attachment of kinetochores along the lateral walls of microtubules is converted into mature attachment to the ends of microtubules (end-on) through a multi-step end-on conversion process. Only end-on attachments generate the mechanical forces that pull and segregate sister chromatids. In human cells, the Aurora B kinase is a master regulator of the end-on conversion process and is important for the stabilisation of lateral attachments, an early event needed for rapid chromosome capture. However, Aurora-B activity should be counteracted to allow stable end-on attachments; phosphatases that counteract Aurora-B and the end-on conversion process were not known. To address this, we used high-resolution microscopy techniques to dissect the role of BubR1-recruited PP2A-B56 and KNL1-recruited PP1 in the establishment of mature kinetochore-microtubule attachments. Although the two phosphatases are involved in a negative-feedback loop for spindle assembly checkpoint signalling, our findings show that PP2A-B56 and PP1 cover separable roles in controlling the plane of kinetochore-microtubule attachment. Next, in an effort to identify downstream targets of Aurora-B that promote kinetochore-microtubule attachments, we explored the significance of Ndc80-tail phosphorylation events. Our work reveals the presence of an Aurora-B dependent and Ndc80-tail independent pathway that controls the plane of kinetochore-microtubule
attachment. Finally, we present a mechanistic model of how chromosome attachment to spindle microtubules in human cells is finely regulated by Aurora-B kinase and a counteracting phosphatase at the outer-kinetochore. These findings shed light on how chromosome stability relies on a careful balance between phospho-networks that operate in a spatially, temporally and mechanically regulated manner.

1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Two-color fluorescence co-localization in 3D (three-dimension) has the potential to achieve accurate measurements at the nanometer length scale. Here we optimized a 3D fluorescence co-localization method that uses mean values for chromatic aberration correction to yield the mean separation with ~10 nm accuracy between green and red fluorescently labeled protein epitopes within single human kinetochores. Accuracy depended critically on achieving small variances in fluorescence centroid determination, chromatic aberration across the measurement field, and coverslip thickness. Computer simulations showed that large variances in these parameters significantly increase 3D measurements from their true values. Our 3D results show that the protein linkage between CENP-A within the inner kinetochore and the microtubule binding domain of Ndc80 complex within the outer kinetochore is on average ~90 nm. The Ndc80 complex appears fully extended at metaphase and exhibits the same subunit structure in vivo as found in vitro by crystallography.

Faithful segregation of chromosomes during cell division relies on multiple processes such as chromosome attachment or correct spindle positioning. Yet, mitotic progression is defined by multiple parameters, which need to be quantitatively evaluated. To study the spatio-temporal control of mitotic progression, we developed a High-Content Analysis (HCA) approach, which combines automated fluorescence microscopy with real time quantitative image analysis and allows the unbiased acquisition of multi-parametric data at the single cell level for hundreds of cells simultaneously. MAARS (Mitotic Analysis And Recording System) provides automatic and quantitative single cell analysis of mitotic progression on an open source platform. It can be used to analyze specific characteristics like cell shape, cell size, metaphase/anaphase delays as well as mitotic abnormalities including spindle mis-positioning, spindle elongation defects or chromosome segregation defects. Using this HCA approach, we were able to visualize rare and unexpected events of error correction during anaphase in wild type or mutant cells. Our study illustrates that such an expert system of mitotic progression is able to highlight the complexity of the mechanisms required to prevent chromosome loss during cell division.

Biology, Harvard University, Cambridge, MA

The spindle partitions chromosomes into the two daughter cells during cell division. The manner by
which the spindle generates and exerts the forces that segregate chromosomes in anaphase remain
poorly understood. We used genetic perturbations, electron tomography, laser ablation, and
quantitative optical microscopy to study chromosome segregation in Caenorhabditis elegans mitotic and
meiotic spindles, and human mitotic spindles. All of these spindles contain a population of microtubules
between chromosomes in anaphase. Perturbing these inter-chromosomal microtubules greatly
influences chromosome motion, while interfering with microtubules between chromosomes and spindle
poles has a minimal impact. In addition, these inter-chromosomal microtubules slide apart in the same
speed as sister chromosomes separate, but in a faster speed than the spindle poles move apart,
suggesting that their sliding is coupled to chromosome motion. Our results argue that inter-
chromosomal microtubules push chromosomes apart by a combination of polymerization and sliding.
Based on these findings, we propose that pushing from inter-chromosomal microtubules is the primary
driver of chromosome motion in anaphase.

The mitotic spindle is chiral due to torques generated by motor proteins.
J. Simunic1, B. Polak1, M. Novak2, Z. Boban2, B. Kuzmić1, N. Pavin2, I.M. Tolić1;
1Division of Molecular Biology, Ruđer Bošković Institute, Zagreb, Croatia, 2Department of Physics,
Faculty of Science, University of Zagreb, Zagreb, Croatia

Mitosis relies on forces generated in the spindle, a micro-machine composed of microtubules and
associated proteins. Forces are required for the congression of chromosomes to the metaphase plate
and separation of chromatids in anaphase. However, torques may also exist in the spindle, yet they have
not been investigated. Here we show that the spindle is chiral. Chirality is evident from the finding that
microtubule bundles follow a left-handed helical path, which cannot be explained by forces but rather
by torques acting in the bundles. STED super-resolution microscopy, as well as confocal microscopy, of
human spindles shows that the bundles have complex curved shapes. The average helicity of the
bundles with respect to the spindle axis is 1.5 degrees/µm. Inactivation of kinesin-5 (Eg5/Kif11)
abolished the chirality of the spindle, suggesting that this motor generates the helical shape of
microtubule bundles. To explain the observed shapes, we introduce a theoretical model for the balance
of forces and torques acting in the spindle, and show that torque is required to generate the helical
shapes. We conclude that torques generated by motor proteins, in addition to forces, exist in the
spindle and determine its architecture.

NuMA Targets Dynein to Microtubule Minus-Ends at Mitosis.

C.L. Hueschen\textsuperscript{1,2}, S.J. Kenny\textsuperscript{3}, K. Xu\textsuperscript{3}, S. Dumont\textsuperscript{1,4};
\textsuperscript{1}Dept. of Cell Tissue Biology, University of California, San Francisco, San Francisco, CA, \textsuperscript{2}Biomedical Sciences Graduate Program, University of California, San Francisco, San Francisco, CA, \textsuperscript{3}Dept. of Chemistry, University of California, Berkeley, Berkeley, CA, \textsuperscript{4}Dept. of Cellular Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

To build the spindle at mitosis, motors exert spatially regulated forces on microtubules. We know that dynein pulls on mammalian spindle microtubule minus-ends, and this localized activity at ends is predicted to allow dynein to cluster microtubules into poles. How dynein becomes enriched at minus-ends is not known. Here, we use quantitative imaging and laser ablation to show that NuMA targets dynactin to minus-ends, localizing dynein activity there. NuMA is recruited to new minus-ends independently of dynein and more quickly than dynactin, and both NuMA and dynactin display specific, steady-state binding at minus-ends. NuMA localization to minus-ends requires a C-terminal region outside NuMA’s canonical microtubule binding domain, and it is independent of direct minus-end binders gamma-TuRC, CAMSAP1, and KANSL1/3. Both NuMA’s minus-end-binding and dynein-dynactin-binding modules are required to rescue focused, bipolar spindle organization. Thus, NuMA may serve as a mitosis-specific minus-end cargo adaptor, targeting dynein activity to minus-ends to cluster spindle microtubules into poles.

Sensing of the Magnitude of Centromeric Tension at Metaphase Elicits a Graded Cellular Response.

S. Mukherjee\textsuperscript{1}, D. Tank\textsuperscript{1}, Q. Yang\textsuperscript{1}, M.K. Gardner\textsuperscript{1};
\textsuperscript{1}Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN

During mitosis, motors associate with microtubules to exert forces that push spindle poles apart, thus establishing a mitotic spindle. These pushing forces in turn cause tension in the chromatin that connects oppositely attached sister chromatids. This tension has been hypothesized to act as a mechanical signal that allows the cell to detect chromosome attachment errors during mitosis. However, the magnitude of any changes in tension that could be detected by the cell to initiate an error correction response during mitosis have not been measured, and so the underlying mechanics of a tension-based error detection pathway remains unknown. In this study, we generated and measured a gradient in tension over multiple isogenic budding yeast cell lines by genetically altering the magnitude of motor-based spindle forces. This allowed us, for the first time, to quantitatively elucidate the mechanics of a tension-based error detection pathway in mitosis. We found that a decreasing gradient in tension led to an exponentially increasing gradient in rates of kinetochore detachment and anaphase chromosome mis-segregation, with a corresponding gradient in metaphase times. Further, these tension-based cellular response gradients were abrogated in the absence of key error-correction pathway proteins. We conclude that the cell is exquisitely tuned to the magnitude of tension as a signal to detect potential chromosome segregation errors during mitosis.

Mechanical maturation of the mammalian centromere regulates force signaling at metaphase.
L.A. Harasymiw1,2, D. Tank1, M. McClellan1, N. Panigrahy1, M.K. Gardner1;  
1Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN,  
2Medical Scientist Training Program, University of Minnesota, Minneapolis, MN

During mitosis, the centromere acts as a dynamic linkage between sister chromatids and can be stretched in a spring-like fashion by mitotic spindle forces. This mechanical action generates spatial spreading between the sister chromatids and, correspondingly, force across the sister-centromeres. Importantly, centromere force acts as a mechanical signal during mitosis that contributes to proper chromosome segregation. However, the contribution of chromosome mechanical properties to mitotic force signaling in mammalian cells remains unknown. Further, these mechanics have yet to be quantitatively characterized in unperturbed, mammalian cells undergoing cell division. In this work, we combined quantitative, biophysical microscopy with computational analysis in order to elucidate the mechanical properties of the centromere during mitosis in mammalian cells. We find that the mechanical properties of the human centromere evolve during mitotic progression following a distinct and reproducible pattern, a process which we refer to as “centromere mechanical maturation”. Importantly, our findings suggest that this mechanical maturation leads to amplified force signaling at the centromere, specifically during metaphase. Strikingly, while we found that centromere mechanical maturation was conserved in a non-primate mammalian species, it was altered in four different cancer cell lines. Centromere mechanical maturation was also impaired in a dose-dependent manner by aneuploidy. These results provide new insights into the mechanical properties of the mammalian centromere during mitosis, their impact on force signaling during mitotic progression, and their relationship with genome stability.

Microtubule destabilizing activity of selfish centromeres drives non-Mendelian segregation.
T. Akera1, E. Trimm1, M.A. Lampson1;  
1Department of Biology, University of Pennsylvania, Philadelphia, PA

One of the very few “laws” in biology is Mendel’s Law of Segregation, which states that each allele has an equal chance to transmit to the gametes. However, it is increasingly clear that this law can be violated by selfish genetic elements, which manipulate the production of gametes to increase their own rate of transmission. This genetic cheating in meiosis, meiotic drive, potentially occurs whenever haploid gametes are produced from diploid parents. In female meiosis, selfish elements drive by preferentially segregating to the egg. Our previous results in a mouse model show that selfish centromeres have higher levels of inner and outer kinetochore proteins compared to centromeres of the homologous chromosomes, and that drive of these selfish centromeres depends on asymmetric microtubule (MT) tyrosination within the spindle. These findings raise the question of how selfish centromeres interact with the asymmetric spindle to bias their orientation towards the egg side. Here we show that selfish centromeres preferentially destabilize interactions with MTs on the cortical side of the spindle, thus promoting re-orientation from the cortical side to the egg side. Several lines of evidence support this conclusion. First, we observe re-orientation events initiating with selfish centromeres losing MT attachments. Second, selfish centromeres have higher levels of MT destabilizing factors, including the depolymerizing kinesin-13 MCAK and Aurora B kinase, compared to their homologous partners,
suggestions that they drive the re-orientation process. Third, tyrosinated MTs enriched on the cortical side of the spindle are less stable, which gives directionality to the re-orientation. Fourth, selfish centromeres frequently lose cold-stable MT attachments only when facing the cortical side. Together, these findings provide the first mechanistic insights into how selfish elements exploit meiotic spindle asymmetry to bias their transmission.

*Determining the molecular requirements for taxol-induced spindle multipolarity.*

C.M. Scribano, J. Wan, B.A. Weaver;

1Cell and Regenerative Biology, University of Wisconsin, Madison, WI, 2Molecular and Cellular Pharmacology Training Program, University of Wisconsin, Madison, WI, 3Physiology Training Program, University of Wisconsin, Madison, WI, 4Oncology, University of Wisconsin, Madison, WI

Recently we measured the intratumoral taxol concentration in breast cancer patients and showed that clinically relevant (low nanomolar) concentrations of taxol cause multipolar divisions rather than mitotic arrest. We have now extended this to demonstrate that low nanomolar concentrations of other microtubule poisons (including docetaxel, epothilone b, ixabepilone, vinblastine, vinorelbine, and eribulin) also induce multipolarity in breast cancer cells, suggesting that multipolar mitotic divisions may be a common mechanism of cytotoxicity for this class of drugs. Importantly, supernumerary centrosomes are not required for microtubule poison-induced multipolar spindles. To gain mechanistic insight into the formation of taxol-induced multipolar spindles, a variety of mitotic regulators were tested for their ability to affect spindle multipolarity in breast cancer cells treated with clinically relevant concentrations of taxol. Our results demonstrate that the mitotic kinesin Eg5 and the kinase Plk1 promote both the formation and the maintenance of taxol-induced spindle multipolarity, while the mitotic kinesin CENP-E and the kinase Mps1 do not. Interestingly, we found that decreasing the time to anaphase onset decreases the number of multipolar divisions in taxol, resulting in reduced cytotoxicity. Previous studies have shown that Mps1 inhibition sensitizes cells to taxol, and this combination therapy has entered clinical trials (NCT02138812 and NCT02366949). However, our evidence suggests that Mps1 inhibition reduces the efficacy of taxol as a result of decreased time to anaphase onset and fewer multipolar divisions. Additionally, our results suggest that inhibitors of spindle pole clustering increase the number of taxol-induced multipolar divisions and therefore have the potential to increase its efficacy. Identification of the cellular requirements for multipolarity induced by taxol, and of agents that increase execution of the metaphase-to-anaphase transition in the presence of multipolar spindles, may improve the clinical utility of taxol and other microtubule poisons.

*The Role of Actin-Microtubule Crosslinker Shortstop in Cell Division.*

E.B. Dewey, C.A. Johnston;

1Biology, University of New Mexico, Albuquerque, NM

Properly executed cell division is crucial to development, maintenance, and longevity of multicellular organisms. Defects in both symmetric and asymmetric divisions can lead to improper developmental patterning, as well as genomic instability, disruption of tissue homeostasis, and cancer. Our research focuses on understanding how regulators of the actin and microtubule (MT) cellular cytoskeleton communicate to orchestrate the orientation and stability of the mitotic spindle, a critical component to
proper cell division and key to maintaining tissue homeostasis. Shortstop (Shot) is a member of the spectraplakin protein family found previously to crosslink actin and microtubule filaments, playing a vital role in stabilizing interphase microtubules in both Drosophila and human cell models. We describe a role for Shot in oriented cell divisions, with both tissue culture and in vivo Drosophila epithelial models showing spindle misalignment in Shot knockdowns (KDs). Further, we show a role for Shot in spindle assembly in these contexts, demonstrating that spindles do not contain tightly focused poles. Shot KDs also produce defects in chromosomal migration to spindle equator (congression) and chromosomal segregation. We show these activities are mediated not only through traditional Shot roles in stabilization of spindle MTs through crosslinks to actin, but also through a direct interaction of Shot actin binding domain to dynein activator subunit actin-related protein 1 (Arp1) filaments. In line with this hypothesis, only the Shot isoform possessing both MT and actin binding activities is capable of rescue of Shot KD phenotypes. We hypothesize Shot interaction with Arp1 functions to crosslink it to spindle MTs, facilitating activation and stabilization of the MT motor protein Dynein, and promoting its activity in spindle assembly, alignment, chromosomal congression, and chromosomal segregation. In support of this model, live cell imaging experiments show defects in cell division timing under Shot conditions. These timing faults implicate involvement of the spindle assembly checkpoint (SAC), with inhibition of SAC components under Shot KD conditions leading to timing rescue. Further, Shot loss in epithelial tissue in vivo leads to an increase in apoptosis, in line with previous findings linking spindle regulators to cell death. Interestingly however, while previous studies have implicated induction of the Jun kinase (Jnk) apoptotic pathway under spindle regulator KD, Shot apoptosis does not implicate Jnk in this activity. Finally, when Shot KD-induced apoptosis is inhibited, tumorigenic-like conditions result, underscoring the importance of Shot as a key component in development and maintenance of multicellular organisms.

**Most kinetochore fibers in human cells form via mechanisms intrinsic to the kinetochores and not by capture of astral microtubules.**

V. Sikirzytyski¹, F. Renda³, I. Tikhonenko⁷, B.F. McEwen¹, A. Khodjakov¹;

¹Transnational Medicine, Wadsworth Center, Albany, NY

The basic principle of mitotic spindle assembly is known as ‘search and capture’ (S&C). In the classic formulation of S&C hypothesis, plus ends of ‘astral’ MTs (MTs) that emanate from the centrosomes (spindle poles) are captured by the kinetochores that reside at the chromosome’s centromere. Repetitive captures lead to formation of MT bundles, termed ‘K-fibers’, that connect kinetochores with spindle poles. Live-cell microscopy proves that direct capture of astral MT by kinetochores does occur occasionally, which supports the S&C hypothesis. However, an alternative mechanism for K-fiber formation has also been observed. In this mechanism, MT bundles grow outwards from the kinetochores. Minus ends of these growing fibers are eventually captured by astral MTs and transported to the spindle poles by dynein. We seek to establish which of these alternative mechanisms dominates mitotic spindle assembly in human cells. Array tomography (fluorescence collected from serial 70-nm sections of the entire cell) reconstructions of the MT density in early prometaphase Rpe1 cells demonstrate that the density of MTs near kinetochores is higher than in those parts of the spindle where kinetochores are absent. This observation suggests that a significant number of MTs form directly at the kinetochores. Correlative light/electron microscopy analyses reveal that <2 min after nuclear envelope breakdown >75% of kinetochores are already in contact with 25-30 MTs residing <250 nm from the kinetochore. These MTs appear to emanate from the kinetochore’s outer plate and they tend
to orient orthogonally to the plate as expected for end-on attachment. Thus, shortly after NEB nascent K-fibers are already present at most kinetochores. Interestingly, we find no correlation between the presence or the number of MTs within the nascent K-fiber and the amount of the checkpoint protein Mad2 at the kinetochore. Further, inhibition of Aurora B activity does not affect the number or orientation of the MTs present at the early prometaphase kinetochores. In contrast, inhibition of the kinesin CenpE known to reside at the kinetochore increases the number of MTs at the kinetochores by ~25% and changes the MT orientation. Upon CenpE inhibition, MTs orient randomly to the outer plate with both their ends residing outside of the kinetochore. Further, live-cell recordings demonstrate that inhibition of CenpE alters the pattern of chromosome movements during early prometaphase. Together, our results suggest that most kinetochores attach to short MTs that are nucleated in their spatial proximity. Motor activity of CenpE brings the plus ends of these initially disoriented MTs into the kinetochore, converting lateral interactions into end-on attachment to a K-fiber with the appropriate MT polarity.

Physical Confinement Impairs Chromosome Segregation during Cell Division.
X. Wan†, K. Konstantopoulos†;
†Chemical Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Microenvironment plays critical roles in many biological processes including development and cancer metastasis. Physical confinement from the local microenvironment is considered to influence the tissue development. Studies have also shown that physical confinement can alter the migration of tumor cells. Examination of cellular dynamics in 3D confined microenvironments has far-reaching implications in regenerative medicine, drug efficacy and toxicity assays, and cancer treatment. In vivo studies suggested that intravascular tumor cell division is confined by the vascular wall. Such confined division may be linked to cancer metastasis. But exactly how physical confinement affects the progress of cell division is largely unknown. Currently cell division studies have been mostly conducted on flat surfaces that pose little to no confinement to the cells. Such flat surfaces do not accurately replicate the physiological environment in which cells grow and spread. By using nanotechnology, we have engineered microchannel devices to simulate the confined microenvironment. With these novel microchannel devices, we can study cell division in varying levels of confinement that more accurately represent physiological spaces. Our study from the microchannel devices shows that physical confinement causes delay and arrest in mitosis and such effects become more pronounced as the dimensions of microchannel decrease. Abnormal mitotic spindle also occurs in microchannel. Our study further shows that physical confinement can introduce aneuploidy. This result provides a new mechanism on the origin of chromosomal instability. The novel findings implicate that the mechanisms of cell division are different in confined microenvironment compared to unconfined condition.

Regulation of microtubule crosslinks during spindle assembly.
A. Ismael†, J.E. Aiken†, J.K. Moore†;
†Cell Developmental Biology, University of Colorado, Anschutz Medical Campus, Aurora, CO

Mitotic spindle assembly is a dynamic process where side-by-side microtubule organizing centers (MTOCs) are driven into a stable, bipolar configuration; a process necessary for proper partitioning of
duplicated chromosomes during cell division. This dramatic rearrangement requires that dynamic microtubules (MTs) from opposing MTOCs interact and form antiparallel crosslinks. MTs are organized in the spindle by Ase1/PRC1, which acts as a homodimer to crosslink antiparallel MTs and stabilize the bipolar configuration. How the crosslinking activity of Ase1/PRC1 is regulated to achieve these states of spindle assembly is not well understood. Here we test the hypothesis that regulation is achieved through Ase1/PRC1 interactions with the MT surface. MTs are made of αβ-tubulin heterodimers, which contain a highly conserved globular structure, and disordered carboxy-terminal tail (CTT) domains that decorate the surface of the MT. CTTs exhibit sequence variation across species and across tubulin isotypes within a species. In higher eukaryotes, the CTTs are hotspots for post-translational modifications, and are thought to regulate interactions with MT associating proteins at the surface of the MT. The Ase1/PRC1 binding site sits at the junction between the αβ-tubulin heterodimer, where the β-tubulin tail resides. Here we show that the β-tubulin CTT is important for proper regulation of Ase1 binding and spindle assembly dynamics. Mutants lacking the β-tubulin tail have increased Ase1 spindle MT localization, delays in spindle assembly, and short bipolar spindles. Furthermore, moving the β-tubulin tail to α-tubulin is not sufficient to rescue the delay in spindle assembly or the short bipolar spindles. Despite the increased recruitment of Ase1, β-tubulin mutants have disorganized, short bipolar spindles with fewer crosslinked antiparallel MTs. Taken together, these results suggest that the β-tubulin tail regulates Ase1 recruitment to spindle MTs to promote proper crosslinking during spindle assembly.

Minimal ingredients for coupled spindle assembly and chromosome bi-orientation in a computational model of fission yeast mitosis.
C. Edelmaier1, A. Lamson1, Z.R. Gergely2, J.R. McIntosh2, M.A. Glaser1, M.D. Betterton1,2;
1Physics, University of Colorado Boulder, Boulder, CO, 2MCDB, University of Colorado Boulder, Boulder, CO

Mitosis ensures the proper segregation of chromosomes into daughter cells, which is accomplished by the mitotic spindle. During fission-yeast mitosis, chromosomes establish bi-orientation as the bipolar spindle assembles, meaning that sister kinetochores become attached to microtubules whose growth was initiated by sister poles. This process must also correct erroneous attachments made by the kinetochores during the attachment process. Our goal is to build a 3D computational model of spindle assembly based on a realistic description of microtubule, kinetochore, and chromosome dynamics, in order to interrogate the role of specific mechanisms in these chromosome bi-orientation and error correction processes. We have added chromosomes to our previous computational model of spindle assembly [1], which included microtubules, a spherical nuclear envelope, motor proteins, crosslinking proteins, and spindle pole bodies (centrosomes). In the new model, each chromosome is represented by a pair of sister chromatids, and sister kinetochores are represented as chromatid-associated discs. In preliminary work, we have explored the mechanical properties of kinetochores and their interactions with microtubules that achieve amphitelic spindle attachments at high frequency. A plausible set of minimal assumptions yields simulations that generate chromosome attachment errors, but resolve them, much as normal chromosomes do.

Mechanisms of spindle assembly and scaling across Pipid frogs.
K. Miller1, R. Heald1;
1Molecular and Cell Biology, UC Berkeley, Berkeley, CA

The molecular mechanisms by which the mitotic spindle scales in size, as well as how it adapts its morphology to a wide range of genome sizes across different cell types and organisms, is poorly understood. In recent years, our laboratory has utilized two model frog species, the larger Xenopus laevis and the smaller Xenopus tropicalis, which have correspondingly larger and smaller cells, organelles, and genomes, to identify spindle scaling factors. However, it remains unclear whether these mechanisms are conserved across different species, or whether novel ones exist. To this end, we have developed an egg extract system using the tiny related Pipid frog Hymenochirus Boettgeri which recapitulates spindle assembly in vitro and enables identification and functional testing of potential scaling factors. Interestingly, mixing egg extracts of X. laevis with those from H. boettgeri results in spindles of intermediate size in a dose-dependent manner, as it does for mixing extracts of X. laevis and X. tropicalis, indicating that cytoplasmic factors are responsible for regulating spindle size. However, although spindles formed in H. boettgeri extracts are statistically similar in length to those of X. tropicalis, mechanisms of spindle scaling appear to be different. Unlike X. tropicalis, H. boettgeri egg extracts have low microtubule severing activity and spindle microtubules recruit reduced amounts of previously identified scaling factors, such as TPX2 and Eg5. Interestingly, the microtubule depolymerizing kinesin Kif2a is enriched on H. boettgeri egg extract spindles compared to those in Xenopus, highlighting a novel mechanism for spindle scaling across species. Additionally, we are starting to examine mechanisms of spindle scaling in response to very large genome size using the rare dodecaploid frog Xenopus longipes.

The Effects of Microtubule Length, Dynamics and Bundling on Spindle Assembly.
Z.R. Gergely1,2, P.J. Flynn1, C. Edelmaier1, N. Santander1, J.R. McIntosh1, M.D. Betterton1;
1Department of Physics, University of Colorado at Boulder, Boulder, CO, 2Department of MCD Biology, University of Colorado at Boulder, Boulder, CO

The features of mitotic microtubules important for mitotic spindle assembly are not fully known, and descriptive parameters have proved challenging to measure directly. We are studying the dynamic instability of single and bundled mitotic microtubules (MTs) that originate from the spindle pole bodies of fission yeasts. We have labeled cellular MTs with an m-Cherry-α-tubulin chimera expressed at low levels to perturb MT dynamics as little as possible while viewing polymer dynamics with a spinning disk confocal microscope equipped with a sensitive camera. Using a temperature sensitive kinesin-5 allele (cut7-24) at restrictive temperature (37°C), in which bipolar spindle assembly is blocked, we observe monopolar spindles whose dynamic MTs can be imaged directly. This persistent monopolar spindle allows the measurement of growth, shrinkage, catastrophe, and rescue rates for both single and bundled MTs. For comparison we have made monopolar spindles with various average lengths: 2-3 times longer and more bundled MTs in a klp6 (Kinesin-8) deletion mutant, and significantly shorter MTs in an alp14 (XMAP215) deletion mutant. We have also made monopolar spindles with less bundling using a cls1 (CLASP) temperature sensitive mutant and an ase1 (Prc1) deletion mutant. We detect
image features, track fluorescent MTs, and compare MT dynamics and bundling, using four-dimensional data from each of these strains, observing the effects of each mutation on spindle assembly. To quantify relevant parameters, we have written software to automate detection and measurement of single MT and spindle dynamics as well as their changes over time in both monopolar and bipolar spindles, and in the transition from one spindle form to the other. We find that the highly bundled MTs do not play a role in the establishment of an initial bipolar spindle, while short, unbundled and highly dynamic MTs readily form an initial bipolar spindle despite the temperature block. To quantify the rate of tubulin turnover in this system, we have examined the rates of fluorescence redistribution after photobleaching (FRAP) on monopolar and bipolar spindles in which we quantify the substitution of unbleached tubulin dimers for bleached ones.

Adaptor binding sites in the clathrin terminal domain directly recruit the microtubule stabilizing protein GTSE1 to the mitotic spindle.
Y. Lin1, A. Rondelet1, P. Brinkert1, A.W. Bird1;
1mechanistic cell biology, Max Planck Institute of Molecular Physiology, Dortmund, Germany

The precise regulation of microtubule dynamics and stability ensures accurate chromosome segregation during cell division. Clathrin has recently emerged as an unexpected player controlling mitotic microtubule stability. Clathrin heavy chain (CHC) interacts with TACC3 in mitosis to form a complex that binds to microtubules and localizes to spindles. The CHC-TACC3 complex is important for microtubule stability and chromosome alignment, but the mechanisms by which this complex affects microtubules stability are still being unraveled. We previously identified GTSE1 as a novel microtubule-stabilizing protein that inhibits MCAK activity during mitosis. How GTSE1 is recruited to spindles for this function has remained unclear. Here we show that GTSE1 is recruited to the spindle via direct interaction with CHC, analogous to clathrin-adaptor protein interactions that recruit clathrin to sites of endocytosis. Either mutating conserved adaptor-interaction sites in the CHC N-terminal domain (NTD), or inhibiting interactions with the CHC clathrin-box binding site via the Pitstop-2 compound, dramatically reduce the interaction with GTSE1 in vitro. We also identified multiple LID (Leu-Ile-Asp) motifs in GTSE1, which are putative binding-sequences of the CHC NTD. Mutation of these motifs abolishes GTSE1 interaction with CHC both in vitro and in cells, and delocalizes GTSE1 from spindles, leading to mitotic defects. Thus, one mechanism by which the CHC-TACC3 complex promotes MT stability in mitosis is by directly recruiting GTSE1 to inhibit MCAK.

Clathrin promotes mitotic spindle assembly via interaction with the microtubule depolymerase inhibitor GTSE1.
A. Rondelet1, Y. Lin1, S. Bendre1, P. Brinkert1, N. Schmidt1, A.W. Bird1;
1Mechanistic cell biology, Max Planck Institute of Molecular Physiology, Dortmund, Germany

Genome integrity relies on the faithful segregation of chromosomes, a process driven by the dynamic microtubules of the mitotic spindle. Clathrin, a major component of the endocytosis machinery in interphase, locates to the spindle in mitosis and promotes both spindle assembly and chromosome alignment. Clathrin is recruited to the spindle via its interaction with TACC3, and the clathrin-TACC3 complex contributes to an inter-microtubule “mesh” that bridges microtubules together. The clathrin
heavy chain amino-terminal beta propeller is an interaction-hub for clathrin adaptor proteins that regulate clathrin functions in interphase. Interfering with the function of the clathrin beta-propeller in mitosis, either chemically or by mutagenesis, induces strong mitotic defects despite clathrin retaining its ability to interact with TACC3 and thereby localising to the spindle. It is therefore likely that clathrin also promotes timely mitosis independently of its bridging function. Here, we show that GTSE1, a protein that stabilizes mitotic microtubules by inhibiting the microtubule-depolymerase MCAK, associates with the clathrin-TACC3 complex in mitosis. In vitro analysis of the GTSE1-clathrin interaction (Lin Y.-C. et al. poster abstract) identified the binding site of GTSE1 on the clathrin heavy chain N-terminal beta propeller and the corresponding clathrin-binding motifs on GTSE1. GTSE1 mutated at the clathrin-binding motifs failed to bind to the clathrin-TACC3 complex and localize to the spindle, resulting in a strong mitotic delay due to a chromosome congression defect. Depleting MCAK in the mutant background restored a timely mitosis, suggesting that the observed mitotic delay results from excessive depolymerisation of spindle microtubules by MCAK. Consistent with this idea, we observed mitotic microtubule stability defects and aberrant spindle morphology in the GTSE1 mutant. We thus propose that the clathrin-TACC3 complex not only bridges microtubules but also promotes microtubule stability by recruiting GTSE1, an inhibitor of the microtubule depolymerase MCAK. Interestingly, both GTSE1 and the binding site for clathrin on TACC proteins are conserved only in vertebrates, raising the possibility that the mitotic function of clathrin may only be observed in vertebrates and might be substantially linked to GTSE1.

Studies have implicated the halogenated flame retardants TDCPP, TDBPP, HBCDD, and TBBPA as potential male reproductive toxicants; however, these flame retardants have not been assessed for their direct effects on human spermatogenesis. We have previously shown that our human stem cell-based *in vitro* model of spermatogenesis recapitulates human exposure phenotypes to known reproductive toxicants. We utilized this innovative human model to evaluate the effects of the flame retardants TDCPP, TDBPP, HBCDD, and TBBPA on spermatogenic cell lineages under acute conditions. Using flow cytometry to analyze markers of apoptosis, mitochondrial membrane potential, reactive oxygen species generation, cell cycle progression, and haploid cell production as well as high-content imaging of the spermatogenic markers PLZF and HILI, we showed that TDCPP, TDBPP, HBCDD, and TBBPA are human male reproductive toxicants *in vitro*. While not specifically impacting the survival of haploid spermatids, these toxicants affect viability of spermatagonia and primary spermatocytes during *in vitro* spermatogenesis through mitochondrial membrane potential perturbation, ROS generation, and by disrupting the cell cycle. Taken together, these results show that TDCPP, TDBPP, HBCDD, and TBBPA
all affect human spermatogenesis and highlight the need for increased surveillance of these chemicals in the human population.

Regulation of cell cycle progression by cell-cell and cell-matrix forces.
M. Uroz¹, S. Wistorf¹, X. Serra-Picamal¹, V. Conte¹, M. Sales-Pardo², P. Roca-Cusachs¹, R. Guimera², X. Trepat¹,²,³,⁴,⁵;
¹Institute for Bioengineering of Catalonia (IBEC), Barcelona, Spain, ²Departament d’Enginyeria Química, Universitat Rovira i Virgili, Tarragona, Spain, ³Unitat de Biofísica i Bioenginyeria, Facultat de Medicina, Universitat de Barcelona, Barcelona, Spain, ⁴Institució Catalana de Recerca i Estudis Avançats , Barcelona, Spain, ⁵Center for Networked Biomedical Research on Bioengineering, Biomaterials and Nanomedicine, CIBER-BBN, Barcelona, Spain

It has long been proposed that the cell cycle is regulated by physical forces at the cell-cell and cell-extracellular matrix (ECM) interfaces. The evolution of these forces during the cycle has never been measured, however, and whether this evolution impacts cell cycle progression is unknown. We quantified cell-cell tension and cell-ECM traction throughout the complete cycle of a large cell population in a growing epithelium. These measurements unveil temporal mechanical patterns that span the entire cell cycle and regulate its duration, the G1-S transition, and mitotic rounding. We show that cells subjected to higher intercellular tension exhibit a higher probability to transition from G1 to S, as well as shorter G1 and S-G2-M phases. Moreover, we show that tension and surface energy are better predictors for the duration of G1 than any geometric property, including cell and nuclear area and their growth rates. Tension increases smoothly during the cell cycle but decreases three hours before mitosis. Using optogenetic control of contractility, we show that this tension drop favors mitotic rounding. Finally, we show that traction forces peak during mitosis due to the protrusion of neighboring cells under the dividing cell. Together, our results establish that cell cycle progression in a monolayer is regulated cooperatively by forces between the dividing cell and its neighbors.

Temperature-induced uncoupling of cell cycle regulatory mechanisms.
H. Falahati¹, S. Di Talia², E. Wieschaus³;
¹Quantitative and Computational Biology, Princeton University, Princeton, NJ, ²Cell Biology, Duke University, Durham, NC, ³Molecular Biology, HHMI/Princeton University, Princeton, NJ

Cell cycle progresses through a specific sequence of events, the timely order of which is pivotal to successful mitosis. Several regulatory mechanisms are in place to ensure that cell cycle events follow the right sequence. The main regulator of cell cycle is cyclin-dependent kinase 1 (CDK1), the activity of which drives entry into mitosis. In addition, other kinases such as Aurora’s and Polo-like kinases also regulate specific mitotic events. However, the overlapping function of these kinases does not allow us to determine how the exact sequence of cell cycle events are reached. We utilized a temperature-based approach to disentangle the regulatory mechanisms that control different steps of the cell cycle. If different steps of the cell cycle are controlled by distinct regulatory mechanisms, changing temperature will likely uncouple them, as such distinct processes will scale differently with temperature. We used a microfluidic device to control the temperature in the minimal cycles of Drosophila syncytial blastoderm, and employed biosensors of cell cycle regulators to monitor their activity in the living embryos. Using
this assay, we are able to show that an increase in CDK1 activity is necessary for entry into prometaphase, but not prophase. Aurora B drives entry into prophase in a CDK1-independent manner.

Elucidating the Role of Securin in Regulating Separse during Cortical Granule Exocytosis.  
C. Turpin1, J.N. Bembenek1;  
1BCMB, University of Tennessee-Knoxville, Knoxville, TN

Meiosis involves a tightly regulated series of events leading to the production of haploid gametes. A key player during meiosis is the cysteine protease separase (SEP-1), which is well known for its canonical role in chromosome segregation. SEP-1 has an additional function during anaphase to promote cortical granule exocytosis, which blocks polyspermy. SEP-1 localizes to cortical granules and regulates their exocytosis during anaphase I. Before it appears on cortical granules, SEP-1 localizes to poorly characterized cytosolic filaments with other kinetochore proteins. We hypothesize that the cell cycle machinery known to control SEP-1 during chromosome segregation also controls its localization and function during exocytosis. Following chromosome alignment during metaphase, proper attachment of microtubules to kinetochores inactivates a signaling pathway known as the spindle assembly checkpoint, which allows cell cycle progression. This involves activation of the anaphase promoting complex/cyclosome (APC/C) to promote entry into anaphase I by targeting the SEP-1 inhibitory chaperone, securin (IFY-1), for degradation. We have shown that SEP-1 colocalizes with IFY-1 on filaments beginning in prometaphase, and both disassociate from these structures after the onset of anaphase I. Inhibition of APC/C activity prevents SEP-1 and IFY-1 from leaving the filaments and inhibits cortical granule exocytosis. Depletion of IFY-1 allows SEP-1 to localize to cortical granules, but prevents their exocytosis. This suggests that APC/C degradation of IFY-1 may regulate timely localization and proper activity of SEP-1 at vesicles. To further address this, we generated a non-degradable IFY-1 (IFY-1DM::GFP). Consistent with enhanced IFY-1 stability, IFY-1DM::GFP is not degraded following anaphase I onset, persisting on chromosomes and in the cytoplasm. As expected, expression of IFY-1DM::GFP causes embryonic lethality. IFY-1DM::GFP localizes to filaments normally and, in contrast to wild-type, can be observed on vesicle-like structures at the cortex during anaphase I. Interestingly, IFY-1DM::GFP causes polar body extrusion failure, which could be related to defects in cortical granule exocytosis. In the future we will investigate whether IFY-1DM::GFP affects SEP-1 localization to cortical granules. This will provide insight into how key regulatory components of the cell cycle control SEP-1 localization and activity to promote timely cortical granule exocytosis during anaphase I.

Spatiotemporal characterization of the human proteome.  
D. Mahdessian1, D.P. Sullivan1, F. Danielsson1, C. Gnann1, R. Schutten1, M. Uhlén1, E. Lundberg1;  
1Affinity Proteomics, Science for life laboratory (KTH), Stockholm, Sweden

The Cell Atlas, a subgroup of the Human Protein Atlas HPA, focuses on localizing the human proteins on a subcellular level using immunofluorescence and confocal microscopy. Using the image collection in the Cell Atlas as a starting point, my research aims to characterize variability of protein expression at a single cell level, both in terms of abundance and spatial distribution. The aim of my research project is to investigate the cell-cycle dependency of the human proteome and quantify changes both in expression
levels and spatial distribution in non-perturbed asynchronous cells with single cell resolution, using affinity proteomics, microscopy and image analysis.

Cells derived from the same clonal population may display variability in protein expression patterns. This variability in protein expression is easily noted within immunofluorescence images and we denote it single cell variation (SCV). This project aims to identify the human proteins that show such a dynamic property both in terms of expression levels and spatial distribution. By re-analyzing all images in the Cell Atlas we have classified around 1,500, corresponding to 13% of all studied proteins, to display such variability. We hypothesize this variation to mainly be linked to parameters such as cell cycle position, stress and cell confluence. It is reasonable to expect a big fraction of these variations to be related to cell cycle progression, as cells are grown under asynchronous conditions. To investigate the correlation to cell cycle, the SCV classified proteins were stained in the U-2 OS FUCCI cell line. The FUCCI cells are tagged with two different fluorescent proteins fused to cell cycle regulators that allow cell cycle monitoring; Cdt1, expressed in G1 phase, and Geminin, expressed in S and G2 phases.

In this manner we could identify 600 proteins with expression variation correlated to cell cycle progression, corresponding to 44% of the tested proteins.

**Cell fate decision via p53 status in response to nucleoside analog-inducing DNA replication stress.**

M. limori¹, Y. Kataoka¹,², K. Matsuoka², E. Okis³, H. Saeki³, Y. Maehara³, H. Kitao¹; ¹Department of Molecular Cancer biology, Graduate School of Pharmaceutical Sciences, Kyushu University, Fukuoka, Japan, ²Drug Discovery and Development I, Taiho Pharmaceutical Co., Ltd., Tsukuba, Japan, ³Department of Surgery and Science, Kyushu University, Fukuoka, Japan

DNA replication stress is induced by divergent causes, such as replication fork retardation, its collapse, or DNA damages. We have reported that trifluridine (FTD), a tri-fluorinated thymidine analog, was incorporated into DNA, and exhibited S phase delay without DNA damages-including single- or double-strand breaks (Matsuoka et al. Mol Cancer Ther 2015). Here we show that, in vitro, FTD interrupts DNA synthesis by the replicative DNA polymerases, Pol and Pol, at different types of behavior, that is, the inefficient incorporation of FTD triphosphate (FTD-TP) into the nascent DNA strand and the inefficient DNA synthesis at repetitive FTD sequence in the template DNA strand. Furthermore, we found that FTD led to a dramatic decrease in cellular dTTP, which could act as a dominant competitor of incorporation of FTD-TP into DNA, and hence this phenomenon might be a cause of incorporation of FTD-TP, even though FTD interrupted DNA synthesis. Together, these data suggest that FTD is a DNA replication stress-inducible reagent through interrupting DNA polymerase progression by incorporating FTD per se into DNA. We found that treatment of HCT116 cells, which have wild-type p53, with FTD exhibited the phenotypes such as cyclin B1 degradation and mitosis skip, resulting in cell cycle arrest at G1 phase and induction of senescence-associated beta-galactosidase activity. In contrast, treatment of HCT116 p53 knock-out cells, generated using CRISPR/Cas9 genome editing system, with FTD did not exhibit these phenotypes. Conversely, such cells entered mitosis, resulting in a remarkable abnormality of chromosome segregation accompanying chromosome bridges during anaphase and subsequent apoptotic cell death. Our findings strongly suggest that FTD-induced DNA replication stress results in an induction of cellular senescence in p53 wild-type cells and marked chromosomal instability in p53 knock-out cells. We propose the critical role of p53 in the cell fate decision in response to DNA replication stress induced by FTD, that is, whether cells undergo cellular senescence or apoptotic cell death.

Phosphorylation regulates protein-RNA phase separation.
T.M. Gerbich¹, A.S. Gladfelter¹;
¹Biology, UNC-Chapel Hill, Chapel Hill, NC

How cells control the position, timing and lifetime of phase-separated compartments in cells is not understood. The RNA-binding protein Whi3 regulates (or contributes to) the cell cycle, cell polarity and stress responses in the multinucleate, filamentous fungus Ashbya gossypii. When Whi3 is deleted or mutated, the nuclear division cycle in the continuous cytoplasm becomes more synchronous, the cells have difficulty establishing and maintaining polarized growth, and the cells show heightened sensitivity to certain environmental stresses. Whi3 contributes to these disparate cell processes by its ability to form different complexes with distinct spatial localizations and mRNA targets. For example, CLN3 (a G1 cyclin) transcripts are heterogeneously positioned near nuclei in a Whi3-dependent manner. BNI1 (a formin) transcripts are positioned at growing tips and nascent polarity sites in a Whi3-dependent manner and colocalize with Puf2, a pumilio family protein that also binds BNI1 mRNA. Additionally, the Whi3 protein can undergo a liquid-liquid phase separation in the presence of target mRNAs in vitro. We are using this system where distinct Whi3 complexes coexist in a cell to address how, when and where specific identities are established for phase-separated compartments. We hypothesized that local post-translational regulation of Whi3 protein confers specificity to establish these distinct complexes and encodes their function. We found by mass spectrometry that certain sites on Whi3 are phosphorylated specifically in response to perturbations in the cell cycle or environmental stresses. Creating genetic backgrounds in which individual sites have been mutated to be phosphomimetic or unphosphorylatable has biological consequences for the Whi3 target pathways and where and when Whi3 forms phase-separated compartments. Understanding how post-translational modification can be used to regulate different aspects of phase separated complexes is an important part of understanding the physiological role and regulation of these compartments in all cells.

The p38 MAP kinase pathway promotes cell size uniformity by linking cell cycle progression to cell size.
S. Liu¹,², M.B. Ginzberg¹, N. Patel¹, M. Hild³, Z. Li⁴, J. Jenkins³, M.W. Kirschner⁵, R. Kafri¹,²;
¹Cell Biology, The Hospital for Sick Children, Toronto, ON, ²Department of Molecular Genetics, University of Toronto, Toronto, ON, ³Novartis Institutes for BioMedical Research, Cambridge, MA, ⁴Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI, ⁵Department of Systems Biology, Harvard Medical School, Boston, MA

Regularity in cell size is a characteristic feature of healthy tissues in multicellular organisms. We previously showed that mammalian cells autonomously correct deviations from target size on a cell-cycle-dependent manner. To date, the molecular mechanisms that control the regularity of cell size remain unidentified.

To investigate the signaling underlying size determination, we performed a drug screen searching for perturbations that disturb size regularity. Using fluorescent microscopy, each screen condition yields readout of a cell population with single-cell measurements of both cell size and cell cycle state. The data consistently identified a negative correlation between cell size and the fraction of G1 cells – suggesting
that small cells have a longer G1 – which we confirmed by live-cell imaging. This result suggests that animal cells regulate G1-length to buffer deviations in size, as has been previously suggested for yeast. To identify the pathways linking cell size to G1 length, we discriminated two types of compound hits. One: conditions that perturb either size or cell cycle but retain the coordination between the two, producing reciprocally correlated influences on cell size and G1 length (on-axis hits). Two: compounds that disproportionally affect size and cell cycle progression, falling off-axis to the negative correlation defined by the majority of screened conditions (off-axis hits). The off-axis hits may disrupt the coordination between cell size and G1 length.

Interestingly, mTOR pathway is enriched as the top scored targets for the on-axis compounds, suggesting that mTOR pathway functions to regulate cellular growth, but not the coordination between size and cell cycle. Supporting the conclusion, mTOR inhibition produces a significant decrease in cellular growth rate which is partially compensated by a prolonged cell cycle, limiting the effect on cell size. In contrast, the p38 pathway is highly enriched for the off-axis compounds, implicating its role in coordinating cell size and G1 progression. Additionally, we identified the p38 pathway significantly associated with increase in cell size variability, further suggesting its role in controlling size uniformity. Follow-up experiments with western blot and a p38 live-cell reporter have demonstrated that p38 activity upregulates in small-sized cells to retain the cells in G1 for a longer period of growth. Inhibition of p38 MAPKs, by either specific inhibitors or siRNA, leads to loss of the compensatory G1 length extension in small cells, resulting in faster proliferation, smaller cell size and increased size heterogeneity. Together, we propose a model wherein the p38 pathway responds to changes in cell size and regulates G1 exit accordingly, promoting cell size uniformity.

LKB1 links metabolic homeostasis to accurate chromosome segregation in mitosis.
Y. Huang¹, M. Wang¹, W. Wang¹, X. Liu¹, X. Yao¹;
¹Anhui Key Laboratory for Cellular Dynamics Chemical Biology, University of Science and Technology of China, Hefei, China

LKB1-MST4 kinase signaling plays an array of functional importance in cell fate determination. It has been shown that LKB1 exhibits a context dependent signaling in T cells to orchestrate metabolic and immunological homeostasis. Our recent studies show that MST4 cooperates with cAMP-dependent kinase to orchestrate polarized vesicular trafficking and exocytosis (Jiang et al., 2015. J. Biol. Chem. 290, 28272-85; Yuan et al., 2017. J. Biol. Chem.). However, the molecular mechanisms underlying metabolic homeostasis and accurate chromosome segregation were poorly understood. Here, we identified a novel LKB1 signaling axis independent of MST4 and AMPK which orchestrates metabolic homeostasis and accurate chromosome segregation during cell division. LKB1 activity is elicited at mitotic entry via a combination of CDK1 and metabolic homeostasis. Surprisingly, an activation of LKB1 activates SIRT1 via a phosphorylation-dependent conformational switch which promotes the deacetylation activity of SIRT1 and accurate segregation of chromosome in mitosis. Currently, we are measuring spatiotemporal gradient of LKB1 during chromosome segregation and assess how LKB1 dynamics is regulated during cell division cycle.

Deletion of Cul3 in the mouse mammary gland.
K. Schmidt¹, N. Rosa¹, C.M. Cummings¹;
¹Biology Program, Stockton University, Galloway, NJ

Many proteins are involved in the process of cell division. Precise control of mitotic factors is crucial for the proper regulation of cell division. A major means of regulating proteins, including those involved in cell division, is by ubiquitin-mediated protein degradation, where a specific protein is targeted for destruction. The small molecule, ubiquitin, is attached to a protein, marking it for destruction by the proteasome. In the process of ubiquitination, an E3 ligase is used to determine which substrate protein will be targeted. Cul3 is an E3 ligase which has been shown to target many different substrates for ubiquitination, by pairing up with different substrate adaptor proteins. One substrate of interest for Cul3 is cyclin E, which regulates the G1/S transition of the cell cycle. When cyclin E is overexpressed, cells remain for prolonged periods in S-phase and are unable to proceed through mitosis normally. Previous studies indicate that when there is decreased Cul3 activity, large amounts of cyclin E protein accumulate in the cell.

Some breast cancers and cell lines derived from breast cancers are shown to have overexpressed cyclin E. We hypothesized that this may be due to reduced Cul3 activity. Therefore, we created a conditional knock-out of Cul3 in the mouse mammary gland to assess the effects of reduced Cul3 expression in this tissue. In the absence of Cul3, we observed hyperplasia in the mammary tissue, an increase in BrdU staining, and alterations to cyclin E expression. We also detected abnormalities in development in mammary glands deficient for Cul3. We conclude that Cul3 may play a role in development of the mouse mammary gland, and that in its absence, misregulation of proteins involved in cell division ensues.

Protein kinase C delta drives HGF-induced proliferation of equine satellite cells.
A.M. Brandt¹, M. Gonzalez², S.E. Johnson¹;
¹Animal and Poultry Sciences, Virginia Tech, Blacksburg, VA

Horses are athletic creatures with the vast majority engaged in physical exercise at either the amateur or professional level. Despite a large proportion of exercise-related activities, little is known about equine satellite cells (eqSC), the resident skeletal muscle stem cell and a contributor to exercise adaptation. Satellite cells exist in a state of quiescence expressing the transcription factor Pax7, and reside between the basal lamina and sarcolemma of the myofiber. Exercise prompts SCs to become alert, enter the cell cycle, proliferate, and differentiate before fusing to the myofiber. The objective of this study was to determine the role hepatocyte growth factor (HGF), a growth factor expressed in equine skeletal muscle following exercise, plays in time to first division, proliferation, and differentiation of eqSC in vitro. Equine SCs were derived from the gluteal muscle of previously raced thoroughbred geldings (n > 4) by a novel isolation protocol resulting in exceptional myogenicity as confirmed by Pax7 and Myogenin immunocytocchemistry. To determine whether HGF accelerates the time to first division, fresh isolates of eqSC were incubated with varying doses of HGF and briefly pulsed with EdU to mark cells in S-phase of the cell cycle. Though time in culture increased the percentage of EdU+ cells, HGF did not promote EdU incorporation until 96 h following isolation. Hepatocyte growth factor is likely not accelerating entry into the cell cycle, but rather, serving as a mitogen at these later time points. In a
subsequent study, serially passaged eqSC were supplemented with HGF and proliferation rate was measured. HGF stimulated proliferation of eqSC in a dose-dependent manner. Using chemical inhibitors to intracellular kinases, it was discovered that PKC was involved in HGF-mediated mitosis. Specifically, RT-PCR identified PKC alpha, delta, and epsilon expression in eqSCs. Lipid-mediated siRNA knockdown was utilized to determine which of the identified isoforms promoted HGF-induced proliferation. Only knockdown of PKC delta abrogated HGF-induced proliferation. The same dose of HGF that promoted proliferation slightly reduced differentiation as determined by differentiation index. These results indicate that, following exhaustive exercise in horses, HGF likely serves to promote proliferation of eqSC that have already entered the cell cycle.

Proximity based proteomic screen identifies novel associations of the polo like kinase 1 (Plk1).
Y.A. Garcia¹, N. Filbert¹, W. Cohn¹, J. Whitelegge¹, J.Z. Torres¹;
¹Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA

Human cell division is a dynamic set of events that promotes accurate transmission of genetic material. This conserved and sequential process is time-dependent and rigorously verified. The mitotic spindle is a critical component of this process, which ensures the safe transmission of chromosomes from a mother cell to a daughter cell with high fidelity. Disruption of the mitotic spindle can lead to aneuploidy, an atypical chromosome number, which is one of the hallmarks of cancer that is proposed to drive tumorigenesis. The polo like kinase 1 (Plk1) is a master regulatory kinase with important roles in mitotic spindle assembly and chromosome segregation. To better understand the functions of Plk1 during cell division we employed a proximity-based association mapping approach that utilized biotinylation of Plk1 associated proteins followed by biochemical purification of biotinylated proteins and liquid chromatography tandem mass spectrometry (LC-MS/MS). Among the associated proteins, we identified proteins known to be involved in the cell cycle and novel associations such as a kinesin-like protein. To further validate the associations identified in the proteomic screen, we performed in vitro co-immunoprecipitations with in vitro transcribed and translated S35 labeled proteins. The co-IP’s confirmed the interaction between Plk1 and the Kinesin-like protein. We further demonstrated that this interaction occurs not only in mitosis, but also in interphase. Additionally, in vitro experiments indicated that Plk1 was able to phosphorylate the kinesin-like protein at several serine residues. Our current and future work includes mapping out the determinants needed for binding and/or phosphorylation that may be critical for this interaction and the significance of this interaction for cell division.

Details Matter: Noise and Model Structure Set the Relationship between Cell Size and Cell Cycle Timing.
F. Barber¹, P. Ho², A.W. Murray¹,³, A. Amir²;
¹Molecular and Cellular Biology, Harvard University, Cambridge, MA, ²School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, ³FAS Center for Systems Biology, Harvard University, Cambridge, MA

Organisms across all domains of life regulate the size of their cells. However, the means by which this is done is poorly understood. We study two abstracted "molecular" models for size regulation: inhibitor dilution and initiator accumulation. We apply the models to two settings: bacteria like *Escherichia coli,*
that grow fully before they set a division plane and divide into two equally sized cells, and cells that form a bud early in the cell division cycle, confine new growth to that bud, and divide at the connection between that bud and the mother cell, like the budding yeast *Saccharomyces cerevisiae*. In budding cells, delaying cell division until buds reach the same size as their mother leads to very weak size control, with average cell size and standard deviation of cell size increasing over time and saturating up to 100-fold higher than those values for cells that divide when the bud is still substantially smaller than its mother. In budding yeast, both inhibitor dilution or initiator accumulation models are consistent with the observation that the daughters of diploid cells add a constant volume before they divide. This "adder" behavior has also been observed in bacteria. We find that in bacteria an inhibitor dilution model produces adder correlations that are not robust to noise in the timing of DNA replication initiation or in the timing from initiation of DNA replication to cell division (the C+D period). In contrast, in bacteria an initiator accumulation model yields robust adder correlations in the regime where noise in the timing of DNA replication initiation is much greater than noise in the C+D period, as reported previously. In bacteria, division into two equally sized cells does not broaden the size distribution.

**Functional characterization of the ORFs YJR141W & YJL055W in Saccharomyces cerevisiae.**  
O. Rosenow\(^1\), C. Balfany\(^1\), S. Shields\(^1\);  
\(^1\)Biology, Gustavus Adolphus College, Saint Peter, MN

Although the sequence the genome of *Saccharomyces cerevisiae* (baker’s yeast) has been known for several decades, approximately 10% of the genes still have unknown functions for the gene ontology terms (GO terms) cellular component, molecular function and biological process. These uncharacterized open reading frames (ORFans) are the focus of the Yeast Gene ORFan project, which seeks to understand the function of these genes by utilizing bioinformatic methods to characterize previously unannotated stretches of genome. Two such examples of these ORFans are YJR141W (IPA1) and YJL055W (LOG1). IPA1 is an essential protein with an unknown function that contains a highly conserved HECT2 ubiquitin-conjugating domain and is predicted to be a E3 ubiquitin-protein ligase. Combined with transcriptional data, we hypothesized that IPA1 is a ubiquitin ligase involved in cell cycle regulation. Initial attempts to localize IPA1 within the cell via GFP-tagging were unsuccessful and current efforts are underway to identify specific substrates of IPA1 as well as the biological role of IPA1. LOG1 is a hypothesized to contribute to the degradation of mRNA via metabolism of purine and pyrimidine bases. Domain homology predicts that LOG1 to have cytokinin riboside 5'-monophosphate phosphoribohydrolase activity as well as places it in the pfam domain family 03641 which have conserved PGGXGTXXE motif presumed to be vital for enzymatic activity. Additionally, LOG1 is found to interact with several nuclear RNA-binding proteins and to localize within the nucleus and the cytosol. Initial localization studies found increased localization of LOG1 to the nucleus under nutrient limiting conditions. Currently functional assays are underway to characterize the conserved PGGXGTXXE motif found as well as phenotypic assays to determine the biological role of LOG1.
Tumor Suppressors and Regulation of Oncogenes

Is the Eicosanoid Producing Enzyme 12-Lipoxygenase (ALOX12) a Tumor Suppressor?
G.F. Gerlach, P. Niethammer; 1Cell Biology, Memorial Sloan Kettering Cancer Center, New York, NY

Epithelial barrier disruption causes inflammation, which if unchecked over time can cause malignant transformation. The pathways that link chronic epithelial barrier disruption to transformation remain largely unknown. Emerging evidence suggests arachidonic acid (AA) metabolites, collectively termed eicosanoids, may play a central role in this process. Cyclooxygenases convert AA into proliferative and trophic eicosanoids, the prostaglandins, which are mediators of tumorigenesis. Lipoxygenases, on the other hand, convert AA into pro- and anti-inflammatory eicosanoids, such as leukotrienes and lipoxins. One of the least studied, yet most highly expressed epidermal lipoxygenases, ALOX12B, is essential for epithelial barrier integrity throughout phyla. We hypothesize that this enzyme acts as a tumor-suppressor in two ways: first, through its known function in epithelial barrier maintenance, preventing epithelial inflammation. Second, by shunting AA away from the pro-tumorigenic prostaglandin metabolism. Intriguingly, ALOX12B is co-deleted with p53 in many human tumors. Thus, understanding its cancer-related functions is highly relevant. Transparent zebrafish larvae are especially well suited to test the role of eicosanoid-mediated epithelial barrier maintenance, inflammatory, and malignant transformation by live imaging. Here we show loss, by CRISPR gene editing and morpholino mediated knockdown, of zebrafish alox12, the functional ortholog of ALOX12B, generates hyperplastic lesions in zebrafish epithelium. This phenotype is associated with leukocyte infiltration, and up regulation of inflammatory genes, indicative of a tumor-promoting tissue microenvironment. Through live imaging and lipidomic analysis in zebrafish and cell culture models, we are dissecting the fundamental mechanisms of eicosanoid-induced epithelial barrier homeostasis, inflammation, and malignant transformation that may be exploited for therapeutic benefit in the future.

Tumor suppressive role of Sestrin2 during colitis and colon carcinogenesis.
S. Ro, X. Xue, Y.M. Shah, J. Lee; 1Biochemistry, University of Nebraska, Lincoln, NE, 2Molecular Integrative Physiology, University of Michigan, Ann Arbor, MI

The mTOR complex 1 (mTORC1) and endoplasmic reticulum (ER) stress pathways are critical regulators of intestinal inflammation and colon cancer growth. Sestrins are stress-inducible proteins, which suppress both mTORC1 and ER stress; however, the role of Sestrins in colon physiology and tumorigenesis has been elusive due to the lack of studies in human tissues or in appropriate animal models. In this study, we show that human SESN2 expression is elevated in the colon of ulcerative colitis patients but is lost upon p53 inactivation during colon carcinogenesis. In mouse colon, Sestrin2 was critical for limiting ER stress and promoting the recovery of epithelial cells after inflammatory injury. During colitis-promoted tumorigenesis, Sestrin2 was shown to be an important mediator of p53’s control over mTORC1 signaling and tumor cell growth. These results highlight Sestrin2 as a novel tumor suppressor, whose downregulation can accelerate both colitis and colon carcinogenesis.

PLK1-mediated RIP3 phosphorylation promotes G2/M abundance of RIP3.
K. Gupta¹, B. Liu¹;
¹Surgery, University of Wisconsin-- Madison, Madison, WI

RIP3-mediated necroptosis is a form of programmed cell-death that occurs when caspase 8 is absent or inhibited, promoting the formation of the RIP1-RIP3 complex, which causes MLKL phosphorylation and rupture of the plasma membrane. Since necroptosis does not share proteins with the apoptosis pathway, it has been proposed as an alternate way of eliminating cancer cells which frequently inactivate caspases. To systematically address the effect of mitotic poisons on necroptosis, we treated mouse fibrosarcoma cell line L929 with various commonly used DNA-damaging and cytoskeletal-inhibiting drugs and discovered that instead of enhancing cell-death, many of these drugs in fact reduced necroptosis via the reduction in the expression of RIP3. Although the tumor suppressor p53 is activated, the expression of RIP3 was found to be independent of p53. We asked whether this reduction was dependent on the DNA-damage signaling and cell-cycle changes and found that the regulation by either of these impinged on the cell-cycle protein Polo-like kinase 1, which is both necessary and sufficient for RIP3 expression. Mechanistically, we discover that RIP3 protein levels are dependent on the cell-cycle with lowest abundance in the G1 and S phases whereas high levels are present in the G2/M phase, which also relate with necrosome formation and necroptosis. Further, we observe that RIP3-levels are diminished in the G2/M phase upon inhibition of polo-like kinase 1, indicating that PLK1 could facilitate in stabilizing RIP3. Finally, we identify a conserved cluster of residues in the 366-380 amino acid region of mouse RIP3 that are putative PLK1 phosphorylation and SCF-dependent degradation sites. Our work describes a novel regulatory network where PLK1 ensures abundant levels of RIP3 in the G2/M-phase. Our ongoing work explores whether high G2/M levels of RIP3 are linked to the elimination of aneuploidy cells via mitotic-catastrophe.

Novel Biogenic Role for the Retinoblastoma Protein Rb.
R. Camicia¹, A.C. Lloyd¹;
¹MRC Laboratory for Molecular Cell Biology, UCL, London, United Kingdom

We have identified a novel role for the retinoblastoma protein Rb in regulating cell biogenesis. Whereas oncogenic Ras signaling is sufficient to drive weak and sustained growth via the canonical growth pathway, PI3K-AKT-TOR and is able to preserve the uptake of extracellular nutrients required for biogenesis, we find that loss of Rb acts via signaling pathways distinct from PI3K-AKT-TOR and via an E2F-independent mechanism to drive cell growth, but the mechanisms remain unknown (Collins et al., 2012). We have generated an inducible system to rapidly remove Rb family activity from primary Schwann cells. Using this model, we are investigating the early biosynthetic and degradative changes following Rb family loss. We find that the Rb family acts via a distinct mechanism from mTOR signaling to regulate ribosome biogenic pathways. Additionally we have found that regulation of Pol I transcription is exquisitely sensitive to growth signaling pathways. Understanding how ribosomal biogenesis is linked to cell growth controls and cancer development may result in novel therapeutics that selectively target the growth of tumour cells.

Loss of SPINT2 promotes YAP activation and tolerance to aneuploidy.
H. Zhang1, K. Kotynkova2, D. Pellman1,2,3, N.J. Ganem2,4,

Functional inactivation of the Hippo tumour suppressor pathway is common in solid tumours, yet mutations in key components of the pathway are rare. Consequently, the underlying mechanisms that disable Hippo signalling in cancer cells remain elusive. Using a functional loss-of-function RNAi screen, we identified the protein SPINT2 as a novel activator of the Hippo pathway. SPINT2 is a single-pass transmembrane protein that functions as an extracellular serine protease inhibitor. We used multiple approaches to demonstrate that depletion of SPINT2 silences the Hippo pathway and thus activates the oncogenic transcriptional co-factor YAP. Mechanistically, we found that depletion of SPINT2 increases activation of the protease-activated receptors PAR1 and PAR2, which are known to suppress Hippo signalling. By contrast, overexpression of SPINT2 limits PAR activation, activates the Hippo pathway, and restrains cell proliferation. SPINT2 is a putative tumour suppressor gene that is commonly epigenetically silenced in a broad range of tumours. Interestingly, we discovered that SPINT2 is also epigenetically silenced in several aneuploid, but not diploid, primary human cell lines. While aneuploidy is a hallmark of tumour cells, it paradoxically limits the proliferation of normal cells. Thus, we hypothesized that epigenetic silencing of SPINT2 may represent an adaptation employed by tumour cells to better tolerate aneuploidy. Supporting this hypothesis, we found that depletion of SPINT2 imparts chromosomally stable cells with an increased tolerance for aneuploidy. Collectively, our work has identified SPINT2 as a novel regulator of Hippo signalling, whose loss both activates YAP and promotes tolerance to aneuploidy, two features of cancer cells.

1Molecular Biology, Rowan University SOM, Stratford, NJ, 2Albert Einstein Medical School, Bronx, NY, 3Fox Chase Cancer Center, Philadelphia, PA

In response to oxidative stress, mitochondria undergo extensive fragmentation, exhibit outer membrane permeabilization (MOMP) and release pro-apoptotic factors. Although the mitochondrial fission machinery is required for stress-induced hyper-fission, the molecular switch that induces this process remains elusive. In response to oxidative stress, cyclin C translocates from the nucleus to the outer mitochondrial membrane where it activates the fission GTPase Drp1. Previous studies revealed that cyclin C is both necessary and sufficient to induce extensive mitochondrial fragmentation. Moreover, cyclin C is required for stress-induced Bax activation, MOMP and ensuing apoptosis. Extending these studies in vivo, we show that cyclin C suppresses hyperplasia and adenoma formation in PTEN thyroid and activated KRAS pancreatic tumor mouse models, respectively. These results indicate that cyclin C is a previously underscribed solid tumor suppressor that forms a bridge between the fission and apoptotic machinery. Given that mitochondrial fission is the first step in apoptosis, we tested whether forced
cyclin C cytoplasmic localization could sensitize cancer cells to conventional chemotherapeutics. To do this, we designed a stapled peptide mimic (S-HAD) that interferes with cyclin C binding to its nuclear anchor Med13. In the absence of additional stress, S-HAD induced cyclin C release, mitochondrial fragmentation and mitochondrial superoxide production. Importantly, S-HAD-treated tumor cells but not the non-transformed cells were significantly more sensitive to cisplatin-induced apoptosis as indicated by Annexin V staining. Moreover, we found that adding S-HAD alone is sufficient to activate Bax in a cyclin C- and redox-dependent manner. This role appears direct as cyclin C co-immunoprecipitates with active Bax following S-HAD treatment. Finally, crosslinking revealed that Bax and cyclin C heterodimerize during cisplatin-induced apoptosis. The mechanism by which cyclin C promotes apoptosis may therefore proceed through direct and redox-sensitive activation of Bax.

Suppression of RAC1-driven malignant melanoma by Group A PAK inhibitors.

D. Araiza Olivera Toro1,2, Y. Feng2, G. Semenova2, T. Prudnikova2, J. Rhodes2, J. Chernoff2;

1Instituto de Química, Universidad Nacional Autónoma de México, México City, Mexico, 2Cancer Biology , Fox Chase Cancer Center, Philadelphia, PA

Activating mutations in the RAC1 gene have recently been discovered as driver events in malignant melanoma. Expression of this gene is associated with melanocyte proliferation, and melanoma cells bearing this mutation are insensitive to BRAF inhibitors such as vemurafenib and dabrafenib, and also may evade immune surveillance due to enhanced expression of PD-L1. Activating mutations in RAC1 are of special interest, as small molecule inhibitors for the RAC effector p21-activated kinase (PAK) are in late-stage clinical development and might impede oncogenic signaling from mutant RAC1. In this work, we explore the effects of PAK inhibition on RAC1P29S signaling in zebrafish embryonic development, in the proliferation, survival, and motility of RAC1P29S-mutant human melanoma cells, and on tumor formation and progression from such cells in mice. We report that RAC1P29S evokes a Rasopathy-like phenotype on zebrafish development that can be blocked by inhibitors of PAK or MEK. We also found that RAC1 mutant human melanoma cells are resistant to clinical inhibitors of BRAF but are uniquely sensitive to PAK inhibitors. These data suggest that suppressing the PAK pathway might be of therapeutic benefit in this type of melanoma.

miR-195 regulates the response of non-small cell lung cancer to microtubule targeting agents by targeting CHEK1.

X. Yu1, Y. Zhang1, L. Du3, X. Ma4, A. Pertsemidis1;

1Greehey Children’s Cancer Research Institute, The University of Texas Health Science Center at San Antonio, San Antonio, TX, 2Chemistry and Biochemistry, Texas State University, San Marcos, TX

Introduction: microRNAs (miRNAs) are a family of small non-coding RNAs (18-24 nt) that post-transcriptionally repress gene expression by direct binding to the 3’ untranslated regions (UTRs) of their targets. By targeting cancer-related genes, miRNAs have been shown not only to regulate cancer growth/progression, but also to modulate the response of cancer cells to chemotherapy. Such miRNAs are potential candidates for therapeutic intervention. Aiming to identify functional miRNAs in non-small cell lung cancer (NSCLC), we performed a high-throughput screen and found that miR-195 inhibits the growth of NSCLC cells and sensitizes them to microtubule-targeting agents (MTAs), a family of
chemotherapeutic drugs widely used for NSCLC treatment. The function and mechanism of miR-195 in NSCLC were demonstrated both in vitro and in vivo.

**Results**: We demonstrated that miR-195 synergizes with both an old-school MTA (paclitaxel) and a new-fangled one (eribulin) to repress the growth of NSCLC cells. Over-expression of miR-195 sensitizes NSCLC cells to paclitaxel and eribulin, while knockout of miR-195 confers resistance to paclitaxel and eribulin. Importantly, lung tumors with miR-195 over-expression are more sensitive to eribulin treatment than control tumors. Induced expression of miR-195 in lung tumors potentiates the efficacy of eribulin to repress tumor growth. Additionally, we showed that miR-195 directly targets CHEK1 to regulate the response of NSCLC cells to paclitaxel and eribulin. The direct and specific binding of miR-195 to the 3'UTR of CHEK1 was confirmed by luciferase reporter assay. Repression of CHEK1 using siRNAs and chemical inhibitor synergizes with paclitaxel and eribulin to repress the growth of NSCLC cells. Over-expression of CHEK1 contributes to the resistance to paclitaxel and eribulin in NSCLC cells. Analysis of TCGA data show that CHEK1 is significantly up-regulated in lung tumors compared to adjacent normal tissues and that its up-regulation is associated with worse recurrence-free and overall survival.

**Conclusions**: We report the identification of miR-195 as a sensitizer to microtubule-targeting agents in NSCLC, mediated by its repression of CHEK1. Mouse xenografts with induced or constitutive over-expression of miR-195 show that tumors with high miR-195 expression are more sensitive to drug treatment and that induction of miR-195 potentiates the efficacy of eribulin in repressing tumor growth. These results highlight the possible application of miR-195 expression as a biomarker to predict patient response to MTAs and the potential for delivery of miR-195 mimic as an adjuvant to chemotherapy.

Introduction: Although epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors have revolutionized the treatment of EGFR-mutated non-small cell lung cancer (NSCLC), most patients develop acquired resistance either through secondary EGFR mutations or the activation of EGFR-independent pathways. Therefore, there is an urgent need for the identification and development of a novel therapeutic target molecule for NSCLC treatment. AlkB homolog 3 (ALKBH3) is a member of the AlkB family comprising nine paralogs (ALKBH1-8) and fat mass and obesity associated gene (FTO) and belongs to the 2-oxoglutarate and Fe2+-dependent dioxygenase superfamily. ALKBH3 demethylates 1-methyladenine (m1A) and 3-methylcytocine (m3C) in DNA/RNA and protects from DNA damage which caused by methylation. We have shown that ALKBH3 is overexpressed in prostate cancer, NSCLC, and pancreas cancer. ALKBH3 overexpression was detected in over 50% of NSCLC patients with poorer relapse-free survival. In vitro studies revealed m1A and m3C in DNA as the substrates for ALKBH3 and aberrant accumulation of methylation such as m1A and m3C in the genome may induce DNA damage-responsive signaling. Moreover, ALKBH3 knockdown induced powerful anti-tumor effect in tumor models of some cancer cells, including NSCLC cells. However, the underlying signal transduction mechanism of its anti-apoptotic effect on cancer cell proliferation is questionable. Methods: We evaluated the effect of TP53 on the phenotypes induced by ALKBH3 knockdown in NSCLC cells by establishing a TP53-knockout cell clone using A549 cells carrying wild-type TP53. Results: In this study, we found that ALKBH3 knockout induces cell cycle arrest or apoptosis depending on the TP53 gene.
status in NSCLC cells. TP53 gene encoding p53 is known to be frequently mutated in human cancers. Abnormality in TP53 gene is one of the most significant events in NSCLC and plays an important role in the tumorigenesis of lung epithelial cells. TP53 knockout not only promotes the ALKBH3 knockdown-induced DNA damage-responsive signaling but also shifts the phenotypes of ALKBH3-knockdown NSCLC cells from cell cycle arrest to apoptosis. These results suggest that the TP53 gene status is a critical factor for the phenotypic outcome of ALKBH3 knockdown in NSCLC cells, suggesting that ALKBH3 targeting may act as a novel approach for the treatment of NSCLC.

Akt 1 and PA28 do not have a synergistic effect on the Wnt pathway in cancer.
E.J. Thornburg¹, T.B. Nguyen¹, L.F. Barton¹;¹
¹Biology, Austin College, Sherman, TX

Uncontrolled cellular proliferation is one of the defining hallmarks of cancer. One pathway that may contribute to enhanced proliferative signaling in cancer cells is the Wnt signaling pathway. In the absence of Wnt signals, GSK3β triggers β-catenin degradation. Previous research has shown that expression of β-catenin is increased in skin tumors, which may be related to the inhibition of GSK3β. Two additional proteins that inhibit GSK3β and also display increased expression in cancer are Akt 1 and PA28. The purpose of this research was to examine a possible synergistic relationship between Akt 1 and PA28 on GSK3β. Regulation of GSK3β directly affects β-catenin levels and its subsequent transcriptional targets that are important for cellular proliferation. In order to examine the Wnt pathway, total and phosphorylated version of GSK3β and Akt 1, and total β-catenin expression was measured in cell lines containing various expression levels of PA28, Additionally, the transcriptional targets of β-catenin, cyclin D1 and fgf18, were measured by qPCR. Interestingly, the lowest levels of β-catenin were identified in the two cancer lines, with the highest expression in the cells lacking the PA28 gene. Conversely, the transcriptional targets of β-catenin, cyclin D1 and fgf18, showed a different pattern of gene expression than the levels of β-catenin, suggesting additional mechanisms for transcriptional regulation. Levels of phosphorylated Akt 1 did not vary in these cell lines. Total expression and phosphorylation status of GSK3β did increase with transformation in cell lines, but it did not correlate with PA28 expression. In conclusion, there was insufficient evidence to suggest a synergistic relationship between Akt 1 and PA28 on the Wnt signaling pathway, and further research needs to be conducted in order to understand if PA28 is involved in the activation of cellular proliferation by the Wnt pathway in cancerous cells.

Metastasis is the leading cause of death in breast cancer patients. The epithelial-to-mesenchymal transition (EMT) has a crucial role in metastasis and is highly critical for tumor cell dissemination. A set of transcriptional repressors of E-cadherin (CDH1) gene expression, including Snail1, Snail2 and Zeb2
mediate E-cadherin downregulation in breast cancer. Here, by using global gene expression approaches, we uncover a novel function for Cdc42 GTPase-activating protein (CdGAP) in the regulation of expression of genes involved in EMT. We found that CdGAP used its proline-rich domain to form a functional complex with Zeb2 to mediate the repression of E-cadherin expression in ErbB2-transformed breast cancer cells. In vivo, loss of CdGAP in ErbB2-transformed breast cancer cells impaired tumor growth and suppressed metastasis to lungs. The strong expression of CdGAP was correlated with poor prognosis in breast cancer patients. Furthermore, we have identified that CdGAP interacted with 14-3-3 adaptor proteins through its Ser1093 and Ser1163 residues in the C-terminal region, which sequestered CdGAP into the cytoplasm and inhibited its nucleocytoplasmic shuttling. Altogether, these data support a previously unknown nuclear function for CdGAP where it cooperates in a GAP-independent manner with transcriptional repressors to function as a critical modulator of breast cancer through repression of E-cadherin transcription. 14-3-3 binding to CdGAP may behave as an important negative regulator of CdGAP transcriptional activity by cytosolic sequestration, leading to the inhibition of EMT, cell motility and invasion of breast cancer cells. Targeting Zeb2– and 14-3-3-CdGAP interactions may represent novel therapeutic opportunities for breast cancer treatment.

Steroid receptors can facilitate the binding of each other and the pioneer factor FoxA1 to active enhancers in breast cancer cell lines through a dynamic assisted loading mechanism.
E.E. Swinstead¹, V. Paakinaho¹, D.M. Presman¹, T.B. Miranda¹, S. Baek¹, D.A. Ball¹, T.S. Karpova¹, G.L. Hager¹;
¹NCI, NIH, Bethesda, MD

Steroid receptors (SRs), such as the estrogen receptor (ER), play an important role in breast cancer development. The transcription factor (TF) FoxA1, has been implicated in ER binding patterns serving as a pioneer factor. However, the molecular interactions between ER and other TFs such as SRs are not well understood. Classically it has been proposed that pioneer factors have a slow residence time on DNA allowing chromatin to remain open. This permits access of SRs to binding sites in an ATP-independent manner, implying chromatin remodeling factors are not required to facilitate in the opening of chromatin at these sites. Here we established, by single-molecule tracking in living cells, that the DNA residence time of FoxA1 at specific sites is at a rate of ~8-10 seconds. This rate is similar to that of ER and the glucocorticoid receptor (GR). This finding is supported by the lack of a detectable FoxA1 DNase footprint together suggesting fast chromatin interactions. Complementing these results, we determined that SRs can alter the binding landscape of TFs, facilitating selective access to the chromatin by a mechanism termed dynamic assisted loading. To further investigate the functionality of this mechanism we characterized the chromatin landscape of ER, GR, and FoxA1 assisted loading sites in the MCF-7 breast cancer cell line. Here we utilizing ChIP-seq of H3K27ac and P300, both marks of active enhancers, and BrG1, ATPase subunit of SWI/SNF chromatin remodeling complex. Genome-wide analysis showed that the newly acquired ER, GR, or FoxA1 binding sites are highly associated with active enhancers due to an overall increase in H3K27ac and P300 at these sites. Most importantly, BrG1 binding patterns are correlated with ER, GR, and FoxA1 assisted loading sites. This indicates that the dynamic assisted loading mechanism requires ATP-dependent complexes. Together these results do not support a simplified model wherein a specific set of pioneer factors bind to closed chromatin and establish the binding landscape for other TFs. Rather, that many TFs have the potential to affect the binding landscape of other TFs. These newly acquired sites are associated with active enhancer marks, open chromatin, and chromatin remodeling factors. Suggesting these TFs can regulate the binding patterns of...
each through a bimodal switch, in a highly dynamic manner, with fast DNA residence times. In addition, this process involves Brg1, an ATP-dependent chromatin remodeling factor. This study has shifted our classical understanding of the functionality of pioneer factors in breast cancer, demonstrating multiple TFs have the capability to recruit and alter the response of other TFs via ATP-dependent processes.

Investigating the Epigenetic Regulation of the Breast Cancer Susceptibility Gene, BRCA1.
L.A. Duran 1, L. Delgado-Cruzata 1;
1Science, John Jay College of Criminal Justice, New York City, NY

Disrupted DNMT1 and DNMT3B, proteins that maintain methylation, function and amounts have been associated with aberrant DNA methylation levels in cancer. However, less is known about the downstream effect of the loss of DNMTs in specific genes related to breast carcinogenesis. In this investigation, DNMT1 and DNMT3B were knocked down utilizing siRNA and inhibited utilizing 5-aza-2’-deoxycytidine. Levels of both transcripts were determined by real-time qPCR. Levels of DNMT1 were found to be 27.32 +/- 19.56% in cells treated with DNMT1-6 siRNA. Transfection with DNMT3B-10 siRNA decreased DNMT3B mRNA to 46.64 +/- 22.34%. We found that levels of BRCA1 are aberrant when DNMT1 is knocked down but not when it is inhibited. Global DNA methylation was assayed by LUMA showing a decrease of about 20% when treated with 10um 5-aza which correlates with a percent decrease of 40% in enzyme activity. In addition, miRNA expression levels in knocked down and inhibited cells are also being investigated. Our study can further inform on the possible use of DNMT1 targeting drugs in breast cancer as well as suggest a possible crosstalk between the two proteins.

Understanding the Role and Regulation of the SENP1 SUMO Isopeptidase in Pancreatic Cancer.
D.M. Bouchard 1, M.J. Matunis 1;
1Biochemistry and Molecular Biology, Johns Hopkins School of Public Health, Baltimore, MD

The small ubiquitin-related modifier, SUMO, is an essential posttranslational protein modification that controls nearly every aspect of cell function. Consequently, disruptions in the balance of SUMO pathway components are linked to abnormal cell function and disease, including the development and progression of human cancers. For example, it was recently proposed that misregulation of the SUMO isopeptidase, SENP1, contributes to the development and progression of pancreatic ductal adenocarcinoma (PDAC) (Ma et al. (2014) Tumor Biol. 35:12729-35). To further explore this finding, we first set out to validate that SENP1 expression levels were higher in PDAC as compared to normal tissues by characterizing SENP1 protein and mRNA levels in multiple PDAC cell lines. We were surprised to find that the SENP1 levels in these cells were not consistent with the published results. However, immunoblot analysis comparing SENP1 levels in the PANC-1 PDAC cell line to an immortalized “normal” pancreas cell line did show 60% more SENP1 in the PANC-1 cells. This finding is consistent with the hypothesis that elevated SENP1 plays a role in pancreatic cancer. To further test and validate this hypothesis, we are investigating SENP1 protein levels in PDAC patient tissues. To achieve this goal, we have generated formalin-fixed paraffin embedded faux-tissue samples using the PANC-1 PDAC cell line with or without SENP1 siRNA depletion. We are using these faux-PDAC tissue samples to validate the specificity of our SENP1 primary antibody and to develop a reproducible, robust and quantitative
immunohistochemical assay. This method will then be used to stain replicates of PDAC patient samples to evaluate SENP1 expression in the cancerous and adjacent normal tissues. In future studies, we aim to identify SENP1 substrates and understand how changes in the sumoylation of these proteins contributes to the development and progression of pancreatic cancer.

**Matrix stiffness influences oral squamous cell carcinoma behaviour through EMT changes.**  
B. Franzen Matte1,2, J.K. Placone1, A. Kumar1, M. Lamers2, A.J. Engler3;  
1Bioengineering, University of California San Diego, San Diego, CA, 2Oral Pathology, Universidade Federal do Rio Grande do Sul, Porto Alegre, Brazil

A significant challenge in treating squamous cell carcinoma (SCC) is to completely eradicate neoplastic cells that have migrated and invaded the surrounding tissue. Squamous cells exist on a continuum from less aggressive, E-cadherin-rich epithelial, e.g. Cal27 and FaDu cell lines, to more invasive N-cadherin-rich mesenchymal phenotypes, e.g. SCC-9 and SCC-25; while in other tumor types, e.g. mammary, increased tissue stiffness contributes to epithelial-mesenchymal transition (EMT) and tumor progression, it is not clear whether this sensitivity applies to SCC given their phenotypic range. Thus we evaluated the structures that form and invasivity of SCC cells to determine their stiffness sensitivity across their initial phenotypic range using an organotypic model of oral cancer. To mimic the niche, we made a 3D gelatin-methacrylate (GelMA) extracellular matrix, which has tuneable matrix stiffness and mirrors the collagen-rich nice of SCC, and compared it across a range of stiffness to conventional collagen type I matrices. In the collagen gel after 21 days, the less invasive, more epithelial cell line Cal27 proliferated into cell layers without invading the collagen gel. However, an invasive, mesenchymal-like cell line SCC25 invaded the collagen gel and formed tumour islands and keratin pearls resembling what is seen in human specimens. When the GelMA system was stiffened from normal 2 to tumorigenic 20 kiloPascals (kPa, a unit of stiffness), differential cell behaviors were observed depending on the initial SCC phenotype, which together suggests for the first time that stiffness may affect SCC EMT.

**Differential Regulation of Mammary Cancer Invasivity due to Matrix Stiffness and Oncogenic Mutation.**  
C.M. Plunkett1, A. Kumar1, J.K. Placone1, J. Yang2, A.J. Engler1;  
1Bioengineering, University of California San Diego, La Jolla, CA, 2Pharmacology, University of California San Diego, La Jolla, CA

Mammary epithelial cells (MECs) form polarized 3D structures in vivo, i.e. acini, which can be mimicked in 3D extracellular matrix (ECM) cultures in vitro. Results from the past decade indicate that normal MECs are highly responsive to matrix stiffness, undergoing epithelial-to-mesenchymal transition (EMT) with increasing stiffness. However mammary tumors are a complex mixture of MECs with varying phenotypes and mutations and the adjacent stroma ranges from normal mammary stiffness, ~150 Pascal (Pa), to high malignant and stiff, ~5700 Pa. Thus we sought to understand how specific isogenic variants change MEC sensitivity to matrix stiffness. Pre-malignant MCF10A, Ras-transformed MCF10AT, MCF10DCIS obtained from ductal carcinomas, and MCF10CA1 cells derived from in vivo MCF10AT cells...
were utilized to span this spectrum of accumulating mutations. Consistent with previous in vitro 3D culture models of variable stiffness, cells were cultured on collagen-coated polyacrylamide gels with stiffness ranging from 150 to 5700 Pa. Though all cell lines were more proliferative and spread at 5700 Pa, only MCF10AT cells exhibited spread behavior at 150 Pa whereas other lines require 2- to 5-fold higher stiffness, e.g. MCF10CA1 and MCF10A, respectively. Nuclear localization of the EMT marker TWIST could be seen in all cell lines at 5700 Pa whereas in the softest niche, i.e. 150 Pa, only MCF10AT exhibited nuclear TWIST localization. Interestingly, MCF10AT cells displayed a uniquely pro-invasive phenotype regardless of stiffness despite lacking the additional mutations accumulated in MCF10DCIS and MCF10CA1 cell lines. Taken together, these data suggest a differential threshold to matrix stiffness on cellular phenotype that is largely dependent on the underlying oncogenic mutations present, a property that may be leveraged to better combat invasive breast cancer in humans.

The Morphological Characteristics of Carcinoma Migration Phenotypes are Differentially Regulated by the ROCK Isoforms.
R.J. Jerrell1, A. Parekh1,2,3,4, M.J. Leih1;
1Otolaryngology, Vanderbilt University Medical Center, Nashville, TN, 2Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, TN, 3Biomedical Engineering, Vanderbilt University, Nashville, TN, 4Cancer Biology, Vanderbilt University, Nashville, TN

Rho-associated kinase (ROCK) drives migration by cancer cells through the extracellular matrix (ECM) via actomyosin contractility. To breach dense tissues, migrating cancer cells utilize invasive structures called invadopodia to proteolytically degrade the ECM. We previously found that the ROCK isoforms, ROCK1 and ROCK2, regulate invadopodia activity but through contractile and non-contractile mechanisms, respectively. Furthermore, we also found that both isoforms regulate invasion while ROCK2 was not necessary for migration. However, it was unclear whether these functional differences coincided with morphological properties that distinctly define the mesenchymal and amoeboid migration phenotypes. Therefore, we evaluated the physical characteristics of these cancer cells by quantitating cell size and shape as well as focal adhesion formation. Interestingly, we found that the ROCK isoforms differentially regulate cancer cell morphology resulting in intermediate phenotypes that share characteristics of both mesenchymal and amoeboid phenotypes. In particular, cancer cells were able to maintain a mesenchymal-like phenotype with ROCK2 inhibition despite a decrease in ECM degradation suggesting a hybrid phenotype still capable of migration. Overall, our data indicate that the ROCK isoforms may play unique roles in the phenotypic plasticity of mesenchymal carcinoma cells.

A novel Twist1-PKD1 axis promotes epithelial dissemination.
D. Georgess1, O.K. Sirka1, G. Frid1, A. Choi1, N.M. Neumann1, A.J. Ewald1;
1Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Metastasis is initiated by tumor cells adopting an invasive, migratory program that allows them to disseminate and colonize distant organs. The minimal molecular requirement for metastasis is incompletely understood. We focused on elucidating the molecular mechanisms of cell detachment and migration downstream of Twist1, a transcription factor that is overexpressed in metastatic breast cancers and correlates with poor prognosis.
Using 3D organotypic culture of the mammary epithelium, we show that gain of Twist1 expression drives single cell dissemination without loss of epithelial identity. RNAseq of Twist1+ versus WT organoids revealed that Twist1 upregulates the expression of 107 genes, 9 of which are targetable with commercially available small molecules. We tested these inhibitors in our Twist1-induced dissemination assay. In particular, inhibition of protein kinase D1 (PKD1) blocked dissemination completely without affecting growth of WT epithelium. Knockdown of PKD1 in Twist1+ organoids confirmed its specific requirement for dissemination. We then investigated the cellular processes controlled by PKD1. Timelapse microscopy revealed that early pharmacologic inhibition of PKD1 prevented Twist1+ cells from protruding into the extracellular matrix (ECM) and detaching from the epithelium, while late PKD1 inhibition in disseminated cells abrogated their motility. The requirement of PKD1 for invasion and dissemination was also validated in organoids generated from a breast cancer mouse model (C3(1)-Tag) and in organoids isolated from primary human tumors. To study signaling downstream of the Twist1-PKD1 axis, we utilized phosphoprotein arrays which showed that PKD1 promotes the phosphorylation of the oncogene Myc, the tumor suppressor Brca1, the adherens junction protein β–catenin, the microtubule-associated protein Tau, and integrin partner FAK. Immunofluorescence staining confirmed that β–catenin phosphorylation (but not expression) increased in cells as they detached from the epithelium. Inhibition of FAK revealed that its activity was required for cells to disseminate. Moreover, PKD1 activity converged with microtubule depolymerization, likely through Tau phosphorylation. Microtubule depolymerization itself had a positive feedback on PKD1 as treatment with nocodazole, but not paclitaxel, weakened the anti-disseminative effect of the PKD1 inhibitor. Our data proposes a new working model whereby Twist1 drives epithelial dissemination by triggering PKD1 expression. In turn, PKD1 hijacks the cytoskeleton, thus forcing the cell to invade the ECM, then detach from the epithelium, and finally migrate with high persistence into the surrounding stroma. These results also highlight PKD1 as a new potential target for anti-metastatic therapy.

G1P3-induced mtROS augment caveolae mediated endocytosis of E-cadherin to promote breast cancer metastasis.

N. Chowdhury1, J. Mccullough1, A. Davenport1, V. Cheriyath1;

1Biological and Environmental Sciences, Texas AM University-Commerce, Commerce, TX

Although a myriad of mechanisms are responsible for cancer metastasis, the mitochondria’s role in this process remains unclear. Our studies identified a role for G1P3, a mitochondrial localized survival protein, in cancer cell redox regulation. Moreover, G1P3-induced mitochondrial reactive oxygen species (mtROS) promoted the migration and invasion of breast cancer cells. In network based differential gene expression analysis, both epithelial to mesenchymal transition (EMT) and vesicle mediated endocytic pathways were enriched in G1P3 expressing cells (MCF-7G1P3). Since cell-cell adhesion protein E-cadherin suppresses EMT, we hypothesized that G1P3-induced mtROS augments endocytosis of E-cadherin to promote breast cancer metastasis. This hypothesis was tested by comparing the expression and localization of E-cadherin in vector control (MCF-7Vector) and MCF-7G1P3 cells. Although E-cadherin expression was similar in MCF-7Vector and MCF-7G1P3 cells, confocal imaging studies identified that in vector control cells, E-cadherin was predominantly localized on the plasma membrane, whereas in MCF-7G1P3 cells, the majority of E-cadherin was in endocytic vesicles. Compared to MCF-7Vector cells, E-cadherin was 1.5-fold lower in MCF-7G1P3 cell membrane fractions with a concurrent increase (6.45-fold) in cytosolic fractions (P≤0.05). Additionally, qRT-PCR and confocal immunofluorescence analysis identified
4.3-fold upregulation of Caveolin-1, a major mediator of endocytosis, in MCF-7G1P3 cells. Colocalization of E-cadherin with Caveolin-1 and early endosome antigen 1 (EEA1) was markedly increased in MCF-7G1P3 cells, suggesting caveolae mediated upregulation of E-cadherin endocytosis. Moreover, Mito-TEMPO, a mitochondrial specific ROS scavenger, reduced mtROS in MCF-7G1P3 cells, reversed G1P3’s effects on E-cadherin endocytosis, and restored the membrane localization of E-cadherin. Similarly, Methyl-beta-cyclodextrin, a caveolin inhibitor, suppressed the endocytosis of E-cadherin to reestablish its membrane localization in MCF-7G1P3 cells. Consequently, both mtROS and endocytosis suppression resulted in a significant reduction in the rate of migration (40% vs 12% wound closure in untreated vs treated cells) and invasion through matrigel (9.7-fold reduction, p<0.01). In summary, our results demonstrate a novel mechanism of G1P3-induced mtROS in breast cancer metastasis promotion through E-cadherin endocytosis. Considering the association between high expression of G1P3 and poor distant metastasis free survival (DMSF), interrupting G1P3 mediated E-cadherin endocytosis may prevent metastasis and improve clinical outcomes in breast cancer patients.

Prostate Specific Membrane Antigen promotes prostate tumor progression and survival by conferring resistance to hypoxic stress.
A.C. Lewis1, A.M. Ponce2, D. Anukam1, L.H. Shapiro1, L.A. Caromile1;
1Center for Vascular Biology, UCONN Health, Farmington, CT, 2Biology, The University of Texas at El Paso, El Paso, TX

Prostate cancer (PC) is the most commonly diagnosed cancer and is the second leading cause of cancer deaths among men in the United States. The ability of tumor cells to survive in the low oxygen (hypoxic) environment created by the expansion of primary tumors is fundamental to their growth in situ as well as metastatic progression that underlies the majority of disease-related mortality. Prostate Specific Membrane Antigen (PSMA), a type II transmembrane peptidase, is progressively upregulated in ~80% of tumors during PC progression where it correlates negatively with prognosis. We have previously reported that increased PSMA expression on tumor cells alters signal transduction mechanisms downstream of growth factor receptors to promote tumor progression. In addition, we found that expression of PSMA promotes increased survival in hypoxic environments and the current study was designed to determine these PSMA-dependent survival mechanisms. Using the CRISPR/Cas9 system, we engineered a panel of human and murine PC cell lines (LnCaP, 22rv1, TRAMP-C1) to lack PSMA expression. Interestingly, loss of PSMA (PSMAKO) in these highly metastatic PC cell lines resulted in a significantly lower proliferation rate than PSMA expressing cells (PSMAWT), formation of smaller anchorage-independent colonies in soft agar, a shift in the balance of RIPK3/MLKL family of necrosis proteins toward a decreased survival, and a decrease in the migration and intravasation/extravasation potential. Furthermore, in a NOD/SCID xenograft mouse model, LnCaP-PSMAWT cells formed large, well-vascularized tumors whereas LnCaP-PSMAKO showed no evidence of tumor growth, indicating that PSMA is a potent tumor promoter both in vitro and in vivo. Mimicking hypoxic conditions in vitro by treating both PSMAWT and PSMAKO cells with a HiF1 inhibitor, (CoCl2), produced drastic differences in the hypoxia-induced regulation of the calcineurin A and calpain-2 calcium-associated signal-transduction pathways as well as actin regulated cytoskeletal rearrangement highlighting PSMAs role in resistance to hypoxia as well as its potential contribution to a pro-tumor phenotype and increased metastatic potential. In support of this notion, in silico meta-analysis of publically available human gene expression data sets indicated that changes in PSMA and calcium associated genes correlates significantly with PC metastasis to bone and lymph. Dramatic changes in calcium levels are a primary response of many cells engaged in the formation of calcification process.
to hypoxia and typically stimulate cell death. These results suggest that PSMA expression on tumor cells confers resistance to hypoxia via changes in the calcium signal-transduction cascade, thus making the complete disruption of PSMA a promising therapeutic option in management and treatment of PC.

The role of antioxidant enzymes in the proliferation and survival of extracellular matrix-detached SKOV3 cells.

C.A. Davison-Versagli¹, C.L. Libbing¹;
¹Biology Department, Saint Mary’s College, Notre Dame, IN

Epithelial ovarian cancer (EOC) is one of the leading causes of cancer death in women. This could be attributed to the fact that approximately 70% of all cases are diagnosed after the disease has already metastasized, making EOC more difficult to treat. During metastasis, EOC cells shed from the primary tumor and accumulate in ascites before attaching and forming secondary tumors throughout the peritoneal cavity. Throughout this process, EOC cells survive and proliferate without anchorage to the extracellular matrix (ECM) in order to successfully metastasize; however, the specific molecular mechanisms behind the survival and proliferation of EOC cells in anchorage independence has yet to be unveiled. Here, we present data that suggests that the antioxidant enzymes Catalase, Peroxiredoxin 1, and Peroxiredoxin 2 are important and play different roles in the metastasis of SKOV3 cells. SKOV3 cells were genetically engineered to be deficient in Catalase, Peroxiredoxin 1, or Peroxiredoxin 2 through short hairpin RNA (shRNA) techniques, and we report that elimination of any of these antioxidant enzymes in SKOV3 cells results in decreased colony formation in soft agar. Furthermore, Catalase elimination in ECM-detached SKOV3 cells results in increased cell death at 48 hours; whereas elimination of Peroxiredoxin 1 or Peroxiredoxin 2 in ECM-detached SKOV3 cells results in decreased proliferation at 72 hours. Thus, our data reveal that while Catalase, Peroxiredoxin 1, and Peroxiredoxin 2 may be attractive targets for the design of chemotherapeutics aimed at eliminating metastatic ovarian cancer, each enzyme may play a different role in the success of EOC cells during the ECM-bereft metastatic cascade.

Role of NADPH Oxidase (NOX-1) in TNF-α mediated cellular response in regulation of cell death and survival.

B.N. Waghela¹, C.M. Pathak¹;
¹Department of Cell Biology, Indian Institute of Advanced Research (IIAR), Gandhinagar, India

Tumor Necrosis Factor alpha (TNF-α) is known to regulate numerous cell signaling involves proliferation, differentiation, migration, inflammation, cell death and survival. TNF-α modulates NF-κB signaling pathway that plays a pivotal role in defining fate of cells for survival and death. Importantly, cellular redoxstasis also regulates various physiological processes and its imbalance leads to the pathophysiological consequences. NADPH oxidase (NOX) system is a potent pro-oxidant family of enzyme that generates ROS as a primary product. Additionally, NRF-2 is transcription factor that balances the NOX mediated intracellular ROS generation to maintain the cellular redoxstasis. Previous reports suggest that TNF-α modulates receptor interacting serine/threonine protein kinase 1 (RIP-1) and NOX activity and induces necrosis in fibroblast cells but the role of NOX mediated redox signaling in regulation of NF-κB activity remains unclear. In present study, we aimed to elucidate the role of NOX
machinery in TNF-α mediated NF-κB activation and downstream signaling to define fate of cells. In our study, we examined the activity and expression of NF-κB upon TNF-stimulation in HCT-116 cells. We found TNF-α activates NF-κB and translocates into the nucleus. We noticed that TNF-α efficiently induces NOX activity and ROS generation. Further, we inhibited NOX activity by Diphenyleneiodonium (DPI) and observed significant reduction of NF-κB expression and activity. Interestingly, we found that inhibition of NOX activity impedes downstream programmed necrotic cell death signaling by attenuating RIP-1 and anti-apoptotic protein cellular FLICE-like inhibitory protein (cFLIPL). Moreover, inhibition of NOX activity induces apoptotic cell death. Additionally, TNF-α sustains the expression of NRF-2 which may be regulated directly with the NOX activity. Collectively, our results suggest that NOX proteins play an essential role in modulation of NF-κB signaling to define fate of cell death and survival in cancer.

Effects of ASCT2 (alanine/serine/cysteine transporter 2 / SLC1A5) downregulation in human colon cancer HCT-116 cells.
C. Carneiro1, A. Oliveira1, P. Soares-da-Silva1,2;
1Phyzat Biopharmaceuticals, Porto, Portugal, 2Center for Drug Discovery and Innovative Medicines, MedInUP, Porto, Portugal

ASCT2 (alanine/serine/cysteine transporter 2 / SLC1A5) is expressed in colorectal adenocarcinomas and patient survival decreased with increased percentage of ASCT2-positive cancer cells (Anticancer Res 22:2555-2557,2002; Mol Imaging Biol 19:421-428,2017). The present study examined the effect of ASCT2/SLC1A5 gene down regulation by RNA interference on the expression and function of the transporter and cell proliferation of human colon cancer HCT-116 cells. The commercially available siRNA sequence Si00079730 targeting the human ASCT2 mRNA sequence and negative control siRNA commercial sequences NC-Si03650318 and NC-Si03650325 (Qiagen) were tested. The human colon carcinoma HCT-116 cells were transfected with siRNA complexed with Lipofectamine 2000® or Injectin®, and ASCT2 mRNA expression, protein abundance, inward transport of [14C]-L-alanine and the effect of siRNA sequences upon cell proliferation were evaluated after 72 h. The expression of ASCT2 in HCT-116 cancer cells was studied by means of immunoblotting and RT-PCR. Antibodies raised against ASCT2 and GAPDH were used, and images were obtained by scanning at both 700 nm and 800 nm, with an Odyssey Infrared Imaging System (LI-COR Biosciences). Total RNA was converted to cDNA and qPCR analysis was made on the StepOnePlus instrument (Applied Biosystems). Primers for ASCT2 and for the endogenous control gene GAPDH were used. The inward transport of [14C]-L-alanine was examined by incubating cells with non-saturating concentrations (0.25 µM) of [14C]-L-alanine for 1 min. Cell proliferation was evaluated after 30 min incubation with the calcein-AM cell-permeant dye and fluorescence recorded using a 485/530 nm excitation/emission filter in the spectrofluorometer Spectramax Gemini EM (Molecular Devices). The siRNA sequence Si00079730 tested reduced ASCT2 mRNA expression to 30% when compared to the corresponding vehicle. ASCT2 protein expression was also reduced by approximately 50%, and this effect was associated with a 40% reduction upon the [14C]-L-alanine accumulation in HCT-116 cells. Moreover, ASCT2 downregulation markedly decreased (~70%) cell proliferation. The negative control siRNAs were devoid of effects on parameters measured. In conclusion, anti-ASCT2 siRNA decreased [14C]-L-alanine uptake and cellular proliferation in association with downregulation of ASCT2 expression and function. The decrease in cell viability and proliferation of cancer cells induced by anti-ASCT2 siRNAs is expected provide a decrease in tumor growth and metastasis potential in colon cancer.

Board Number: B292

Effects of LAT1 (L-type amino acid transporter 1 / SLC7A5) downregulation in human colon cancer HCT-116 cells.

A. Oliveira¹, C. Carneiro¹, P. Soares-da-Silva¹²;
¹Phyzat Biopharmaceuticals, Porto, Portugal, ²Center for Drug Discovery and Innovative Medicines, MedInUP, Porto, Portugal

L-Type aminoacid transporter 1 (LAT1/SLC7A5) is highly expressed in cancer cells to support their continuous growth and proliferation and has been suggested as a marker of rectal cancer prognosis (Anticancer Res 30: 4223-4227,2010). The present study examined the effect of LAT1/SLC7A5 gene downregulation by RNA interference on the expression and function of the transporter and cell proliferation of human colon cancer HTC-116 cells. Two commercial siRNAs (SI31011000 (Qiagen) and HSS112005 (Invitrogen)) targeting human LAT1 mRNA sequences and negative control siRNA commercial sequences NC-SI03650318 and NC-SI03650325 (Qiagen) were tested. Cells were transfected with siRNAs complexed with Lipofectamine 2000* or Injctin*. LAT1 mRNA expression, protein abundance, inward transport of [14C]-L-leucine and the effect of siRNA sequences in cell proliferation were evaluated after 72 h. Total RNA was converted to cDNA and qPCR analysis was made on the StepOnePlus instrument (Applied Biosystems). Primers for LAT1 and for the endogenous control gene GAPDH were used. Antibodies raised against LAT1 and GAPDH were used, and images were obtained by scanning at both 700 nm and 800 nm, with an Odyssey Infrared Imaging System (LI-COR Biosciences). The sodium-independent inward transport of [14C]-L-leucine was examined by incubating cells with non-saturating concentrations (0.25 μM) of [14C]-L-leucine for 1 min. Cell proliferation was evaluated after 30 min incubation with the calcein-AM cell-permeant dye and fluorescence recorded using a 485/530 nm excitation/emission filter in the spectrofluorometer Spectramax Gemini EM (Molecular Devices). [14C]-L-leucine accumulation in HCT-116 cells was reduced in the presence of the LAT1 inhibitor BCH in a concentration-dependent manner. Both siRNA sequences tested reduced LAT1 mRNA expression around 50% or more when compared to the corresponding vehicle. LAT1 protein expression was also reduced for at least 50%, and this effect was accompanied with a reduction upon the [14C]-L-leucine accumulation in HCT-116 cells. Moreover, LAT1 downregulation decreased cell proliferation, particularly when siRNA sequence HSS112005 was used. The negative control siRNAs were devoid of effects on parameters measured. In conclusion, the [14C]-L-leucine uptake was largely inhibited by the system L selective inhibitor BCH, which suggests that most of L-leucine uptake in HCT-116 cells is mediated by system L. Anti-LAT1 siRNA decreased [14C]-L-leucine uptake and cellular proliferation in association with downregulation of LAT1 expression and function. The decrease in cell viability and proliferation of cancer cells induced by anti-LAT1 siRNAs is expected provide a decrease in tumor growth and metastasis potential in colon cancer.

Insulin inhibits VEGF-induced endothelial permeability and metastasis by inhibiting TGase2 in the lung of diabetic mice.
H. Jeon1, Y. Lee1, Y. Kim1, K. Ha1;
1Molecular and Cellular Biochemistry, Kangwon National University of Medicine, Chuncheon-si, Gangwon-do, Korea, Korea, South

Insulin, which is derived from proinsulin, is an anti-hyperglycemic hormone, but its preventive roles in diabetic vascular permeability and metastasis are unknown. Thus, we investigated the preventive effect of insulin against endothelial cell growth factor (VEGF)-induced endothelial permeability and metastasis in human pulmonary microvascular endothelial cells (HLMVECs) and the lung of diabetic mice. VEGF elevated transglutaminase 2 (TGase2) activity through sequential elevation of intracellular Ca2+ and reactive oxygen species (ROS) levels in HLMVECs. Insulin, TGase inhibitor cystamine and TGase2 small interfering RNA (siRNA) prevented VEGF-induced vascular endothelial (VE)-cadherin disruption, which plays a critical role in modulating endothelial permeability. Furthermore, we showed that VEGF-induced pulmonary microvascular endothelial cell permeability is significantly prevented by insulin and cystamine. Consistently, in the lung of streptozotocin diabetic mice, VEGF-stimulated transaminating activity was inhibited by insulin replacement therapy (58.4 pmol/min/kg) using osmotic pumps. In addition, insulin prevented melanoma metastasis in the lung of streptozotocin diabetic mice. The role of TGase2 in VEGF-induced pulmonary vascular leakage and metastasis were further supported using diabetic TGase2-/- mice. Thus, our findings suggest that insulin inhibits VEGF-induced endothelial permeability and metastasis by inhibiting TGase2 in the lung of diabetic mice. Furthermore, TG2 may be a novel target for prevention of metastasis in diabetes.

Centrosome amplification triggers a non-canonical Senescence-Associated Secretory Phenotype and HIF1-α activation.
S.K. Wu1,2, R. Picone1,2, M.S. Levine3, S. Papathanasiou1,2, M. Kwon1,2, M. Janiszewska4, K. Polyak5, A. Spektor1,2, A.J. Holland5, D. Pellman1,2;
1Pediatric Oncology, Dana Farber Cancer Institute, BOSTON, MA, 2Cell Biology, Harvard Medical School, BOSTON, MA, 3Molecular Biology and Genetics, Johns Hopkins School of Medicine, Baltimore, MD, 4Medical Oncology, Dana Farber Cancer Institute, Boston, MA

Centrosomes promote the assembly and organization of the microtubule, which in turn supports many cellular processes including cell division and migration. In cancer, an abnormal increase in the number of centrosomes is commonly observed. However, tumours are extremely heterogeneous, which usually only have a subset of cells with supernumerary centrosomes. Therefore, whether centrosome amplification in a subpopulation of cells influences an entire population of cells remains an open question. Notably, centrosome amplification in a subset of cells within tissues is sufficient to promote spontaneous tumourigenesis, potentially through cell-autonomous induction of aneuploidy and invasion. But supernumerary centrosomes also trigger p53-dependent proliferation arrest in cells, thus potentially compromising their viability. Hence, how centrosome amplification promotes cancer progression despite triggering a proliferation arrest also remains incompletely understood. Here, we provide novel insights into these outstanding questions. We observe that most cells with centrosome amplification ultimately enter senescence. Senescence has long been recognized as a proliferation...
barrier that is activated in response to tumour initiation and a hallmark of premalignant tumours. Of note, recent evidence indicates that senescent cells can promote tumour invasion and metastasis in a cell non-autonomous manner, by up regulating the expression of cytokines and angiogenic factors - a phenomenon termed as the Senescence-Associated Secretory Phenotype (SASP). Indeed, we find that centrosome amplification increased the expression of extracellular proteins. While persistent DNA damage is the primary activator of SASP and that NF-κB is the major determinant of SASP, we show that centrosome amplification instead triggers an SASP independent of persistent DNA-damage and lacks a prominent NF-κB response. Therefore, indicating that centrosome amplification activates a non-canonical SASP program. Previously, we reported that centrosome amplification, through an increased nucleation of centrosomal microtubules, activates Rac-1 signaling and invasion in a cell-autonomous manner. Here, we find that centrosome amplification induced Rac-1 activation contributes to an increase in cellular ROS, which promotes the stabilization of HIF1α. Indeed, up regulation of cellular ROS is a common feature of senescent cells and may activate HIF1α. As most tumors only have a sub-population of cells possessing supernumerary centrosomes, we provide evidence that centrosome amplification exerts a non-cell autonomous impact by activating a non-canonical SASP and HIF1α.

Metastatic melanoma cells commandeer p53 activity to promote the survival of a therapy resistant subpopulation.

M.R. Webster1, A. Kaur2, B.L. Ecker2, A. Ndoye1, C. Kugel1, S. Basu3, A. Valiga1, J.L. Appleton1, M.E. Murphy3, A.T. Weeraratna1;

1Tumor Microenvironment and Metastasis, The Wistar Institute, Philadelphia, PA, 2Department of Surgery, University of Pennsylvania, Philadelphia, PA, 3Molecular and Cellular Oncology, The Wistar Institute, Philadelphia, PA

Resistance to targeted therapy and chemotherapy increases with age. Previously, we showed that Wnt5A promotes resistance to therapy via the initiation of a pseudosenescent phenotype. Here, we show that Wnt5A correlates with wild type p53 expression in metastatic melanoma. Knocking down Wnt5A decreases the half-life of p53, and blocks a G2/M arrest following DNA damage. These data suggest that Wnt5A may promote the expression of p53 to drive the survival of a subpopulation of cells, which are highly invasive and therapy resistant. To determine if Wnt5A and p53 may be promoting the survival of metastatic melanoma in an aged microenvironment, we examined tumors from young and aged C57/BL6 mice generated using Yumm1.7 cells. We found that tumors in aged mice have a higher percentage of cells expressing p53 compared to tumors in young mice. When we expose human melanoma cells to conditioned media from aged fibroblasts, we see an increase in the percentage of slow cycling cells compared to melanoma cells exposed to conditioned media from young fibroblasts. Knocking down Wnt5A or p53 in melanoma cells decreased the percentage of slow cycling cells. When we isolate slow cycling cells, we see an increase in the expression of Wnt5A, p53, and p21. It may be these slow cycling cells, which are enriched in an aging microenvironment, that are driving resistance to targeted therapy in aged patients.

PLCy1 mediated migration and invasion of HEK293 cells stably expressing non small cell lung carcinoma associated EGFR mutants.
S. Mittal1, M.S. Rajala1;
1School of Biotechnology, Jawaharlal Nehru University, New Delhi, India

Over a decade activating mutations in epidermal growth factor receptor (EGFR) playing a major role in predicting the treatment response of non small cell lung cancer patients to FDA approved tyrosine kinase inhibitors. Patients with mutations in exons19 and 21 of receptor kinase domain by and large have improved outcome in response to these drugs. Nonetheless, a majority of patients eventually develop secondary mutation; T790M in ATP binding site of exon20 region which confers drug resistance. Till date a large number of studies reported the prognostic implications of receptor sensitive and resistant mutations in non small cell lung cancer patients, but the role of these molecular alterations in lung tumor progression and tumor cell invasion remains still unclear. More studies on the regulatory role of mutants in tumor progression may enable to develop a novel class of drugs to target both sensitive and resistant mutant receptors. The current study was designed to investigate the signaling pathways recruited in response to both sensitive and resistant mutants independent of each other. HEK293 cells stably expressing receptor sensitizing mutants; L858R, L861Q of exon21 and resistant mutant T790M of exon20 and double mutant (L858R and T790M) were used in the study. Our experiments demonstrated increased phosphorylation of PLCγ1, c-Cbl, Stat, Mapk, Akt, Shc proteins in cells expressing both sensitizing and resistant mutant receptors as compared to wild type receptor. As PLCγ1 is known to be overexpressed in many tumor types and involved in metastatic development of tumor cells, we further investigated the mutant mediated PLCγ1 activation. Corresponding to EGFR and PLCγ1 phosphorylation, increased invasion and migration of cells expressing mutants was recorded by wound healing, transwell cells migration and invasion assays. Treatment of cells with Gefitinib, Afatinib, Osimertinib; first, second and third generation tyrosine kinase inhibitors reduced the phosphorylation of PLCγ1 in cells expressing receptor mutants. Significant reduction of in vitro migration and invasion of cells following treatment with tyrosine kinase and PLC inhibitors indicates the mutant receptor mediated PLCγ1 deregulation in HEK293 cells.

Myoferlin depletion reduces autocrine TGF-β1 production to regulate epithelial-mesenchymal transition in breast cancer cells.
J. Weist1,2, V. Barnhouse1, V. Shukla1, S.N. Ghadiali1,3,4, D.A. Kniss1,5, J.L. Leight1,2;
1Department of Biomedical Engineering, College of Engineering, The Ohio State University, Columbus, OH, 2The James Comprehensive Cancer Center, The Ohio State University, Columbus, OH, 3Dorothy M. Davis Heart and Lung Research Institute, College of Medicine and Wexner Medical Center, The Ohio State University, Columbus, OH, 4Department of Internal Medicine (Division of Pulmonary, Critical Care and Sleep Medicine), College of Medicine and Wexner Medical Center, The Ohio State University, Columbus, OH, 5Department of Obstetrics and Gynecology (Division of Maternal-Fetal Medicine and Laboratory of Perinatal Research), College of Medicine and Wexner Medical Center, The Ohio State University, Columbus, OH

Tumor cells within an adenocarcinoma can undergo an epithelial-mesenchymal transition (EMT), enabling the cells to break free from the primary tumor and invade surrounding tissue and distant
organs (i.e., metastasis). Recently, myoferlin (MYOF), a protein involved in cell membrane function and repair, was found to be overexpressed in several invasive breast cancer cell lines as well as other types of cancer (e.g., pancreatic, squamous cell and melanoma). Using lentivirus-mediated RNA interference, depletion of myoferlin in the human breast cancer cell line MDA-MB-231 (MDA-231MYOFKD) reduced migration and invasion, and caused the cells to revert to an epithelial phenotype, in contrast to the vector control (MDA-231LVC) which maintained a mesenchymal phenotype. To test if the MET associated with loss of MYOF was permanent, MDA-231MYOFKD cells were treated with transforming growth factor β1 (TGF-β1, 2 ng/mL), a potent stimulus of EMT. After 48 hr of TGF-β1 treatment, MDA-231MYOFKD cells underwent an EMT as indicated by a more elongated, mesenchymal morphology, decreased expression of the epithelial marker E-cadherin, and increased expression of the mesenchymal marker vimentin. Additionally, studies on the effects of TGF-β1 treatment on cell motility in MDA-231MYOFKD cells revealed a decrease in directionality toward more random migration, similar to the highly invasive control MDA-231LVC and wild-type MDA-MB-231 cells. While these results indicated that an MET driven by MYOF depletion was reversible, the mechanism remains unknown. MDA-MB-231s growth and survival has been previously shown to be regulated in part by autocrine TGF-β1 signaling. Using this information, along with myoferlin being known to play a role in the secretion of another signaling factor, VEGF, we hypothesized that MYOF depletion may result in the misregulation of autocrine TGF-β1, prohibiting EMT. A TGF-β1 specific ELISA was used to measure the amount of TGF-β1 secreted into the culture medium. A significant decrease (20%) in TGF-β1 secretion was observed in medium from MDA-231MYOFKD when compared to MDA-231LVC. Similarly, RT-qPCR indicated a significant decrease (30%) in TGF-β1 mRNA expression levels in MDA-231MYOFKD cells. To test if TGF-β1 was necessary to maintain the mesenchymal phenotype, inhibition of the TGF-β1 signaling in MDA-231LVC cells with a pharmacological inhibitor of TGF-β receptor I/II kinases (LY2109761, 2 μM) elicited a decrease in the mRNA expression of the mesenchymal transcription factor Snail and increased E-cadherin mRNA expression. These results identify a novel pathway in the regulation of autocrine TGF-β signaling and establish a possible mechanism by which MYOF regulates the cellular phenotype and invasive capacity of human breast cancer cells.

Hepatitis B virus-human chimeric transcript HBx-LINE1 serves as a molecular sponge specific for hepatocellular miR-122 and promotes hepatocellular carcinoma progression via depleting miR-122.

H. LIANG1,2, X. Chen1, Y. Liu1, K. ZEN1;

1School of life science, Nanjing University, Nanjing, China, 2Department of Biology, Georgia State University, Atlanta, GA

Chronic HBV carriers are at high risk for developing hepatocellular carcinoma (HCC) but the underlying mechanism remains unclear. Recent finding of viral-human hybrid RNA transcripts promoting hepatic cancer cell migration/invasion provides potential link between HBV infection and HCC progression. Here we report that a viral-human hybrid RNA transcript HBx-LINE1 serves as a molecular sponge specific for miR-122 and promotes HCC progression via depleting cellular miR-122. HBx-LINE1 was inversely correlated with miR-122 in HBV-positive HCC tissue and HBx-LINE1 over-expression in Huh7 cells decreased miR-122 level. HBx-LINE1 specifically bound to miR-122 through six miR-122-binding sites, and miR-122 over-expression completely reversed the effect of HBx-LINE1 on activating β-catenin signal pathway and decreasing E-cadherin. Furthermore, expression of HBx-LINE1 in mouse livers decreased miR-122 level and promoted hepatic injury, which was largely abolished by over-expression
of miR-122. In summary, our study provides the first evidence that viral-human chimeric transcripts can serve as a molecular sponge for a particular miRNA and modulate host cell function through depleting the cellular level of that miRNA. In specific, we report that HBV-human chimeric transcript HBx-LINE1 is a molecular sponge for miR-122, and play an important role in promoting HCC progression and activating β-catenin signaling pathway and EMT process in liver tumor cells through depleting cellular miR-122. This finding illustrates a new mechanism by which HBV modulates host cell function and also provides a potential novel therapeutic target for preventing or suppressing the progression of HCC associated with chronic HBV infection.

Hepatitis B virus X protein induces the development of hepatocellular carcinoma by stabilizing HIF-1α.
I. Kang1, S. Kang1, H. Park1, J. Kim1, J. Lee1, J. Ahn1;
1Department of Microbiology Molecular Biology, Chungnam National University, Daejeon, Korea, South

Hepatitis B virus (HBV) infection is the primary cause of the development of various liver diseases including hepatocellular carcinoma (HCC). Among HBV proteins, it has been reported that hepatitis B virus X protein (HBx) is closely involved in the liver carcinogenesis, but its molecular mechanism remains to be elucidated.
In this study, we show that HBx enhances the stability of hypoxia inducible factor-1α (HIF-1α) by regulating VHL binding protein 1 (VBP1). HBx inhibits the interaction between VBP1 and Von Hippel-Lindau protein (pVHL), subsequently reduces the stability of pVHL which is responsible for the degradation of HIF-1α during normoxia.
HIF-1α is a key regulatory factor inducing the tumor formation and enhancing the epithelial-mesenchymal transition (EMT). Here, we also demonstrated that HBx promotes cancer development and EMT by stabilizing HIF-1α. Taken together, our data suggest that HBx stabilizes HIF-1α through interacting with VBP1, and induces the development of HCC.

Selected mitochondrial DNA landscapes activate the UPRmt to promote metastasis.
T.C. Kenny1, D. Germain1;
1Tisch Cancer Institute, Icahn School of Medicine at Mount Sinai, New York, NY

Mitochondrial DNA (mtDNA) has been reported to alter the metastatic behavior of cancer cells. This phenotype was originally associated with specific reactive oxygen species (ROS)-generating mutations. Subsequently mild mtDNA mutations and even mtDNA polymorphism were shown to affect metastasis. Our data suggests that no common mtDNA mutation identifies metastatic cells; rather the metastatic potential of several ROS-generating mutations is largely determined by their mtDNA genomic landscapes, which can act either as an enhancer or repressor of metastasis. However, mtDNA landscapes of all metastatic cells are characterized by activation of the SIRT/FOXO/SOD2-axis of the mitochondrial unfolded protein response (UPRmt). ROS produced by mtDNA mutations can facilitate further mutation of mtDNA and leads to the oxidation of proteins thereby disrupting mitochondrial proteostasis. Metastatic cells with activating mtDNA landscapes may utilize the SIRT/FOXO/SOD2-axis of the UPRmt to handle this stress. Activation of the UPRmt in response to ROS and oxidative stress promotes a complex transcription program that results in increasing mitochondrial integrity and fitness.
Using SOD2 as a surrogate marker of the UPRmt, we found that compared to patient matched primary breast cancers, SOD2 is significantly increased in metastatic lesions. We propose that the ability of selected mtDNA species to activate the UPRmt is a process that is exploited by cancer cells to maintain mitochondrial fitness in the face of oxidative stress and facilitate metastasis.

Glioma mouse models reveal subtype specific cell dynamics.

G.A. Shamsan¹, C.J. Liu¹, B.C. Braman¹, S.K. Rathe², R.L. Klank¹, B.R. Tschida², H. Clark³, S.S. Rosenfeld⁴, D.A. Largaespada⁵, D.J. Odde¹;

¹Biomedical Engineering, University of Minnesota, Minneapolis, MN, ²Masonic Cancer Center, University of Minnesota, Minneapolis, MN, ³Laboratory Medicine and Pathology, University of Minnesota, Minneapolis, MN, ⁴Medical Oncology, Mayo Clinic, Jacksonville, FL, ⁵Pediatrics, University of Minnesota, Minneapolis, MN

Glioblastoma (GBM; WHO Grade IV glioma) is the most common form of malignant glioma with median survival of 15 months and 5-year survival rate of less than 5%. GBM is currently incurable due to the high proliferation and migration rates associated with tumor cells, which allow them to invade healthy tissue and evade current therapies. Utilizing genomic analysis, many genetic drivers have been identified and high grade human glioma has been classified into four subtypes: classical, proneural, mesenchymal, and neural. However, how the different genetic drivers are influencing cell dynamics and consequentially impacting disease progression remains unknown.

PDGFb, platelet-derived growth factor B, has been shown to be expressed in GBM and was used to induce glioma in both mouse and rat models. Here we investigate the consequences of PDGFb overexpression on cell migration and proliferation relative to nRasG12V, a constitutively active nRas, overexpression. We hypothesize PDGFb overexpression will elicit distinct cellular dynamics from nRasG12V overexpression.

The Sleeping Beauty transposon system is used to induce tumor bearing mice using nRasG12V or PDGFb in combination with SV40-LgTA. Histological sections show that both nRasG12V and PDGFb generate high grade glioma. In addition, nRasG12V driven tumor cells are marked by significantly higher migration rate (~27µm²/hr) than PDGFb (~2µm²/hr), as measured ex vivo in mouse brain slices. Using Bioluminescence Imaging, the PDGFb cohort is estimated to have higher proliferation rate than nRasG12V. Higher proliferation rate also correlates with lower survival rate (median survival 31days PDGFb vs. 70 days nRasG12V). Lastly, RNA sequencing of healthy brain tissues and tumors from both cohorts reveals distinct expression profile between the two cohort: nRasG12V cohort resembles the mesenchymal human subtype and PDGFb cohort resembles the proneural human subtype.

Both nRasG12V and PDGFb overexpression leads to the development of high grade glioma resembling two of the human subtypes with distinct cellular dynamics, expression profile and survival rate. To explain the mechanism by which these two drivers are affecting cellular dynamics and tumor progression, further transcriptomic analysis is underway to highlight the pathways driving the observed cellular changes.

¹Bioquímica, Universidade Federal de São Paulo, São Paulo, Brazil, ²Ciências Biológicas, Universidade Federal de São Paulo, São Paulo, Brazil

The resistance of tumor cells to cell death by adhesion loss (anoikis) is a major cellular feature that contributes to tumor progression. Anoikis resistance is an important event in the metastatic cascade, a prerequisite for colonization and spread to distant sites. However, the mechanisms involved in anoikis regulation resistance are not fully elucidated. Various molecules are involved in the survival processes, cell adhesion and proliferation, including the phosphatidylinositol 3-kinase (PI3K). PI3Ks are lipid kinases that regulate signaling pathways important for neoplasia. PIK3CA, the gene encoding the p110α catalytic subunit of PI3K, was recently identified as novel mechanisms of inducing oncogenic PI3K signaling. This gene is frequently mutated in cancers. PI3K signaling pathway regulates several cellular processes and it’s one of the most frequently deregulated pathway in human tumors. Previous data from our laboratory showed that anoikis-resistant endothelial cells exhibit up-regulation of PI3k/Akt pathway and this is accompanied by high proliferation and low apoptosis rate. Aiming to clarify the role of the catalytic subunit of PI3K (p110α) in acquisition of anoikis resistance, we performed the silencing of the PIK3CA gene in anoikis-resistant endothelial cells (Adh1-EC). Silenced cells (miR-PIK3CA-Adh1-EC) were studied comparatively with parental endothelial cells (EC), EC resistant to anoikis (Adh1-EC) and EC transfected with the EJ-ras oncogene (EJ-ras EC) in relation to: gene and protein expression of PI3K, apoptosis, cell proliferation and ability to form colonies. After PIK3CA gene silencing, endothelial cells showed a decrease in the gene and protein expression of PI3K. This was accompanied by an increase in the apoptosis rate and a decrease in the cell proliferation. In addition, miR-PIK3CA-Adh1-EC cells displayed low capacity of colony formation in relation to anoikis-resistant EC. These results may help to understand the involvement of this gene in resistance to anoikis and tumor metastasis, contributing to the development of new compounds for treatment of cancer patients, using this macromolecule as a therapeutic target. Supported by FAPESP, CAPES and CNPq. Keywords: Endothelial cells; Anoikis resistance; PIK3CA gene.

Board Number: B303

Effect of MTA3 overexpression on B16 melanoma cells.
B.A. Frommer¹, J.L. Cox¹;
¹Biochemistry, ATSU, Kirksville, MO

Metastasis associated (MTA) genes function as corepressors or coactivators of a wide variety of cancer related factors. MTA3 expression influences metastatic progression of various cancer types. The effects of MTA3 expression on various metastatic properties are variable among different cancer types. The function of MTA3 in melanoma is unknown. MTA3 gene transfection via pcDNA3 expression plasmid was performed to study migration, proliferation, and invasion functions in the mouse melanoma cell lines B16F0 (low metastasis) and B16F10 (high metastasis). MTA3 overexpression lacks significant influence on melanoma cell migration and proliferation. MTA3 overexpression, however, decreased invasion through Matrigel in vitro for both B16F0 and B16F10 melanoma. MTA3 may have an important role in melanoma’s invasion processes and metastasis.

N. Rodríguez-Ochoa¹, P. Cortes-Reynosa¹, J. Ramirez-Ricardo¹, M. De La Garza Amaya¹, E. Perez Salazar¹; ¹Cell Biology, Center for Research and Advanced Studies of the National Polytechnic Institute, Mexico City, Mexico

Breast cancer is the leading cause of death among women around the world. Several epidemiological studies have established an association between ingestion of ω-6 fatty acids and breast cancer risk. Among these fatty acids, linoleic acid (LA) has been shown to induce a similar epithelial-mesenchymal transition (EMT) process in mammary non-tumorigenic epithelial cells MCF10A and migration and invasion in mammary tumorigenic cells MDA-MB-231. On the other hand, lactoferrins (Lf) has been highlighted as an alternative for the treatment of this disease. Lf is a multifunctional protein present in secretions, mainly in milk, and anticancer properties are attributed to it. However, there are reports indicating that the exposure to human Lf promotes a more aggressive phenotype in breast cancer cells.

The aim of our study is to establish the effect of human and bovine Lf on breast cancer cells MDA-MB-231 and MCF-7. We evaluated cell migration through wound closure assays, expression of proteins related to mesenchymal epithelial transition by Western blot and formation of focal adhesions by confocal microscopy. Our results demonstrate that bovine Lf decreases cellular migration induced by fetal bovine serum (FBS) and LA, and vimentin expression in MDA-MB-231 cells, as well as the stabilization of focal adhesions induced by FBS. In addition, human Lf enhances LA-induced cell migration, induces an increase in vimentin expression, and formation of focal adhesions in MDA-MB-231 cells. We also found that, human and bovine Lf behave in the same way in MCF-7 cells decreasing the expression of vimentin. Our results suggest that human and bovine lactoferrins modulate differentially cell migration and epithelial-mesenchymal transition process in breast cancer cells MDA-MB-231 and MCF-7. This research was partly funded by CONACYT (255429). N R-O and J R-R are recipients of Predoctoral training grants of CONACYT.

Board Number: B305
Extracellular vesicles from MDA-MB-231 cell stimulated with linoleic acid promote migration and invasion through Src/FAK and PI3K/Akt signaling pathways.

J. Ramirez-Ricardo¹, E. Leal-Orta¹, M. Thompson-Bonilla ², E. Perez Salazar¹; ¹Biología Celular, Centro de Investigación y de Estudios Avanzados del IPN, Ciudad de Mexico, Mexico, ²Medicina Genómica, Hospital “Regional 1º de Octubre” ISSSTE., Ciudad de Mexico, Mexico

Extracellular vesicles (EVs) are small membrane-enclosed sacs of endosomal and plasma membrane origin, which are secreted by normal and malignant cells. They are an important mode of intercellular communication by serving as vehicles for transfer of membrane and cytosolic proteins, lipids and RNA between the cells. Particularly, EVs from tumor cells mediate many stages of tumor progression including angiogenesis, escape from immune surveillance, invasion and metastasis. The secretion of EVs is mediated for a variety of stimulus, such as epinephrine, adenosine diphosphate, collagen, calcium ionophore and cytokines. The aim of our work was to determine whether EVs from MDA-MB-231 cells stimulated with linoleic acid were able to induce migration and invasion. Furthermore, we analyzed the role of Src/FAK and PI3K/Akt on these cell processes. EVs were obtained by differential centrifugation.
Activation of Src, FAK and Akt was analyzed by Western blot using phosphospecific antibodies (Abs). The migration was studied by scratch-wound assay and invasion was evaluated by the modified Boyden chamber method. Our results demonstrated that stimulation of MDA-MB-231 breast cancer cells with EVs promoted an increase in the phosphorylation of Src, FAK and Akt2. Treatment with the selective Src family kinase inhibitor pyrazolopyrimidine 2 (PP-2) markedly reduced the phosphorylation of both tyrosine (Tyr)-397 and Tyr-577 induced by EVs. In contrast, PP-2 did not prevent Akt Ser (serine)-474 phosphorylation stimulated by EVs. It demonstrated that activation of Akt is through a Src-independent pathway. In addition, EVs also induced the assembly of focal contacts and MMP-9 secretion, migration and invasion of MDA-MB-231 cells. In conclusion, our findings demonstrate that EVs from MDA-MB-231 cells stimulated with LA induce migration and invasion of MDA-MB-231 cells through Src/FAK and PI3K/Akt signaling pathways. This study was funded by CONACYT (Basic Science 255429 and FOSISS 261637).

Board Number: B306
Role of PI3K/Akt2 on migration induced by extracellular vesicles from MDA-MB-231 breast cancer cells stimulated with linoleic acid in MCF10A cells.
E. Leal-Orta¹, J. Ramirez-Ricardo¹, O. Galindo-Hernandez¹, E. Perez Salazar¹;
¹Biologia Celular, Cinvestav-IPN, Mexico, Mexico

Breast cancer is the most common cancer and the main cause of cancer death in women worldwide. In Mexico, it is the first cause of death by malignant neoplasms since 2006. Several studies suggest an association between a diet rich in fatty acids and risk of breast cancer. Linoleic acid (LA) is an omega-6 polyunsaturated fatty acid and the major PUFA in most diets. Recent studies demonstrate that LA induces an epithelial-mesenchymal transition-like (EMT) process in MCF10A mammary non-tumorigenic epithelial cells, as well as migration and invasion in MDA-MB-231 breast cancer cells. Extracellular vesicles (EVs) are membrane-limited vesicles secreted by normal and malignant cell. Particularly, EVs from MDA-MB-231 cells stimulated with LA promote migration of MCF10A cells. However the signal transduction pathways mediated by these EVs in MCF10A cells remain to be studied. Here, we demonstrate that EVs from MDA-MB-231 cells stimulated with LA promote migration and activation of Akt2 in MCF10A cells. Moreover, our findings show that these EVs promote migration through a PI3K/Akt-dependent pathway, and they also promote activation of FAK and Erk1/2. In summary, our findings demonstrate, for the first time, that EVs from MDA-MB-231 cells stimulated with LA induce migration through PI3K/Akt-dependent pathway in MCF10A cells. This study was funded by CONACYT (Basic Science 255429 and FOSISS 261637).

Cancer Therapy: Novel Techniques and Therapeutics

Fast constitutive turnover of the potential ADC target Prolactin Receptor (PRLR) is mediated by a 21-amino acid region in its cytoplasmic domain.
J. Andreev¹, N. Thambi², A. Perez Bay¹, G. Thurston¹;
¹Oncology Angiogenesis, Regeneron Pharmaceuticals, Tarrytown, NY, ²Research, Advaxis, Princeton, NJ

Antibody-Drug Conjugates (ADCs), generated by linking a cytotoxic agent (such as a tubulin inhibitor, DM1) to a monoclonal antibody (mAb), represent a promising new class of cancer therapeutics. ADCs
exploit cancer-specific expression of cell surface proteins to enable selective delivery of cytotoxins to tumor cells. However, other properties that characterize good ADC targets have not been investigated in detail. The rate of target internalization and the route of intracellular trafficking are likely to be of particular importance. Previously, we compared two targets that are selectively over-expressed in breast cancer: the EGFR family member HER2 and the class I cytokine receptor family member prolactin receptor (PRLR). We have previously shown that PRLR ADC can effectively kill tumor cells that express fairly low levels of PRLR, whereas HER2 ADC conjugated with the same toxin is only effective in cells expressing very high levels of HER2. We discovered that rapid constitutive turnover of PRLR was the mechanism underlying the efficient target cell killing by a PRLR ADC. Hence, PRLR, but not HER2, contains sequence motifs that constantly direct it to lysosomes for degradation (Andreev, J et al. PMID 28108597). We have found that chimeric receptor containing HER2 extracellular and PRLR cytoplasmic and transmembrane domains (termed PRLRcytoTM) contains sequence(s) sufficient and necessary for rapid internalization of the receptor and for efficient cell cycle arrest by ADC. PRLR truncation mutants, unveiled a minimal 21-amino acid region (termed Cyto21-42) in PRLRcytoTM required for constitutive internalization and degradation of the receptor. Although cyto21-42 contains two candidate internalization signals (DAH^{283}LL and ^{292}LL), mutation of most residues within Cyto21-42 resulted in decreased constitutive turnover of the receptor, suggesting that the entire intact Cyto21-42 sequence is needed for the process. Interestingly, PRLR Cyto21-42 sequence is largely conserved in a closely related class I cytokine receptor – growth hormone receptor (GHR), which also undergoes constitutive lysosome-dependent internalization and degradation. CRISPR-based gene deletion experiments suggested that clathrin might not be required for PRLR internalization, and WB analysis showed lack of caveolin expression in T47D cells, suggesting the involvement of an unidentified clathrin- and caveolin-independent endocytic route. Taken together our data show that a 21-amino acid region in the PRLR cytoplasmic domain contains essential information for constitutive ligand-independent turnover of the receptor. This work is the first step towards defining the molecular architecture coupling potential ADC targets to the machinery of constitutive endocytosis and lysosomal degradation.

^1Biology, Concordia University, Montreal, QC, ^2Chemistry, Concordia University, Montreal, QC

Our goal is to develop an anti-cancer compound that selectively kills cancer cells by targeting a selectable biomarker. Many of the cancer drugs that are currently in use are not selective for cancer cells over healthy cells, causing severe side-effects. Furthermore, patients often develop resistance to these drugs, leaving them with fewer alternatives. Thus, it is imperative to increase the repertoire of anti-cancer drugs targeting differentially expressed proteins, which confer a growth advantage for cancer cells. Through collaboration with a medicinal chemist, our lab is characterizing a family of small molecules that share a common scaffold and have several functional groups amenable to modification. The derivatives tested so far show a range in activity, from inert to highly active (IC_{50} < 100 nM), suggesting that the functional groups confer this change vs. the scaffold itself. One of the active compounds, C75, causes mitotic arrest in cancer cells (e.g. HCT116, A549, BTS49, HeLa) at ~2-3-fold lower concentrations in comparison to non-cancer cells (MCF10A, HFF1). Cancer cells treated with 100-300 nM of C75 arrest in pro/metaphase with disorganized or fragmented spindles. HCT116 cells, from colon colorectal adenocarcinoma, were particularly sensitive to C75. ch-TOG/CKAP5, a microtubule polymerase, is highly over-expressed in these cells. ch-TOG counteracts the function of MCAK, a microtubule depolymerase, to regulate spindle length during mitosis. Indeed, C75 phenocopies ch-TOG
knockdown, and similar to ch-TOG knockdown, the spindle phenotypes caused by C75 can be suppressed by MCAK RNAi. We also observed changes in endogenous ch-TOG localization in the presence of C75 using ch-TOG antibodies. Despite causing spindle phenotypes, ch-TOG becomes more highly enriched on the centrosomes and microtubules after C75 treatment. This suggests that C75 could bind to at least one of the TOG domains required for binding to free tubulin dimers, causing an increase in ch-TOG affinity to the polymerized microtubules. We are currently verifying that ch-TOG is the molecular target of C75, and determining if other cancer cells that are more sensitive to C75 also have high levels of ch-TOG, making it a suitable biomarker for a subset of highly progressive cancers.

Hyperthermia upregulates SLC22A16 expression and downregulates ABCG2 expression via ROS production and enhances the cytotoxicity of doxorubicin.
H. Kurokawa1, H. Ito2, H. Matsui3;
1Faculty of Medicine, University of TSUKUBA, 3058575, Japan, 2Graduate School of Medical and Dental Sciences, Kagoshima University, 8908544, Japan

Hyperthermia (HT) is a non-invasive cancer therapy. Treatment temperature between 41 to 44°C has no cytotoxic damage in normal cells, while the temperature does in cancer cells because of the underdeveloped vascular system. HT often used with other cancer therapy such as radiation-therapy and chemotherapy. However mechanisms of synergistic effects among these therapies remains unclear. The 42°C environment is a cellular mild heat stress generating O2- from mitochondrial electron transport chain. We have previously reported that the expression of ATP-binding cassette sub-family G member 2 (ABCG2), which is known as breast cancer resistant protein (BCRP), was suppressed by increasing mitochondrial ROS to induce cancer specific porphyrin accumulations. Since ABCG2 is a transporter of doxorubicin (DOX), we hypothesized that synergistic effect of HT and chemotherapy may be induced by down-regulation of ABCG2 expression via intracellular ROS increase. In this study, we elucidated whether HT with intracellular ROS increase by HT can enhance the cytotoxic effect of DOX for breast cancer cells. The murine breast cancer cell line, 4T1E was incubated at 37 or 42°C for 1h. Intracellular ROS generation was detected by electron spin resonance (ESR). Cytotoxicity of DOX was measured using the Cell Counting Kit 8. ABCG2 expression was analyzed by Western blotting. ESR signal peak with HT treatment became high as compared to without HT treatment, indicating intracellular ROS level was increased by HT treatment. Cell viability and ABCG2 expression were decreased by DOX exposure and by HT treatment. The enhancement of HT treatment effect by DOX is considered to be result of down-regulation of ABCG2 expression by ROS. When cells were exposed to DOX with 5-aminolevulinic acid (ALA), more severe cellular injuries were involved. Since it is known that porphyrin is introduced by ALA and is transported by ABCG2, we speculate that ALA worked as a competitive inhibitor of DOX excretion transporter to enhance cell death. Significant increase in cellular damage by HT treatment was shown by adding ALA, but not without ALA. These results suggest that cellular damage of HT treatment is due to ROS production induced by ALA. HT treatment involved intracellular ROS production and down-regulated the expression of ABCG2 protein. HT treatment also enhanced the cytotoxicity by DOX. Cell death by DOX was enhanced by combination with HT and ALA treatment, possibly via intracellular ROS generation, and was suppressed by additional antioxidants.

A novel anti-cancer drug disrupts or regresses a variety of multi-cellular tumor spheroids.

K. Larocque\(^1\), D. Jaunky\(^2\), S. Hong\(^2\), J. Oh\(^2\), A.J. Piekny\(^4\);

\(^1\)Biology, Concordia University, Montreal, QC, \(^2\)Chemistry, Concordia University, Montreal, QC

We have been developing an anti-cancer compound that selectively kills cancer cells. Many anti-cancer drugs that are currently in use are not selective, causing harmful side-effects to the patient. Moreover, patients can develop resistance to these drugs. Thus, there is a need to expand the repertoire of anti-cancer drugs, especially those that are selective. Through collaboration with a medicinal chemist, we found several analogues of a family of small molecules that share a common scaffold, which kill cancer cells in the nanomolar range. The active derivatives cause mitotic arrest of cancer cells at concentrations ~2-3 fold lower in comparison to non-cancer cells, by causing cells to arrest in pro/metaphase with disorganized or fragmented mitotic spindles. To explore the effects of these compounds on cancer cells within a tumor microenvironment, we grew multi-cellular tumor spheroids (MCTS) from various cancer cell lines, and treated them with varying concentrations of C75, one of the more active derivatives. We grew MCTS’s from HeLa (cervix adenocarcinoma), A549 (lung carcinoma) and HCT116 (colon colorectal adenocarcinoma) cells. HeLa MCTS’s were completely disrupted within two days of a single treatment with 500 nM C75 in comparison to 1 uM C87, an inert derivative. A549 and HCT116 MCTS’s showed regression in growth in response to a single treatment with 500 nM or 1 uM of C75 in comparison to 1 uM C87. Stains for live and dead cells using fluorescein diacetate (FDA) and propidium iodide (PI), respectively, showed that as the tumors decreased in size, dead cells were shed from their periphery. Further, encapsulating C75 in polymeric nanoparticles caused MCTS disruption or regression in growth at lower concentrations in comparison free drug. Therefore, C75 appears to be effective at disrupting MCTS’s derived from multiple cancer cell types, and we are in the process of moving forward with in vivo studies.

The Anterior Gradient protein 2 (AGR2) encodes an endoplasmic reticulum disulfide isomerase that functions as a molecular chaperone. AGR2 is mainly expressed in epithelial cells and has been described as a cancer-associated protein, predominantly in adenocarcinomas. Increased levels of secreted AGR2 (sAGR2) has been correlated with poor prognosis in cancer patients, making it a potential biomarker. Additionally, sAGR2 may be a therapeutic target because neutralizing AGR2 antibodies have shown preclinical effectiveness in murine cancer models. As a result, sAGR2 is becoming recognized as a new theranostic target in cancer biology. We identified a novel peptide that binds sAGR2 by mRNA display. This method enables selection of peptides from a complex library (>109 unique members) and incorporates a protease incubation step to select for serum stable peptides. We performed six
successive rounds of enrichment using a 10-amino acid mRNA display library and identified several AGR2 binding peptides. One of these peptides (H10), demonstrated high affinity binding to AGR2 with an affinity binding constant (KD) of 6.4 nM measure on surface plasmon resonance analysis (SPR). We also investigated the therapeutic utility of H10 peptide and discovered that it inhibits the cancer cell viability at IC50 (16-20 µg/ml) in two cancer cell lines. Furthermore, we determined that 10 µg/ml of H10 peptide is sufficient to inhibit cancer cell migration in breast and prostate cancer cell lines. A control peptide does not show any appreciable activity in these cells.

Stressed out: DNA damage delivered at ultrahigh dose rates reduces cellular stress and apoptosis.

D.H. Al-Rawi¹, M. Rafat¹, S. Vemireddy¹, E. Schuler ¹, P. Maxim ¹, B.W. Loo¹, G. King¹;
¹Department of Radiation Oncology, Stanford Medical School, Stanford, CA

The cellular response to DNA damage is critical for the maintenance of genome integrity. In response to DNA damage, eukaryotic cells rapidly activate a complex network of signaling pathways that localize the DNA lesion, sense the specific type of damage, arrest the cell cycle, and recruit DNA repair machinery. This DNA damage response (DDR) functions as a major barrier to tumorogenesis. Mutational or epigenetic inactivation of the DDR is a critical event that must occur during the early stages of tumor development in order for emerging cancers to bypass oncogene-induced senescence. Elegant work by the Bartek lab and others has demonstrated recruitment of the DNA damage machinery within seconds of microirradiation. Interestingly, most experiments using ionizing radiation occurs on the timescale of minutes. We are interested in determining if irradiating cells on a timescale faster than the activation of the DNA damage response could impact cell decision processes as compared to traditional timescales, in which cells accumulate damage in the setting DNA damage pathway activation. To that end, we modified a clinical linear accelerator to deliver up to 300Gy/s. Using U2OS cells, a p53 and RB WT cell line with intact G2 checkpoint, we did not observe any differences in recruitment of gamma-h2AX, activation and maintenance of the G2 and intra-S phase checkpoints in cells treated with ultrahigh dose rate and conventional radiation. We did, however, note a reduction in p53 stabilization and apoptosis in ultra-high dose treated cells, indicating that the treatment of cells with ultrahigh dose rate radiation improves cell survival, likely due to an overall reduction in cellular stress leading to a more cell survival.

9-Aminoaacididine inhibits ribosome biogenesis and synergizes with cytotoxic drugs to induce selective killing of p53-deficient cells.

L. Anikin¹,², D. Pestov¹;
¹Cell Biology Neuroscience, Rowan University School of Osteopathic Medicine, Stratford, NJ, ²Graduate School of Biomedical Sciences, Rowan University, Stratford, NJ

Common cancer treatments target rapidly dividing cells and do not discriminate between cancer and normal host cells. One approach to mitigating negative side-effects of cancer treatment is to temporarily arrest cell cycle progression and thus protect normal cells during cytotoxic treatments, a concept called cyclotherapy. We recently proposed that transient inhibition of post-transcriptional steps of ribosome biogenesis (RBG) can be used to selectively arrest p53-positive host cells and not p53-null cancer cells. In this study, we investigated whether cytoprotective RBG inhibition can be achieved through small
molecule treatment. We report that treatment of cells with 9-aminoacridine (9-AA) inhibits pre-rRNA processing as well as RNA Polymerase I (Pol I) transcription, in a dose-dependent manner. We propose a mechanism for 9-AA inhibition of RBG by disruption of binding between pre-ribosomes and small nucleolar RNAs (snoRNAs) required for rRNA maturation. Our data also indicate that the mechanism of Pol I inhibition by 9-AA is distinct from that of actinomycin D (Act D), an established Pol I inhibitor. We demonstrate in a model 3T3 cell system that low doses of 9-AA that reversibly inhibit RBG can be protective for p53-positive cells and used in synergy with anti-cancer agents camptothecin and methotrexate to selectively kill p53-negative cells. The ability of 9-AA to cause RBG inhibition, as well as the decoupling of the inhibition of Pol I transcription and pre-rRNA processing, positions acridines as a new tool for RBG and cyclotherapy research.

Functional telomeres play an important role in genome stability. Maintenance of telomeres in cancer cells may differ from that in normal cells because of the specific expression of telomerase in cancer cells. Here we examine the role of heterogeneous nuclear ribonucleoproteins (hnRNP) A1 and A2 in telomere maintenance. Simultaneous suppression of both hnRNP A1 and A2, but not single suppression of hnRNP A1 or A2, produced dysfunctional telomeres and induced DNA damage responses in cancer cells, but not in normal immortal fibroblasts. Ectopic expression of human telomerase reverse transcriptase (hTERT) in normal fibroblasts (hTERT-immortalized normal fibroblasts) rendered the cells sensitive to the production of dysfunctional telomeres and inhibition of cell proliferation through depletion of hnRNP A1/A2. Our work demonstrates that telomerase-positive cancer cells employ factors for maintaining telomeres that differ from those used in telomerase-negative normal cells. We suggest that a strategy designed to inhibit telomerase-dependent maintenance of telomeres could be an attractive novel approach for telomerase-based cancer therapy.

HER2-targeting ADC containing cleavable linker for targeted therapy of HER2-positive gastric cancer.

S. Shin¹², Y. Park³, S. Park¹², E. Ju¹², E. Ko¹², C. Chung³, S. Song¹²⁴, S. Jeong¹², E. Choi¹²⁴;
¹Institute for Innovative Cancer Research, Seoul, South Korea, ²Center for Advancing Cancer Therapeutics, Seoul, South Korea, ³New Drug Research Center, LegoChem Biosciences, Inc., Daejeon, South Korea, ⁴Radiation Oncology, University of Ulsan College of Medicine, Seoul, South Korea

Human epidermal growth factor receptor 2 (HER2) is amplified and overexpressed up to 20% in gastric cancers, which leads to poor clinical outcome. Antibody-drug conjugate (ADC) is composed of the tumor-targeting capacity of monoclonal antibodies with the antitumor activity of cytotoxic agents. T-DM1 (trastuzumab-emtansine, drug antibody ratio (DAR) 3.5, non-cleavable) has been approved by the U.S. FDA as an ADC for HER2-positive metastatic breast cancer treatment and clinical trials in gastric cancer is currently underway. In spite of targeted therapeutic efficacy of T-DM1, patients that have
minimal or non-response to T-DM1 still remain and the main cause of resistance is not clear yet. In this study, we manufactured a new HER2-targeting ADC that can be adjust to accurate DAR (DAR2 or 4) by using cleavable linker. Cleavable linkers effectively release the drug by catalyzing in cancer cell, which induce bystander killing effect. To evaluate antitumor efficacy and mechanisms of action (MOA) in vitro, we performed cytotoxicity assay and cell cycle analysis in N87, HER2-positive gastric cancer cell line. As the results, the HER2-targeting ADC showed equivalent cytotoxic ability to T-DM1 and the ratio of G2/M arrest were 17.3, 30.6, 52.9 and 59.3% in treatment with 0, 0.01, 0.05 and 0.1 ug/ml of HER2-targeting ADC, respectively. Alpha-tubulin structure was investigated by immunofluorescence staining to confirm MOA of the drug and we observed irregular tubulin structure in vitro and in vivo. In vivo anti-cancer efficacy test, HER2-targeting ADC showed noticeable tumor growth inhibition, compared to trastuzumab and T-DM1. At day 56 of N87 transplantation, the treated/control tumor size (T/C) percentage values were 59.1 and 6.8 % in T-DM1 and HER2-targeting ADC (MMAF-DAR4) treated mice, respectively. In addition, HER2-targeting ADC inhibited in vivo tumor growth on patient-derived xenograft model of HER2-positive gastric cancer. Collectively, our results demonstrate that HER2-targeting ADC using cleavable linker exhibits a good MOA and effective anticancer efficacies in both of in vitro and in vivo. This study will contribute to develop a promising ADC for overcoming resistance to HER2 targeted therapy in HER2-positive gastric cancer.

The Anti-melanoma Effects of Heat Shock Protein Inhibitors.
Y. Xiao¹, Y. Yan¹, Y. Yang¹;
¹Department of Biological Sciences, Emporia State University , Emporia, KS

Effective BRAF inhibitor treatment for malignant melanoma loses its strength because of drug resistance. The increasing expression level of heat shock proteins (HSPs) induced by physiological stresses have been found to be associated with tumor initiation, growth and drug resistance. Hsp90 inhibitors CAY10607, Hsp70 inhibitor VER155008 and FDA-approved Vemurafenib were applied separately or in combination with each other to determine the cytotoxic effect on both Vemurafenib sensitive A375 and resistant A375VR melanoma cell lines. In cell viability assay, Hsp inhibitors displayed potent cytotoxicity against the human malignant melanoma cells and achieved a better therapeutic effect when combined with PLX4032. In wound healing assay, Hsp90 inhibitor CAY10607 significantly inhibited cell migration in the resistant cell line A375VR, and Hsp70 inhibitor VER155008 showed a synergistic effect with PLX4032 in inhibiting cell migration in the sensitive cell line A375. In apoptotic assay, Hsp70 inhibitor VER155008 promoted cell apoptosis significantly in both Vemurafenib sensitive and resistant melanoma cells, and the combination of Hsp70 inhibitor and Hsp90 inhibitor synergistically induced apoptosis in the melanoma cells. Furthermore, Hsp90 inhibitor CAY10607 suppressed the activation of Akt and Erk in both Vemurafenib sensitive melanoma cell line A375 and resistant cell line A375VR, while Hsp70 inhibitor VER155008 only inhibited the activation of Akt and Erk in the sensitive cell line A375. Therefore, Hsp inhibitors can serve as novel anti-cancer drugs by inhibiting cell migration, inducing cell apoptosis, and inactivating the PI3K/Akt and Ras-Raf-Mek-Erk pathways.

Antibody–drug conjugates (ADCs) are attractive in cancer therapy because they can directly bind to cancer cells and provide anticancer activity. To kill cancer cells, the target antigens are required to be highly and/or selectively expressed on cancer cells and to be internalized by the cells. HER2, a member of the epidermal growth factor receptor (HER/EGFR/ERBB) family, is well known as an amplified antigen in invasive breast cancer. Trastuzumab emtansine (T-DM1) targeting Her2 is a successful ADC. However, because trastuzumab is used as the targeting antibody, this application is restricted to HER2-positive breast cancer patients. Therefore, novel antigens and targeting antibodies are required for the development of new ADCs. In this study we focused on CD239 that is a specific receptor for laminin α5, a subunit of laminin-511 that is a major component of basement membranes in various tissues. CD239, also known as the Lutheran blood group glycoprotein (Lu) or basal cell adhesion molecule (B-CAM), is an Ig superfamily transmembrane protein. The expression of CD239 is up-regulated in several carcinoma, suggesting CD239 is associated with tumor progression. Immunohistochemical study showed that CD239 was strongly expressed in a subset of human breast cancer tissues and cells. Recently we produced a human single chain variable fragment (scFv) specific to CD239 fused with human IgG1 Fc, called C7-Fc. Although C7-Fc antibody alone does not influence cellular functions, the antibody conjugated with a fragment of diphtheria toxin lacking the receptor binding domain (DT) can selectively kill breast cancer cells. Interestingly, DT-bound C7-Fc shows anticancer activity in CD239-highly positive SKBR3 cells but not in weakly positive cells. Furthermore DT-bound C7-Fc promoted regression of CD239-highly positive cell xenografts in nude mice. Our results show that CD239 is a promising antigen for ADC-based breast cancer therapy.

Dysregulation of human mitochondrial ClpP protease activity by acyldepsipeptides leads to apoptotic cell death.
K.S. Wong2, M.F. Mabanglo1, W.A. Houry1;
1Department of Biochemistry, University of Toronto, Toronto, ON

Acyldepsipeptides (ADEPs) are potential novel antibiotics. They have been shown to dysregulate the activity of the highly conserved tetradecameric bacterial ClpP protease leading to cell death. Here, we identified several ADEP analogs that are potent dysregulators of the human mitochondrial ClpP (HsClpP). These ADEPs interact tightly with HsClpP, causing the protease to unspecifically degrade model substrates. The ADEP-HsClpP co-crystal structure was solved for one of the compound analogs revealing a highly complementary binding interface at the pockets formed by two HsClpP neighbouring subunits with the HsClpP in the compact conformation. Dysregulation of HsClpP activity by these ADEPs was

Monday-194
found to have cytotoxic effects in multiple human cell lines as a result of the activation of the intrinsic, caspase-dependent apoptosis. Given that HsClpP is highly expressed in multiple types of cancers and has important roles in cell metastasis, our findings suggest a novel therapeutic potential of ADEPs in cancer treatment.

Ubiquitination is a regulatory post-translational protein modification that plays important roles in most, if not all, cellular pathways. The conjugation of ubiquitin is a reversible process and can be antagonized by deubiquitinating enzymes (DUBs), also known as isopeptidases. Given its critical role, malfunctions of the ubiquitin pathway are normally associated with human diseases, such as cancers and neurodegenerative diseases. Having a role in multiple cancer pathways, ubiquitin specific peptidase 7 (USP7) is the most well characterized DUB and an attractive therapeutic target for oncology treatment. Progenra has developed a series of selective, covalent, irreversible inhibitors of USP7 that have been widely used to study the biological roles of USP7. These USP7 compounds have been shown to induce degradation of many USP7 substrates in cells as well as inhibit tumor growth in vivo in various models including multiple myeloma, neuroblastoma, lung cancer and colon cancer. However, it remains unclear which tumor types are most sensitive to and what patient population are most likely to benefit from USP7i-treatment. In order to identify potential biomarkers for tumor and patient selection, we have used a variety of cellular assays to investigate the efficacy of our USP7 compounds in tumors with various USP7 expression levels as well as either wild type or mutant versions of p53, and the results will be discussed.

**Toxicological Effects of NCKU-21, a Phenanthrene Derivative, on Cell Growth and Migration of A549 and CL1-5 Human Lung Adenocarcinoma Cells.**

C. Wu1;  
1Pharmacy, Taipei Medical University, Taipei, Taiwan

Background: Chemotherapy insensitivity continues to pose significant challenges for the treatment of non-small cell lung cancer (NSCLC). The purposes of this study were to investigate whether NCKU-21 (3, 6-Dimethoxy-1, 4, 5, 8-phenanthrenetetraone) has potential activity to induce effectively toxicological effect in different ethnic NSCLC cell lines, A549 and CL1-5 cells, as well as to examine its anticancer mechanisms. Methods: Cell viability and cell-cycle distribution were analyzed using MTT assay and flow cytometry in NCKU-21-treated cells. NCKU-21-induced cell apoptosis were verified by Annexin V-FITC/propidium iodide (PI) double staining and measurement of caspase 3 activity. Western blot and wound healing assay were applied to evaluate the regulations of NCKU-21 on signaling pathways and cell migration, respectively. The molecular interaction between target protein and NCKU-21 was predicted and performed by molecular docking. Results: The results indicated that NCKU-21 markedly induced cytotoxic and cytostatic effects to reduce cell viability via cell apoptosis and cell-cycle arrest in tested NSCLC cells. Activation of AMP-activated protein kinase (AMPK) and protein expression of p53.
were also increased in both NSCLC cells stimulated with NCKU-21. However, PI3K-AKT activation repressed by NCKU-21 was found in CL1-5 cells but not in A549 cells. In addition, increases of phosphatidylserine externalization and caspase 3 activity also confirmed apoptotic effect of NCKU-21 in both NSCLC cells. Moreover, cell migration and translational levels of gelatinases, matrix metallopeptidase-2 (MMP-2) and MMP-9, were obviously reduced in both NSCLC cells after NCKU-21 incubation. Experimental data obtained from molecular docking suggested that NCKU-21 can bind to the catalytic pocket of MMP-9 and then has potential to suppress MMP-9 activity. Conclusion: Our results suggest that NCKU-21 can effectively reduce cell growth and migration as well as induce apoptosis in A549 and CL1-5 cells, whose toxicological effects may be partly modulated through PI3K-AKT inhibition, AMPK activation, p53 up-regulation, and gelatinase inhibition.

_In Vitro_ Cytotoxicity Study of Mitochondria Targeted IR780-based NanoGUMBOS in Breast Cancer Cells.

M. Chen1, N. Bhattacharai2, K.C. McDonough2, R. Perez1, I.M. Warner1; 1Department of chemistry, Louisiana State University, Baton Rouge, LA, 2Department of food science, Louisiana State University, Baton Rouge, LA

Heptamethine dye (HP) IR780, has been widely investigated as a mitochondrial toxin for cancer research due to its chemotherapeutic properties, as well as its near-infrared fluorescence allowing for deep tissue penetration. However, the non-selective uptake of this compound leads to toxicity in normal cells as well, which limits its further biological applications. The study presented here focuses on the use of GUMBOS, a group of uniform materials based on organic salts, for selective toxicity as observed previously with Rhodamine 6G-based nanomaterials (nanoGUMBOS) (Magut et al.). NanoGUMBOS display enhanced and uniform properties at the nanoscale level similar to typical nanodrugs; however, they can serve as the drug themselves rather than the drug carrier giving them several distinct advantages. Herein, a simple counter-ion variation strategy has been proposed to design different IR780-based nanoGUMBOS towards enhanced selective antineoplastic activity. These nanomaterials were synthesized by directly nanoengineering hydrophobic IR780-based nanoGUMBOS using a reprecipitation method, without addition of other materials, which allowed the use as a carrier-free nanodrug. Our in-vitro studies indicate an enhanced selective toxicity of all these nanoGUMBOS towards breast cancer cells as a result of improved cellular uptake as compared to the parent IR780 dye. The mechanism of toxicity for the nanoGUMBOS was also examined by study of their sub-cellular localization as well as using a mitochondrial toxicity assay. Analysis of data from these studies revealed that all nanoGUMBOS primarily accumulate in the mitochondria of cancer cell and dysfunction mitochondria to induce cell apoptosis. In order to elucidate other factors that contribute to the observed enhanced toxicity, we further studied the internalization pathways of all nanoGUMBOS. The anions were observed to play a role in regulating the internalization process of nanoGUMBOS by enhancing the interactions between nanoparticles and their transportation receptors on cancer cells, which can eventually affect the final therapeutic outcome of these nanoGUMBOS. From these studies, we demonstrate tunable chemotherapeutic properties of IR780-based nanoGUMBOS through simple variation of counter ions of GUMBOS, which may provide a promising strategy for future design of better nanomedicine for cancer treatment.

Cancer remains a leading cause of death worldwide because most of the cancers acquire genetic mutations that protect them from therapies designed to trigger classical caspase-dependent apoptosis. Meanwhile, there has been increasing interest in designing novel therapies that would target alternate cell death pathways. Here, we show that gold nanoparticles (NPs) functionalized with a mixture of positively [+] and pH-sensitive, negatively [-] charged ligands, so-called mixed charge [±/±] NPs, selectively kill cancer cells while being non-toxic to non-cancerous cells. Cellular uptake of [±/±] NPs is dependent on net surface charge with NPs of corresponding [±/±] charge ratios uptaken equally well in all cell types. Combination of confocal reflection and fluorescence microscopy imaging reveals that the main mechanism of uptake is through endocytosis -- via Rab5-labeled compartments into Lamp1-labeled lysosomes — and is similar in cancer and non-cancerous cells. In contrast, [±/±] NPs, but not purely cationic NPs, selectively compromise the integrity of the membranes of cancer lysosomes. The optimal destabilization of cancer lysosomes is determined by the fraction of [+] and [-] charged ligands attached to the NPs. The selective destruction of cancer lysosomes is attributed to pH-dependent aggregation -- MC NPs are stable at neutral pH, but aggregate rapidly at pH ~ 5.5 -- inside endolysosomal compartments leading to increased osmotic pressure, swelling of the lysosomes and leakage of their contents into cytosol triggering apoptosis-like cancer cell death. Taken together, these results show that tuning of the surface charge balance by functionalization of NPs with a combination of, [±], and pH-sensitive [−], charged ligands could be a useful design strategy for “smart” pH-sensing anticancer therapeutics that selectively destabilize cancer lysosomes.

Nanoparticle-Neural Stem Cells for Targeted Ovarian Cancer Treatment.

Z.A. Patel¹, J.M. Berlin¹, W. Abidi¹;
¹Molecular Medicine, City of Hope, Duarte, CA

One of the drugs used to treat ovarian cancer is cisplatin. However, cisplatin kills healthy tissue in addition to cancer cells. It has been shown that neural stem cells (NSCs) accumulate near ovarian tumors and are used for efficient tumor targeting. If free cisplatin is loaded into NSCs, the NSCs will die. To prevent cytotoxicity, silica nanoparticles (SiNPs 100nm) are used as a protective carrier. The SiNPs encapsulate cisplatin and are then loaded into NSCs. The big picture is to maximize efficiency of tumor targeting using NSCs and minimize toxicity to these NSCs using SiNPs. When tested in vivo, the SiNPs leaked cisplatin before reaching the tumor. The objective of this project is to optimize the stability of SiNPs without cisplatin in efforts of achieving efficient drug loading and delivery. To do this, the concentration of tetraethyl orthosilicate (TEOS), one of the main components of SiNPs, was varied. We hypothesized that the more TEOS added, the more stable the particles will be. The reasoning is that
more TEOS means more carbon in the chemical structure of SiNPs, and thus an intact SiNP results in a stable particle. Using the microemulsion method, six batches of SiNPs were synthesized: 200, 400, 800, 1000, 1400, and 1800 µL TEOS. Then, the SiNPs were placed in cell media and phosphate buffered saline (PBS) for an evaluation of their stability. This step is required because the NSCs grow in cell media and the SiNPs will be in PBS when injected into mice. In order for the particles to effectively carry the drug without leakage, they must be stable in both cell media and PBS. Lastly, the SiNPs were analyzed for their porosity using the transmission electron microscope (TEM). Our results align with our hypothesis: more TEOS equates to more stable SiNPs. In the TEM images, white spots were observed in the SiNPs for the 200-800 µL TEOS batches. The white spots are pores, which indicate instability. However, the 1000-1800 µL TEOS batches had no white spots. Based on the qualitative TEM results, SiNPs with a higher TEOS concentration are stable in cell media and PBS. Our next step was to determine if organic substances, other than TEOS, resulted in stable SiNPs. The organic substance phenyl trimethoxysilane (PTMS) was added to the 400 µL TEOS unstable SiNPs. The stability of these SiNPs was then checked in cell media and PBS. TEM imaging proved that the SiNPs do not form pores in either solution with the added PTMS. Thus, more organic substance made the unstable SiNPs stable. We concluded that the ultimate factor that determines the stability of our microemulsion-synthesized SiNPs in PBS and cell media is the concentration of organic substance. Based on these data, we will now load the stable SiNPs with cisplatin for studies in vivo.

Internalization and Uptake of Targeted Molecular Imaging Agents (TMISs) Through Clathrin-Mediated Endocytosis.
N.A. Omar¹, E.A. Pattie², T.C. Anderson¹, C. Donahue¹, H.F. Schmitthenner², I.M. Evans¹;
¹GSOLS, Rochester Institute of Technology, Rochester, NY, ²Chemistry and Materials Science, Rochester Institute of Technology, Rochester, NY

Targeted molecular imaging agents (TMIs) that bind to biomarkers on cancer cells and illuminate the presence of cancer can be a powerful tool in the battle against cancer. Purpose: The goal of this research is to develop specific targeted molecular probes for detecting prostate cancer and understand their interaction with cells. Methods: The TMIs used are near-infrared fluorescent binding agents that will illuminate cancer cells for cancer detection. The Cy5.5-DCL-DSS-K-NH2 (B1) TMIA that has been developed has a fluorophore conjugated to a urea inhibitor moieties bridged by a linker group. The urea inhibitor will act as the ligand for Prostate Specific Membrane Antigen (PSMA) and bind to it. The cell line used in this research to evaluate the uptake of TMAs is C4-2, a PSMA-positive prostate cancer cell line. Results: It is believed molecules binding to PSMA on cell membranes are taken up by receptor-mediated endocytosis via clathrin-coated pits. Therefore, the uptake of the B1 TMIA is investigated in order to better understand the process of molecule internalization by PSMA. The internalization and uptake of B1 TMIA was evaluated by observing the co-localization of B1 and transferrin-receptor complex using confocal laser scanning microscopy (CLSM). Confocal images of the stained C4-2 cells (PSMA+) at various time-points showed the process of internalization and co-localization of B1 TMIA and fluorescein-tagged transferrin receptor, which indicate that B1 TMIA is being taken up by the cells through clathrin-mediated endocytosis. Antibody tagged with fluorescein to transferrin receptor was used as the control due to the fact that its endocytosis is well-understood and has become the model for studying clathrin-mediated endocytosis. Confocal images of the stained C4-2 cells at various time-points showed the process of internalization and co-localization of B1 TMIA and transferrin, which indicate that B1 TMIA is being taken up by the cells through clathrin-mediated endocytosis the same as

Monday-198
Antibody-drug-conjugates (ADCs) induce cell killing by specifically delivering a toxin to the cytosol or nucleus of cancer cells. ADC efficacy requires both the ADC target to be expressed on the cell surface and to traffic efficiently to lysosomes. We have previously reported that HER2, the target of the clinically approved ADC ado-trastuzumab emtansine (T-DM1), does not traffic efficiently to lysosomes. In contrast, the prolactin receptor (PRLR), another potential ADC target in breast cancer, is rapidly and constitutively internalized into lysosomes, where it is degraded (Andreev et al., 2017). Accordingly, cell killing by HER2-ADC requires ~10^6 HER2 surface receptors/cell, while PRLR ADC cell killing requires only ~30,000 PRLR surface receptors/cell. Although the faster PRLR internalization dramatically compensates for lower surface expression, cells with less than 10,000 PRLR surface receptors are not effectively killed by PRLR-ADC. On the post-translational level, the number of surface PRLR is determined by the relative rates of receptor delivery to the cell surface and internalization. Identification of proteins that control delivery of PRLR to the cell surface or that regulate PRLR internalization might provide biomarkers that help predict the efficacy of PRLR-ADC in breast cancers. CRISPR-based genome editing can be used to specifically inactivate genes with fewer off-target effects than siRNA or shRNA approaches. Arrayed CRISPR screens allow studying the effect of gene inactivation on cell surface expression or internalization of a cargo protein, such as PRLR. Here we studied the role of 151 genes in the trafficking of fluorescent anti-PRLR antibody in the breast cancer cell line T47D. To this end we combined an arrayed CRISPR screen, high content microscopy and quantitative imaging of the amount of fluorescent antibody internalized into endocytic vesicles. The largest inhibition of anti-PRLR internalization observed in this screen was caused by knockout of the coatamer subunit alpha (COPA), a protein involved in trafficking between the endoplasmic reticulum and the Golgi complex. Validation experiments confirmed an inverse correlation between the degrees of COPA KO and anti-PRLR internalization. Surface biotinylation assays in COPA KO cells showed decreased PRLR surface expression without reduction in total PRLR expression, suggesting impaired biosynthetic delivery, rather than reduced internalization. This study suggests that COPA is necessary for efficient intracellular accumulation of anti-PRLR antibodies and establishes a platform to use arrayed CRISPR screens to study the trafficking machinery responsible for the internalization of other therapeutic antibodies.

Potential lung cancer therapy by the development of stigmasterol-solid lipid nanoparticles as drug delivery system.
Z. Torres1, Y. Delgado2, K.H. Griebenow3;
1Chemistry, University of Puerto Rico, Rio Piedras, PR, 2Biochemistry Pharmacology, San Juan Bautista School of Medicine, Caguas, PR

Lung cancer is the second most common cancer in the US and is by far the leading cause of cancer death. Development of new therapies for this type of cancer using nano-formulations has become one of the most important strategies to minimize the lack of drug inactivation after administration into patients. An alternative to increasing the effectiveness of the drugs is by the development of drug delivery systems using solid-lipid nanoparticles (SLN). Stigmasterol (Stg), an unsaturated phytosterol found in plant fats or oils, has shown potent anti-carcinogenic properties. Herein, we developed a Stigmasterol-SLN (≈200 nm) nano-formulation by the use of a microemulsion method. This size is compatible with tumor accumulation through the irregular vasculature observed in cancer tissue. Our system demonstrated strong cytotoxicity on lung cancer A549 cells with an IC50 of 11 µM after 24 h. The mechanism of action of the Stg-SNL has been confirmed to involve activation of caspase-3/7 and is necrosis independent. Stability of the Stg-SLN formulation in the liquid phase was investigated by incubation at 37ºC by for 3 days. More in vitro studies will be completed to confirm the selectivity of Stg-SLN. In conclusion, we have designed a system for phytosterols delivery from nanoparticles with low poly-dispersity which could accumulate in cancerous tissues.

A novel bicyclic binder of a prostate cancer marker Glutamate Carboxypeptidase II.
K. Blažková1,2, P. Šácha3, J. Konvalinka1,2;
1Developmental and Cell Biology, Faculty of Natural Sciences, Charles University, Prague, Czech Republic, 2Proteases of Human Pathogens, Institute of Organic Chemistry and Biochemistry, Prague, Czech Republic

Targeting to cancer cells can be achieved by small-molecular ligands of known cancer markers. The discovery of novel binders is possible through phage display of variable peptide libraries. We describe the discovery and assessment of a bicycle peptide binder of glutamate carboxypeptidase II, a membrane metalloprotease expressed in prostate cancer cells.

For this study, we used phage library displaying bicyclic peptides with differently sized loops developed by Christian Heinis. We performed phage display selection and analyzed the final phage pool using next generation sequencing. The resulting phage clone was isolated and prepared using the same cyclization reagent. The binding was assessed in biochemical assays, mostly using ELISA. Alternative cyclization reagents have been used to test the importance of the specific reagent for the binding of the target protein.

Since the next generation sequencing revealed that 74% of the resulting pool was composed by single candidate binder, it was relatively easy to isolate the phage clone. The preparations of the phage candidate with different linkers show on ELISA that binding is strictly dependent on the same cyclization that was used in the display itself. The inhibitory properties of the resulting peptide are being analyzed.
The study shows that in principle, bicycle phage display can be used to discover novel binders to cancer markers. The prepared bicyclic peptide could then be used for the functionalization of nanoparticles for therapeutic purposes.

A human full length preparation of ERCC1-XPF suitable to test compounds targeted to DNA repair mechanisms.
D.J. Jay¹, M. Weinfeld¹;
¹Experimental Oncology, Cross Cancer Institute, Edmonton, AB

Different human recombinant and native preparations of ERCC1-XPF have been obtained in order to assess kinetic parameters of the enzyme and the effect of compounds directed to target DNA repair mechanisms. Truncated recombinant forms of ERCC1-XPF can be obtained in high yield, however, some of these shorter sources of ERCC1-XPF have been found to contain low molecular weight contaminants which are needed for the nuclease activity. A similar scenario has been found for reconstituted native ERCC1-XPF systems where additional enzymes were required for DNA nicking. Here, we decided to express, purify and validate a full length, wild-type recombinant ERCC1-XPF protein from a bicistronic expression plasmid introduced in E. coli (Bowles B. et al Nuc. Acids Res. (2012) 40 (13): e101). The purpose was to obtain a source that could be used to test compounds directed against ERCC1-XPF. Methods: ERCC1-XPF purification involved three main steps: nickel agarose, heparin Sepharose and filtration on a Superdex column. ERCC1-XPF incision activity was measured with a 5’-6-FAM, 3’-dabcyl stem-loop oligonucleotide substrate. Results: a close-to-homogeneity preparation of ERCC1-XPF could be obtained following these procedures with a yield of 20-50 ug protein/L culture. The enzyme showed an specific activity of 2.76 nmol product/min x mg protein, which, although it is somehow lower than a previously reported activity of a similar preparation of the enzyme (8.2 nmol product/min x mg protein), it is still several orders of magnitude higher than the activity found in truncated forms of ERCC1-XPF. Enzyme activity could be inhibited with low concentrations of specific nuclease inhibitors. Conclusion: An active, full length ERCC1-XPF was obtained. Yield and ease of obtaining have to be considered before generalizing its use for high throughput screening.

Human radon exposure and a medium throughput system to study alpha particle irradiation in cellular assays.
F.K. Stanley¹, S. Zarezadeh¹, J.L. Irvine¹, C.D. Dumais², K. Dumais², A.A. Goodarzi¹;
¹Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, ²Canadaian Association of Radon Scientists and Technologists, Calgary, AB

Radon represents the greatest single lifetime source of ionizing radiation (IR) exposure in humans. Radon emits alpha particle radiation a form of high linear energy transfer (LET) IR believed to cause significantly greater genomic instability than low LET IR such as x-rays and gamma-rays. The impact of alpha particle radiation on genomic instability is an understudied area, and by understanding the molecular and cellular consequences of this is likely to have a significant impact on human health. Here, I present data on human household radon exposure in the Canadian province of Alberta. Approximately 3,500 residential homes were radon tested for 90+ days, as per national guidelines. Subsequently remediated homes were retested to determine efficacy of radon reduction techniques in

Monday-201
this region. Homes had an average indoor air reading of 126 Bq/m$^3$ radon, equating to an effective absorbed radiation dose of 3.2 mSv/yr. 48% of households were ≥100 Bq/m$^3$ and 12.4% were ≥200 Bq/m$^3$, with homes measuring as low as <15Bq/m$^3$ and as high as 3,441 Bq/m$^3$. Newer homes had on average >30% higher radon compared to homes built prior to 1992. To study the impact of alpha radiation in a higher throughput manner, we have developed a unique Am241 irradiation system to expose cells to alpha particles in a 96 well plate-based assay. Using this setup, we present a spatiotemporal study of alpha particle induced DNA damage responses and repair. We measure DNA double strand breaks caused by alpha particles using a 3D analysis of the nuclear DNA damage γH2AX signaling response. We’ve demonstrated a persistence in the DNA damage response significantly compared to gamma rays, and are exploring a panel of previously reported radioprotective compounds to investigate possible interventions for alpha particle exposure in humans. This work demonstrates that radon and alpha particle irradiation is a genuine public health concern, and legitimizes efforts to understand the consequences of radon exposure to human health.

Validation of label-free impedance-based technology for potency assessment of immune cell-mediated cytolysis and immune checkpoint modulation.

F. Cerignoli$^1$, B. Xi$^1$, B. Lamarche$^1$, N. Yu$^1$, L. Muir$^1$, Y. Abassi$^1$;

$^1$ACEA Biosciences Inc, San Diego, CA

In vitro characterization of reagents efficacy for cancer immunotherapy reagents is a necessary step before moving to expensive animal models and clinical studies. Currently in use potency assays like Chromium-51 release, ATP-based luminescence cell proliferation monitoring or flow cytometry are difficult to implement in a high throughput environment and are based on end point methodologies that are unable to capture the full dynamic of the immune response. Here we present the validation of an impedance-based platform for monitoring cytotoxic activity of immune cells in the context of cancer immunotherapy assays. The technology detects cell death and proliferation of adherent cells by measuring changes in conductance of microelectrodes embedded in 96 and 384-wells cell culture plates, without the use of labeling or cell modification. Immune cells are unable to bind the microelectrodes; hence the technology directly monitors adherent target cells proliferation/survival without signal interference by effector cells. Furthermore, we adapted the approach to B cell leukemia suspension cells through adhesion mediated by coating antibodies. We provide a large set of validation including most of the tolls that are currently utilized in the immunotherapy space: CD19 Car T models, EpCAM/CD3 BiTE antibodies and immune checkpoint inhibitor combination therapies. Based on our observation, PD-1 specific antibody can dose-dependently modulate the potency of human-derived PBMC against PC3 prostate cancer cell lines. Using PD-1 checkpoint antibody in combination with antibodies directed against other checkpoint proteins including Tim-3, Lag-3 and in combination with PDL-1 antibody, we can demonstrate either additive effects or no net increase in potency. Data comparison with Annexin V staining/Flow Cytometry shows perfect correlation between the drop in impedance signal and % of apoptotic cells, as well as correlation between immune checkpoint protein expression in PBMC populations and immune blockade. In summary, we have developed a quantitative and reproducible functional assay that can be efficiently used to characterize immune cytotoxic response across the temporal scale, an aspect that is otherwise very difficult to assess with more canonical end point assays. Thanks to the availability of 384-wells format and minimal sample handling, the technology is ideally suited for applications in large drug screening campaigns or therapeutic protocol validation directly on patient samples.

Pro-inflammatory macrophages-derived extracellular vesicles facilitate anticancer drug delivery to metastatic ovarian cancer.
L. Guo\textsuperscript{1}, Y. Zhang\textsuperscript{1}, C. Wang\textsuperscript{1}, M. Feng\textsuperscript{1};
\textsuperscript{1}School of Pharmaceutical Sciences, Sun Yat-sen University, guangzhou, China

Over 80% of ovarian cancers are diagnosed at an advanced-stage (stages III and IV), when peritoneal metastasis has commonly occurred. Primary tumors can often be treated with radiation or surgery, however, cancer cells spreading within the body are resistant to conventional therapy. Therefore, how to completely eliminate ovarian cancer cells remains a great clinic challenge to address. In this study, we developed a new therapeutic approach to treat metastatic ovarian cancer on the basis of pro-inflammatory macrophages-derived extracellular vesicles (M1-type EVs) which were encapsulated with anticancer drug doxorubicin. M1-type EVs were produced by differentiated macrophages RAW 264.7 cells stimulated with lipopolysaccharide (LPS) and interferon-\(\gamma\) (IFN-\(\gamma\)). In contrast to synthetic liposomes, cellular uptake efficacy of M1-type EVs by human ovarian carcinoma SKOV3 cells was significantly higher in vitro. Moreover, M1-type EVs were more likely to adhere to both primary and metastatic ovarian cancer cells in peritoneum and extra-ovarian pelvic organs (i.e., colon, liver and bladder) than in non-target normal tissues. Thus, accumulation levels of doxorubicin delivered by M1-type EVs to primary and metastatic tumors were highly enhanced. It prevented non-specific distribution of toxic drug in the liver where liposomal nanoparticles showed remarkable accumulation leading to severe adverse effect. This approach facilitated doxorubicin to suppress ovarian cancer growth and metastasis, and thereby improved the overall survival rate. Taken together, all the results demonstrated that M1-type EVs may represent nature shuttles for anticancer drug delivery to advanced ovarian cancer.

Acoustic Force Cytometry: high throughput cell-cell avidity screening and sorting.
W. Scheper\textsuperscript{1}, R. Braster\textsuperscript{2}, G. Sitters\textsuperscript{2}, F. Oswald\textsuperscript{2}, R.P. Driessen\textsuperscript{2}, T. Schumacher\textsuperscript{1}, A. Candelli\textsuperscript{2};
\textsuperscript{1}department of Immunology, the Netherlands Cancer Institute, Amsterdam, Netherlands, \textsuperscript{2}LUMICKS B.V., Amsterdam, Netherlands

Communication between cells consist of a multitude of receptors interacting simultaneously. The intensity of interactions plays an important role in various instances, the immune system being one of the most prominent examples. Techniques to study the cell-cell interactions are therefore highly valuable both in fundamental research as well as in the development of cellular therapies. Immune cell therapies hold great promise as an effective novel treatment for a wide range of diseases such as cancer and autoimmune diseases. However, the response rate to this kind of therapies can still be improved due to the lack of tools to quantitatively select and sort the most effective immune cells at high throughput. Here, we employed acoustic force manipulation, a technology with a proven track record in the study of molecular interactions, to query the interactions of live cells. This platform, termed acoustic force cytometry (AFC), provides a novel, high-throughput technology capable of measuring thousands of cell-cell interactions in parallel.

The AFC platform is being developed to provide an accurate method to screen and sort cells based on their direct cell-cell avidity to specific targets such as proteins, peptides, viruses or other cells such as...
tumor cells. As a proof of concept, we aimed to assess the interactions between T cells and tumor cells. We validated the AFC technology by analyzing the cell-cell avidity of T cells transduced with different tumor recognizing T cell receptors with respect to patient-derived tumour cells. AFC is a lab-on-a-chip technology that employs ultrasounds to generate controllable forces on individual cells in a label-free, non-contact and high-throughput way. These data demonstrate the potential of the AFC in profiling T cell-tumor cell interaction and pave the way to quantitative cell-cell avidity studies.

In the last two decades, nanoparticles have experienced an increased interest both in terms of diagnostics and in relation to therapy as drug delivery for various diseases including cancer therapy. In our research, we have worked with Falcarindiol incorporated nanoparticles and solid lipid nanoparticles (SLNs) to function as drug delivery systems in cancer therapy. In the first study, we examined the cellular uptake and effect in hMSC cells of (i) free Falcarindiol by white light microscopy and fluorescence microscopy, and (ii) Falcarindiol incorporated nanoparticles using fluorescence and confocal microscopy. Falcarindiol has been found to prevent and reduce the number of neoplastic lesions in the colon and to increase the number of cholesteryl-ester lipid droplets in treated cells, an effect seen when using other anticancer drugs. By examining the uptake of free Falcarindiol we were able to confirm previous results found using Raman spectroscopy showing that Falcarindiol leads to an increased number of lipid droplets in the treated cells. The nanoparticles designed in this study consisted of PEGylated monolayer of the phospholipids DSPC and cholesterol. From the uptake study of these nanoparticles, we found that they can function as stable drug carriers for Falcarindiol.

The second study concerned the synthesis of antibody conjugated SLNs in the sub-500 nm range to function as an active and targeted drug delivery system in cancer therapy. The SLNs were formulated using a one-step solvent injection method where the organic phase, containing the lipid, and a reagent, was injected into an aqueous solution containing albumin and antibodies (anti-EGFR) resulting in the formation of SLNs where both albumin and antibodies were covalently bound to the surface. In this study, we used this method to make SLNs with diameter down to 89 nm and a zeta potential of -29 mV. We further did in vitro cellular uptake of the SLNs and examined the uptake in different cell lines using confocal microscopy and flow cytometry. The results indicated that (i) SLNs were internalized by the cells, (ii) by incorporating hydrophobic molecules into the SLNs the unspecific uptake of SLNs could be reduced and, (iii) conjugation of the antibody (anti-EGFR) initiated an elevated cellular uptake. Based on the findings, we, therefore, conclude that the SLNs produced in this study may function as an active targeted drug carrier for hydrophobic therapeutics in cancer therapy. Additionally, due to the properties of the SLNs, developed in this study, we plan to study their potential as cancer drug carriers.

Combined nanotherapy based on MAPK kinase inhibitor and clinically approved cytotoxic agent for colorectal cancer.  
B.A. Cisterna¹,², S. Alamos¹, C. Vilos¹,²;  
¹Laboratory of Nanomedicine and Targeted Delivery, Center for Integrative Medicine and Innovative Science, Faculty of Medicine, Center for Bioinformatics and Integrative Biology, Faculty of Biological Sciences, Universidad Andres Bello, Santiago, Chile, ²Center for the Development of Nanoscience and Nanotechnology (CEDENNA), Santiago, Chile

Colorectal cancer (CRC) is highly prevalent worldwide and despite notable progress in its treatment still, leads to significant morbidity and mortality. Notwithstanding the high efficiency of chemotherapeutic agents used to treat CRC, their low specificity often produces a range of dose-limiting side effects. Cancer cells have developed different strategies to escape cell death induction by chemotherapeutics. Consequently, therapies intending to interfere signal transduction pathways using a single drug may be insufficient to accomplish the tumor recession. Several studies have described that the upregulation of p38 mitogen-activated protein kinase (MAPK) in CRC represents a critical factor during the cell migration, and invasion, as well as, in the maintenance of cell metabolism promoting cell survival. Then, the combined therapy against different pathways encourages excellent potential for CRC. Recently, the use of hybrid nanoparticles (lipid-polymer) as drug delivery system for cancer therapy has become one of the most promising strategies against cancer. Moreover, the combined drug therapy loaded-nanoparticles could boost the therapeutic effect. Here, we combine the cytotoxic drug 5-FU and the p38 inhibitor skepinone-L into PLA–DHPE-PEG nanoparticles (NPs) prepared by the single emulsion method, and we evaluated their cytotoxic effect and cellular internalization in HTC-116 and SW480 cells (colorectal cancer cell lines). NPs analyzed by transmission electron microscopy exhibited spherical shape nanoparticles with a homogeneous size. The quantification of size by dynamic light scattering (DLS) confirmed the diameter ~100 nm in both, empty and loaded nanoparticles. The superficial charge of particles evaluated using DLS displayed negative charge in both, distilled water and PBS. Also, the stability performed in PBS for 96 hours showed a uniform diameter and absence of agglomerates. Cell viability was measured by the cell counting kit-8 (CCK-8) in cell lines treated with non-loaded drug combined therapy, and loaded-nanoparticles for 48 hours. The IC50 value was calculated for each treatment using the GraphPad Prism 6.0 software from triplicated experiments. The obtained results exhibited that combined therapy based on 5-FU + skepinone-L loaded polymeric nanoparticles exhibited significant cytotoxic effect than non-loaded drugs on HTC-116 and SW480 cells. The uptake of NPs studied on HTC-116 and SW480 cells at 0, 2, 4, 8, 16 and 24 hours of incubation by confocal microscopy displayed a time dependence internalization rate in the cell line evaluated. The results suggest that combinatorial therapy using nanoparticles improves effectiveness and may decrease side effects of CRC therapy.

**Novel Conjugation Chemistry for Antibody-Drug Conjugates.**  
T.I. Chio\(^1\), K. Mukherjee\(^2\), H. Gu\(^1\), S. Ghosh\(^1\), S.L. Bane\(^1\);  
\(^1\)Chemistry, State University of New York at Binghamton, Binghamton, NY, \(^2\)Medicine, Massachusetts General Hospital/Harvard Medical School, Boston, MA

Antibody-drug conjugates (ADCs) have been an attractive target of research in the development of cancer therapeutics. Conventional linkers for drug conjugation to the antibody utilize N-hydroxysuccinimide ester chemistry with amines (N-terminal amine or lysine) or maleimide reaction with thiols (cysteine). Given the relative abundance of amines in proteins and the level of circulating thiols in the body, these chemistries carry the drawbacks of producing heterogeneous products with different pharmacokinetic properties and/or premature release of the drug due to retro reaction. There is thus a growing interest within the field of ADCs toward conjugation chemistries that are site-specific, efficient, and can produce stable conjugates. Here, we demonstrate the potential of 2-formylphenylboronic acid (2fPBA) chemistry as a novel conjugation strategy for meeting these needs. Recent reports have shown that 2fPBA exhibits fast reaction kinetics and selectivity toward \(\alpha\)-aminothiol and \(\alpha\)-aminoimidazolidine to form stable boron-nitrogen heterocycles (BNHs). The bioorthogonality of these reactions is herein demonstrated further by selective protein labeling within a complex mixture (i.e. cell lysate). In addition, we demonstrate efficient protein-small molecule as well as protein-protein coupling via this chemistry. Finally, the BNH bond is found to be stable over time as well as in the presence of biologically relevant molecules. Altogether, the results show promise of utilizing 2fPBA chemistry with \(\alpha\)-aminothiol and \(\alpha\)-aminoimidazolidine in the linker design for ADCs.

**Investigating the role of microenvironmental stress in transcriptional control and cancer progression.**  
S. Chittiboyina\(^1\), S. Jayaraman\(^1\), K.B. Hodges\(^1\), S.A. Lelievre\(^1\);  
\(^1\)Basic Medical Sciences, Purdue University, West Lafayette, IN

Oxidative stress (OS), resulting from an imbalance in reactive oxygen species generated and cleared by antioxidants in the body, is a feature of the tumor microenvironment involved in cancer progression. How OS leads to chromatin alterations and epigenetic modifications that drive cancer progression by influencing gene transcription is not well understood. We have been studying the structural protein, nuclear mitotic apparatus (NuMA) for its function at the boundary of nuclear architecture and chromatin organization with an impact on major aspects of cellular homeostasis, such as phenotypically normal differentiation; nucleolus-based stress response and DNA repair. Through mass spectrometry analysis we have identified the transcriptional coactivator lens epithelium derived growth factor (LEDGF), which is also protective against OS, as an interacting partner for NuMA. Our preliminary investigation indicated that LEDGF expression was decreased in invasive triple negative breast cancer (TNBC) compared to the preinvasive stage. It is known that increased H3K9me2 expression represses LEDGF and correlates with increased expression of chromatin protein, remodeling and spacing factor (RSF-1) that also binds to NuMA from our findings. RSF-1 is a transcriptional repressor when overexpressed under OS and is a marker of aggressive breast cancers. Our central hypothesis is that NuMA-LEDGF-RSF1 interaction
controls cancer progression under microenvironmental stress by influencing transcriptional regulation. To test our hypothesis we use the HMT-3522 model of TNBC progression that in 3D cell culture mimics the phenotypically normal luminal epithelium (non-neoplastic S1 cells), ductal carcinoma in-situ (DCIS; S1-derived S2 cells) and invasive ductal carcinoma (IDC; S2-derived T4-2 cells). Induction of OS with 250 μM H2O2 in S1 cells decreases NuMA expression, yet NuMA interaction with LEDGF is strengthened compared to control, but in S2 cells NuMA-LEDGF interaction is weakened under OS when compared to control. NuMA and RSF-1 follow a similar expression pattern as LEDGF with lower expression in T4-2 cells compared to S2 cells, and increased expression under OS in S2 cells. However, prolonged exposure to ROS (25 μM H2O2 for four weeks) results in a loss of NuMA and LEDGF and increase in expression of RSF1 in preinvasive TNBC, hence mimicking the changes observed in vivo. These results highlight the need to investigate whether RSF-1 over-expression under chronic OS in the S2 cells triggers H3K9me2 increase, and consequently loss of LEDGF, hence pushing cells toward an invasive phenotype. Also, important is to understand whether loss of RSF-1 or LEDGF controls the interaction of NuMA with either of these co-transcription factors and cancer progression.

Oscillatory HIF-1α induction promotes proliferation of hypoxic cells through a lactate dependent quorum autophagy response.
Kshitiz1,2, J. Afzal2, H. Chang1, Y. Suhail1, M. Hubbi2, C. Dang2,3, A. Levchenko1;
1Biomedical Engineering, Yale University, New Haven, CT, 2Medicine, The Johns Hopkins Medical Institutions, Baltimore, MD, 3Abramson Cancer Center, University of Pennsylvania, Philadelphia, PA

Response to hypoxia is a highly regulated process controlling multiple cell and tissue level functions. However, we still know little about dynamic single cell responses to hypoxic conditions. Here, using fluorescent reporters of hypoxia response factor-1 alpha (HIF-1a) activity, we show that hypoxic responses in individual cells can be highly dynamic and variable across the population. These responses fall into three classes, including oscillatory activity. We identify a molecular mechanism that can account for all three response classes, demonstrating that the oscillations of HIF-1a activity and abundance are controlled by the reactive oxygen species-dependent chaperone-mediated autophagy in a subset of respiring cells. Furthermore, we find that the oscillatory response is modulated by the abundance of extracellular lactate in a quorum sensing-like mechanism. We show that oscillatory HIF-1a activity can help overcome hypoxia-mediated inhibition of cell division, suggesting a mechanism for aggressive behavior in a subset of hypoxic tumor cells.

Environmental availability of cystine drives usage of glutamine as a TCA cycle substrate and causes glutamine addiction.

1Koch Institute for Integrative Cancer Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, 2Whitehead Institute for Biomedical Research and Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, 3Dana-Farber Cancer Institute, Boston, MA

The tri-carboxylic acid (TCA) cycle is primarily known for its role in generating NADH from the oxidation of pyruvate, which is used to power ATP production by oxidative phosphorylation. Beyond ATP production, the TCA cycle also supplies biomass precursors needed for the growth and proliferation of
cells. Thus, supplying the TCA cycle with carbon is an essential metabolic feature of proliferating cells. Many mammalian cancer cell lines depend on extracellular glutamine as a major TCA cycle substrate to support their proliferation in vitro. However, recent studies have suggested that some cells that depend on glutamine to fill the TCA cycle and proliferate in culture rely much less on glutamine catabolism for these functions when growing as tumors in vivo. This has led to the conclusion that environmental differences between tumors and cell culture influence the extent of glutamine catabolism. We sought to identify such environmental differences that cause differential dependence on glutamine for TCA cycle maintenance. We hypothesized that differences in available nutrients between standard culture conditions and tumors could account for differences in glutamine utilization. Therefore, we cultured cancer cell lines in 100% adult bovine serum, a condition that more closely reflects the nutrients available to cells in vivo. Cells cultured in adult bovine serum have decreased glutamine catabolism and rely less on glutamine metabolism for proliferation compared to growth under standard tissue culture conditions. The small molecule nutrient component of adult bovine serum was responsible for the differential utilization of glutamine. By analyzing the nutrient differences between bovine serum and media, we find that levels of a single nutrient, cystine, can account for the differential dependence on glutamine in these different environmental contexts. We show that increasing cystine availability to cancer cells growing as tumors in vivo increases glutamine catabolism in these tumors. Lastly, we find that cystine levels dictate glutamine dependence via the cystine/glutamate antiporter xCT/SLC7A11, and that environmental cystine levels in conjunction with xCT/SLC7A11 expression are necessary and sufficient to drive increased glutamine anaplerosis. Collectively, these results define important determinants of glutamine metabolism and glutamine dependence in cancer cells, and highlight that cellular metabolism is determined not only by cellular genetics, but by the interplay of the cell with the nutrient environment.

One carbon metabolism-mediated protein methylation triggered by histidine regulates the filaments formation and preservation of CTP synthase.

W. Lin\textsuperscript{1,2}, A. Chakraborty\textsuperscript{3}, P. Wang\textsuperscript{1,2}, Y. Lee\textsuperscript{1}, L. Pai\textsuperscript{1,2,3};

\textsuperscript{1}Department of Biochemistry, College of Medicine, Chang Gung University, Taoyuan, Taiwan, \textsuperscript{2}Molecular Medicine Research Center, College of Medicine, Chang Gung University, Taoyuan, Taiwan, \textsuperscript{3}Graduate Institute of Biomedical Sciences, College of Medicine, Chang Gung University, Taoyuan, Taiwan

CTP synthase form compartmentalized filament in respond to environmental nutrients status. However, the physiological role of filaments and mechanisms for filaments assembly are not understood. Here, we demonstrate that CTP synthase form filaments under glutamine deprivation in response to the influx of histidine. The protein level of CTP synthase could be preserved in the presence of histidine, which associated with rapid growth following nutrients replenishment. Tetramer conformation based filament formation reflected the downregulation of CTP synthase enzyme activity. Induction of activating transcription factor 4 (ATF4) by nutrients restriction, which was essential for filament formation. Comprehensive analysis identified that methylenetetrahydrofolate dehydrogenase 2 (MTHFD2) involved one carbon metabolism regulated by ATF4, which affected filaments formation. One carbon metabolism mediated protein methylation triggered by histidine was critical for filament formation. Collectively, we demonstrate that CTP synthase filament formation through one carbon flux mediated protein methylation could be one of strategies for cancer cells to recovery quickly after stress relief and maintain homeostasis under adverse environments.
Galectins are multifunctional soluble beta-galactoside-binding proteins capable of modulating cell differentiation, proliferation, survival, and adhesion. These cellular events are critical in fundamental biological processes such as embryogenesis, angiogenesis, neurogenesis, immunity, and tissue repair. The expression pattern of twelve members of the human galectin family changes substantially in differentiated cells, tumor cells, and cells exposed to environmental stress stimuli such as oxidative stress [1,2]. The level of galectins in circulation also changes under conditions of physiological (e.g. physical exercises) and pathological (e.g. cancer) stresses. These findings suggest that galectins are potential biomarkers and regulators of cellular and organismal stress responses. However, molecular mechanisms that are responsible for regulating the complex galectin network in cells are not well known. The goal of our study was to examine a role of global stress-associated glycosylation of intracellular proteins with O-linked beta-N-acetylglucosamine (O-GlcNAc) as a new signaling paradigm for controlling galectin gene expression in human cells. Changes in the galectin expression profiles were compared between several human cell lines (MCF7, MDA-MB-231, HT-29, and HL-60) treated with biochemical inhibitors of two enzymes which add (O-GlcNAc transferase, OGT) or remove (O-GlcNAcase, OGA) O-GlcNAc residues. The expected modulation of global O-GlcNAc levels by drugs and stress stimuli was confirmed and quantified using immunodot blot analysis with an anti-O-GlcNAc antibody, RL2. Remarkably, a significant decrease of O-GlcNAc was noticed in differentiated HL-60 cells (1.3% DMSO treatment) and HT-29 cells (crowding stress). Quantitative RT-PCR assay revealed both cell-specific galectin expression profiles and significant differences between cells treated with OGT versus OGA inhibitors. Pearson correlation analysis showed a positive correlation between the expression levels of specific galectins and O-GlcNAc, although no or negative correlations were observed in other cases. We conclude that O-GlcNAc-mediated regulation of galectins may interfere with other signaling systems as, for instance, COX-2-positive MDA-MB-231 breast cancer cells were less sensitive to OGT/OGA inhibitors in comparison with COX-2-negative MCF7 cells. In sum, our findings provide novel evidence that O-GlcNAc-mediated signaling pathways are involved in remodeling galectin networks in human cells in association with cellular stress responses and cellular differentiation.

LIPIIDIMAGINGIN PROSTATE CANCER.

C.A. Bader1, A. Sorvina2, R.D. Brooks1, I.D. Johnson1, E. Carter1, P. Lay2, E. Parkinson-Lawrence1, M. Massi3, S.E. Plush1, D. Brooks1;

1School of Pharmacy and Medical Science, University of South Australia, Adelaide, Australia, 2Vibrational Spectroscopy Core Facility and School of Chemistry, The University of Sydney, Sydney, Australia, 3School of Chemistry, Curtin University, Perth, Australia

Prostate cancer remains one of the most commonly diagnosed cancers in males. Distribution and metabolism of lipids is known to be altered in cancer cells in particular prostate cancer. Though a
number of approaches have described these changes in lipids, visualisation of cellular lipid distribution and metabolism is still restricted by the availability of specific imaging tools. Fluorescent complex ReZolve-L1TM has been showed to have an affinity towards cholesterol, phosphatidylethanolamine, sphingosine and sphingomyelin and localise that is consistent with these lipids in cells and tissues. By utilising this imaging agent to investigate lipid distribution at the cellular level, we revealed a different pattern of staining in malignant prostate cancer compared to non-malignant cells. Following lipid loading there was also significant differences in lipid staining by ReZolve-L1 revealing an altered cell response to lipid availability between malignant 22RV1 and non-malignant PNT1a cells. This suggested that malignant prostate cancer cells had enhanced uptake of exogenous lipids compared to non-malignant cells. Biochemical analysis confirmed that there were significant differences in lipid profiles for malignant prostate cancer cells when compared to non-malignant prostate cells, and this was also confirmed by IR spectroscopy. These findings demonstrate that ReZolve-L1TM lipid staining could be utilised to aid in understanding lipid distribution and metabolism at a cellular level. Further ReZolve-L1 may provide a tool for prostate cancer diagnosis/prognosis. This is important as early accurate detection and appropriate intervention will have a significant impact on patient morbidity and mortality.

Optimization of a Chromatin Immunoprecipitation Assay to Assess Target Genes of the FOXC2 Transcription Factor in Melanoma.
D.Z. Bushhouse1, K.M. Hargadon1;
1Biology, Hampden-Sydney College, Hampden-Sydney, VA

characterized by rapid growth and metastasis. Increased expression of the transcription factor FOXC2 has been associated with more aggressive melanoma outgrowth and metastasis. We sought to optimize a chromatin immunoprecipitation assay to identify novel gene targets bound by FOXC2 in B16-F1 melanoma, specifically investigating genes regulating cell adhesion proteins and genes regulating tumor invasion and metastasis that we have been found to exhibit altered expression in wild-type B16-F1 versus a novel CRISPR-Cas9-engineered B16-F1ΔFocc2cell line with a homozygous disruption of the Foxc2 gene. Wild type B16-F1 chromatin was ChIPed using an anti-FOXC2 Ab, an anti-Histone H3 positive control Ab, and a normal goat IgG negative control Ab. Enrichment of known FOXC2 gene targets in the promotor regions of Itgb3 and PAI-1 was measured by qPCR for each condition. We demonstrated consistent enrichment of gene targets by anti-Histone H3 ChIP and anti-FOXC2 ChIP. We also reduced background from 14% of Input to 5.5% of Input by altering our protocol to accommodate a preclearing step and magnetic beads of a different protein-binding subtype. While background remains higher than our goal of 0.01% of Input, current work is focused on generating a novel CRISPR-Cas9-engineered variant of the wild-type B16-F1 melanoma with a homozygous disruption of the DNA-binding domain sequence of the Foxc2 gene for use as a strong negative control in further comparative ChIP-qPCR studies.

Optogenetic manipulation and monitoring of YAP signalling in tumours.
A.M. Dowbaj1, M. Montagner1, R. Jenkins1, M. Jiang2, K.M. Hahn3, M. Howell2, E. Sahai1;
1Tumour Cell Biology Laboratory, The Francis Crick Institute, London, United Kingdom, 2High Throughput Screening Laboratory, The Francis Crick Institute, London, United Kingdom, 3Department of Pharmacology, UNC Chapel Hill School of Medicine, Chapel Hill, NC

It is known that the complexity of the cancer is created by a fine interplay between the cancer cells and their microenvironment. Cancer cells interact with various stroma components during tumour growth and development of metastasis. Many signalling pathways influence cross talk between cancer cells and their environment. For example, YAP/TAZ has already been implicated to be an important determinant of cancer progression. However, so far no method provided means of activating signalling specifically in the subset of tumour cells.
We use optogenetic approach to specifically modulate YAP signalling both in vitro and in vivo. By using blue light illumination we can control signalling pathways in space and time. We are developing two different methods to modulate signalling: by translocation of a downstream transcription factor to the nucleus (opto-release) or by controlling expression of transcription factor from light inducible promoter. The specific activation of YAP signalling through the light inducible promoter is followed by in-depth analysis of the possible phenotypic changes in cancer cells and cancer associated fibroblasts (CAFs). Additionally, the opto-release tool is used alongside mathematical modelling to study YAP protein dynamics and nucleocytoplasmic shuttling on single cell level in cancer cells. Finally, we investigate YAP nucleocytoplasmic shuttling machinery. The optogenetic tools allow detailed and previously unachievable analysis of YAP signalling in cancer cells and CAFs.

A low affinity leukotriene B4 receptor-2 regulates proliferation of malignant Colon Cancer Cells.
J. Park1, J. Kim1;
1Department of Biotechnology, College of Life Sciences and Biotechnology, Korea university, Seoul, Korea, South

Inflammation and inflammatory mediators are intimately linked with colorectal cancer progression through complex pathways. However, the mechanism by which leukotriene B4 (LTB4) and 12S-hydroxy-5Z,8Z,10E,14Z-eicosatetraenoic acid (12-HETE) contribute to colorectal cancer progression remains elusive. In this study, we determined that the low-affinity leukotriene B4 receptor-2 (BLT2) and its ligands leukotriene B4, 12-HETE were highly up-regulated in KRAS mutated SW480 and LOVO colorectal cancer cells and affect the proliferation through the activation of Phosphoinositide 3-kinase (PI3K)-Protein kinase B (Akt) and the subsequent up-regulation of Cyclin D1. BLT2 depletion with siRNA and LY255283 clearly down-regulated the proliferation of KRAS mutated colorectal cancer cells and further increased G1 phase cell cycle arrest by down-regulating the PI3K-Akt cascade. Enlarged tumour formation due to the KRAS mutation of LOVO and SW480 cells in xenografted mice was also obviously reduced by treatment with the BLT2 inhibitor in vivo. Our study elucidates that BLT2 is a novel contributor to inhibit growth effect in KRAS mutated colorectal cancer cells and thus may be a potential therapeutic target for the treatment of KRAS mutated colorectal cancer.

Transmembrane 4 L six family member 5 (TM4SF5) forms complex with SLC members for cell survival and homeostasis.
J. Kim¹, J. Lee¹;
¹Pharmacy, Seoul National University, Seoul, Korea, South

TM4SF5 is one of the transmembrane 4 L 6 family which has similar domain structure and function with tetraspanin. Tetraspanin associates and interacts with several partner proteins in plasma membrane to form TERM (Tetraspanin-enriched microdomains). Protein complex formed by TM4SF5 contribute to cell adhesion, invasion and migration. To investigate other diverse roles of TM4SF5 and TERM, mass spectrometry analysis was performed. Mass spectrometry data show TM4SF5 interacts with many SLC (Solute Carrier) family. However, the roles and significance of TM4SF5 to regulate SLC family remain unclear. We focused on the complex formation of TM4SF5 with an antiporter which imports cysteine into cells and exports glutamate. TM4SF5 upregulates a CD44 variant, which increases protein stability of the antiporter. In addition, TM4SF5 interact directly with the antiporter together with the CD44 variant. TM4SF5 increases intracellular GSH dependent on the antiporter and the CD44 variant. In addition, TM4SF5 attenuates cellular ROS level in response to extracellular and intracellular ROS stimuli. Moreover, RNA-seq data show TM4SF5 upregulates antioxidant genes in cell line and knockout mouse model. In conclusion, our study reveals the novel mechanism of SLC regulation and its function contributing to cell survival and cellular homeostasis.

Large-scale expansion and banking of novel 2D and 3D cancer models from the Human Cancer Models Initiative: Results of a pilot study.
J. Clinton¹, A. Ruchinskas¹, P. McWilliams-Koeppen¹, S. Paul¹, D. Yin¹, R. Newman¹;
¹ATCC Cell Systems, ATCC, Gaithersburg, MD

The Human Cancer Models Initiative (HCMI) is an international collaboration between the National Cancer Institute, Cancer Research UK, Wellcome Trust Sanger Institute, and the foundation Hubrecht Organoid Technology, devoted to the development of approximately 1,000 novel human primary tissue derived tumor models. These models will utilize advanced in vitro cell culture techniques that better mimic human in vivo tumor physiology than traditional cancer cell lines, and will be supported by clinical and genomic data. Some of these next-generation cancer models will be derived from tumors that are rare, lack effective treatments, originate from patients from underrepresented populations, or are otherwise not well represented amongst currently available cancer cell lines. While the laboratories supporting the HCMI project are focused on early-stage model development, little attention has been given to issues of scale up for expansion, the need for quality control assays, and the standardization of protocols. Additionally, the advanced culture techniques being utilized to generate these models pose challenges for typical large-scale expansion and banking, including the requirements for specialized feeder cells, growth in undefined extracellular matrices, complex media formulations containing multiple growth factors and small molecules, and use of undefined conditioned media from multiple other cell lines. Herein we describe the results of a pilot project to determine the feasibility of performing large-scale expansion and banking of novel cancer models derived from esophageal, colon, pancreatic, and mammary tissues. We found significant laboratory to laboratory differences in protocols, reagents and culture conditions even for models derived from the same culture technology.
and primary tissue. Tissue to tissue and donor to donor variation was also evident in model characteristics, including morphology, growth rates and genetic instability. All the models tested were amenable to scale up from multiwell plates to flasks, though more specialized consumables were required than with typical continuous cell lines. Conversely, population doubling times and yields per cm² for many models were similar to traditional 2D cell lines, though viability as assessed by trypan blue exclusion was often low (<80%). Models exhibited tissue-like architecture and cell-type relevant markers as assessed by immunocytochemistry and immunohistochemistry. Multiple commercially available cryopreservation media were able to support cryopreservation and recovery. Our results suggest that despite challenges, next-generation in vitro models are suitable for large-scale manufacture and distribution to support researchers in a variety of applications in the field of cancer biology.

Breast cancer (BC) is the most threatening cancer type among the women in many countries. Despite of the major developments in medical sciences and technologies, the incidence and mortality rates of BC is still increasing, making it the number one cause of death among women. Detection of BC at an early stage increases the chance of survival and reduces the burden of the disease. Although there are certain BC biomarkers routinely used for prognostic and predictive purposes, none of these biomarkers are useful for the early detection of the BC. Therefore, the early diagnosis of BC still remains an important challenge and there is a great need for the early-diagnostic biomarker(s). The aim of this study is to discover a (or more than one) biomarker molecule(s) that will allow early diagnosis of the BC. For this purpose, tissue samples from BC patients were collected for analysis. Patients with invasive or infiltrative ductal carcinoma have been included to this study. Based on their clinicopathological data, patients were classified into 3 molecular subtypes: Luminal A (LA), Luminal B (LB), Luminal B-like Her2+ (LB-Her2+) and each group contained 34, 33, and 14 patients, respectively. The control group was created using part of the healthy breast tissues obtained from the same BC patients. Protein extracts were prepared and protein pools for each group were created and subjected to 2-DE coupled with MALDI-TOF/TOF. Comparative 2-DE analysis revealed the presence of a total of 39 differentially regulated protein spots among the groups. However, of these, 37 proteins displayed changes in their abundance for at least 2-fold when the BC groups were compared with the control group. The highest level of differential regulation was observed in proteins monoglyceride lipase, carboxypeptidase B, Pyruvate kinase isozymes M1/M2, Stress-70 protein, L-lactate dehydrogenase B chain, Carbonic anhydrase 1 and Aldo-keto reductase. The proteome profiles of LA, LB, and LB-like Her2+ subtypes were more conserved indicating that the subtyping of hormone receptor positive tumor tissues was not profoundly reflected onto the regulations occurring at the proteome level.

The importance of cellular oxygenation measurements in the analysis of hypoxia-induced signalling and related metabolic adaptation.

M. Potter1, J. Hynes2, A. Nijhuis3, C. Carey2, C. Zois1, A. Harris1, H. Keun3, K. Morten1;
1University of Oxford, Oxford, United Kingdom, 2Luxcel Biosciences, Cork, Republic of Ireland, 3Imperial College London, London, United Kingdom

There is a growing appreciation that typical cell culture conditions reflect a hyperoxic condition for the majority of cell types. In an effort to more accurately reflect the in vivo condition, a growing number of researchers are conducting in vitro measurements at what are deemed to be more physiologically relevant oxygen concentrations (1-8% O₂). The importance of oxygen concentration in in vitro model design is underscored by observations that O₂ levels influence a wide range of cellular phenomena, including metabolic poise and senescence while the development of localised hypoxic environments are implicated in a variety of disease including stroke, and cancer. Impaired O₂ supply can reduce O₂ concentrations to below normal physiological levels, initiating a graded series of complex interconnected adaptive responses mediated by regulators including the hypoxia-inducible factor (HIF). These processes are particularly relevant within solid tumours, where oncogene-driven proliferation causes nutrient and oxygen deprivation, aberrant angiogenesis, and the activation of O₂-sensitive survival pathways. Despite the importance of cellular oxygenation, research using in vitro models makes the assumption that oxygenation can be defined by simply altering the oxygen condition applied i.e. cells cultured in a 5% O₂ environment are assumed to have an intracellular O₂ level of 5%. To test this key assumption, cellular oxygenation measurements are performed using a nanoparticulate intracellular oxygen probe (MitoXpress-Intra), while tumour hypoxia/oxygenation is modelled on a fluorescence plate reader equipped with an atmospheric control unit (CLARIOstar). Data is presented illustrating that the depth of hypoxia experienced by the cell model is impacted significantly by respiratory activity, and that this additional oxygen deprivation is a dynamic process, effected by respiratory substrate availability. Data is also presented demonstrating that, in in vitro models, additional respiration-induced hypoxia directly impacts glycolytic flux and metabolic pathways. Together these data invalidate the assumption that cellular oxygenation can be inferred from ambient oxygen measurements. If ignored, the significant and dynamic deviations between ambient O₂ and oxygenation at the cellular level leads to erroneous conclusions regarding the relationship between oxygen concentration, HIF stabilisation and related metabolic adaptations. This in turn can impair the physiological relevance of experimental observations.

Tunneling nanotubes (TNTs) have been recently recognized as a new form of intercellular connection and communication. They allow for the transfer of various cellular components, including proteins, RNAs, vesicles and organelles, such as mitochondria, between two distant cells. They have been proposed as an important way by which signals propagate in cancer, neurodegeneration and many other situations. Here we have studied the presence and role of TNTs formed between chronic myeloid leukemia (CML) and stroma cells. Using different microscopy methods, including live imaging and 3D reconstruction, we have found that leukemia cells possess very limited capacity to form TNTs between each other (1 TNT/100 cells). However, upon co-culture, the number of TNTs formed between leukemia and stroma cells significantly increased (35 TNTs/100 cells) and they constituted almost 27% of all formed TNTs. This correlated with leukemia cells receiving vesicular cargo, transferred specifically when cells could be in direct contact. Vesicular exchange, quantified by tracking vesicles labeled with DiD by flow cytometry, was more efficient when stroma cells served as donor and leukemia as acceptor cells (51.4 +/- 3% of leukemia cells received cargo after 24 hours), compared to the opposite direction (20 +/- 2.1% of stroma cells). Functionally, separate analysis of leukemia acceptor cells (DiD+) which received fluorescently-labeled vesicles from stroma and those which did not exchanged cargo (DiD-) indicated that transferred vesicles may provide protection from apoptosis caused by imatinib, a first line drug in CML treatment, resulting in decrease of apoptotic population by 40% (n=4, p<0.005). Importantly, trans-SILAC MS identification and quantification of proteins transferred from donor to acceptor cells showed that different groups of proteins are exchanged bidirectionally between leukemia and stroma cells. In conclusion, TNTs formed between leukemia and stroma cells facilitate the intercellular transfer of vesicular cargo and specific proteins, which may be important in facilitating drug resistance in cancer cells.

3-D Carcinoma Cell Culture Model for in vitro Evaluation of Anticancer Drugs.

N. Hansraj1, F. Guittaye1,2, A. Madabushi1, L. Jackson1,3;
1Natural Physical Sciences, Baltimore City Community College, Baltimore, MD, 2Department of Biology, Morgan State University, Baltimore, MD, 3Department of Biology, University of Maryland, Baltimore County, Baltimore, MD

3-dimensional (3D) culture of human lung carcinoma cells can favorably replace the conventional 2-dimensional (2D) culture for a closer simulation of in vivo conditions. Lung adenocarcinoma alveolar basal epithelial cells (A549) are known to grow 2-dimensionally in tissue culture dishes. Cells can be cultures in vitro in an adaptable 3D environment using alginate beads or specialized cell culture dishes to form spheroids. In this project, we grow lung cells 3-dimensionally using alginate beads. The alginate beads incorporating lung cells were formed and maintained in mammalian cell culture media. The cell viability of A549 cells was studied using trypan blue assay as needed. We are utilizing our 2-D versus 3-D cell culture models to do a variety of assays testing the efficacy of chemotherapeutic agents. We are also exploring them as an excellent alternative for long-term, low-cost cell propagation.

In contrast to their well-studied condensation and folding during mitosis, the dynamics of interphase chromosomes are less understood. We developed a multicolor and sensitive system, CRISPR-Sirius, allowing us to track the dynamics of pairs of loci on a single human chromosome in real time throughout interphase. We measured the inter-locus distances from kilobase to megagase scales as compared to the DNA physical map and found cell cycle stage-dependent changes in the inter-locus distance. In addition, we resolved two distinct modes of dynamics: local saltatory movements as well as longer-range domain translational movements. The magnitude of both of these dynamic substantially increased from early to late G1, whereas the domain translational movement was greatly reduced in early S. The local saltatory fluctuations decreased slightly in early S and declined further in late S. These unanticipated movements are indicative of both a compression-relaxation dynamic of the chromosome fiber operating concurrently with changes in the extent of long-range movements of an observed domain. It should now be possible to address the relationship these dynamic phenomena to DNA replication and repair, epigenetic modification, transcription regulation, and stem cell differentiation.

Measuring local chromatin compaction using fluorescence lifetime imaging.
P. Choppakatla\textsuperscript{1}, H. Funabiki\textsuperscript{2};
\textsuperscript{1}Funabiki Lab, Rockefeller University, New York, NY

The linear length of genomic DNA is many orders of magnitude greater than the size of the nucleus. To fit a eukaryotic genome into the nucleus, DNA undergoes several different levels of compaction. DNA compaction also affects protein accessibility of DNA elements and thus can contribute to transcriptional regulation. Traditional size estimation methods to study compaction, such as DNA volume measurements or proximity of distant chromosomal loci are limited in their resolution by the wavelength of light. This presents a large-scale picture that aggregates many different compaction processes. Thus data regarding local changes in compaction has been difficult to obtain. To circumvent this problem, we apply a new microscopy technique that uses changes in fluorescence lifetime of DNA binding dyes to measure local changes in DNA compaction. We have shown that the lifetime faithfully responds to a number of established protocols that induce DNA compaction, such as nucleosome formation, and addition of magnesium or spermine. We also used the sensor to study the impact of linker histone H1, related remodeling complex and condensin on local chromatin structure. The implication in the differential regulation of the local and global chromatin compaction will be discussed.

Structure and dynamics of the Polycomb body.
J. Smigova, P. Juda, O. Raska, E. Bartova, I. Raska;
1Charles University, First Faculty of Medicine, Prague, Czech Republic, 2Institute of Biophysics of the CAS, v.v.i., Brno, Czech Republic

The subcompartmentalization of the cell nucleus into nuclear domains seems to be the fundamental principle that regulates the functioning of the nucleus. Our research has been concentrated on one of the nuclear domains known as a Polycomb (PcG) bodies. The PcG body is observed by fluorescence microscopy as a nuclear subcompartment in the form of a fluorescent PcG focus enriched in Polycomb repressive complex 1 (PRC1) proteins. In our work, we were first interested in the structural basis of the PcG body in mammalian (primarily human) cells. Using correlative light-electron microscopy, we visualized the fine structure of the PcG body. We observed that the so-called PcG body (PcG focus) corresponds to a local accumulation of heterochromatin structures. To strengthen chromatin nature of PcG foci, crowding experiments were carried out. We observed that the behaviour of PcG foci in cells grown under changed molecular crowding conditions vastly differs from the behaviour of proteinaeous nucleoplasmic bodies, but is in harmony with the behavior of chromatin domains. Further, we were interested in the dynamics of PRC1 proteins within PcG foci and the structural changes of the PcG chromosomal domain during DNA replication. Dynamics of PRC1 proteins within PcG foci was high and, interestingly, we observed the presence of PRC1 proteins on replicating PcG domains and the asynchrony in replication timing of PcG foci. We also detected a decompaction of the PcG chromosomal domains during their replication. Together, our findings show that the PcG body is a chromosomal domain, the dynamics of PRC1 proteins in PcG foci is high, and the replication of the PcG chromosomal domain is accompanied with changes in chromatin structure within the PcG focus. Condensin II drives large-scale chromatin folding and genome compartmentalization in Drosophila.
L.F. Rosin, S. Nguyen, O. Crocker, E. Joyce;
1Genetics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

Proper nuclear organization is essential for development and organism viability. Both chromosome confirmation capture (3C)-based methods and fluorescence in situ hybridization (FISH) have shown that chromosomes occupy distinct nuclear domains called chromosome territories (CTs). The fact that CTs have been observed in a broad range of species suggests that their formation may play a role in vital cellular processes, such as transcription and DNA repair. In support of this, CT disruption has been seen in several human diseases, including numerous forms of cancer, correlating CT loss with gene misexpression and genome instability. However, the genes involved in the formation and maintenance of CTs remain unknown. Using a combination of forward and reverse genetics, we address these fundamental questions in Drosophila, targeting their relatively small number of chromosomes with whole-genome, multi-color, and chromosome arm-specific Oligopaint FISH probes. Our data reveal that Drosophila cells form largely non-overlapping CTs, indicating that heterologous chromosomes minimize their intermingling during interphase. Additionally, the use of whole-genome Oligopaints on metaphase
chromosome spreads illustrate that large chromosomal rearrangements can be correlated with the spatial orientation of DNA during interphase. Finally, we have identified the condensin II complex as an essential factor that inhibits interchromosomal interactions and facilitates chromosome folding during CT formation. Collectively, these analyses show that Drosophila cells and Oligopaint FISH provides a powerful platform for assessing CT function and characterizing the regulatory pathways that control chromosome packaging and positioning in a metazoan.

BAC transgene arrays as a system to dissect regulatory elements of large-scale chromatin organization.

B. Zhao¹, A.S. Belmont¹;
¹Cell and Developmental Biology, University of Illinois, Urbana, IL

Dissecting mechanisms regulating large-scale chromatin organization in mammalian cells is difficult largely due to the complexity of the mammalian genome and the lack of efficient ways both to manipulate the sequence and then to visualize the consequences of these manipulations on chromatin folding and nuclear localization. Adding to these difficulties is the significant functional redundancy of cis elements controlling large-scale chromatin organization. Here we show how bacterial-artificial chromosomes (BACs) may be a powerful tool to dissect determinants of large-scale chromatin organization. BACs can integrate into the mammalian genome as tandem arrays of up to mega-base pairs in size. These arrays have much lower DNA complexity than endogenous genomic regions of comparable size, yet they retain near normal levels of expression for the genes contained within the BAC genomic inserts. Moreover, BAC DNA sequences can be efficiently manipulated by BAC recombineering within E.coli. We reconstituted differentially compacted chromatin regions in mouse NIH 3T3 cells by altering the genomic inserts within the BAC scaffold. BAC arrays formed from a BAC harboring an actively transcribed Dhfr-Msh3 gene locus (DHFR BAC) showed extended, fiber-like structures. In contrast, BACs harboring a transcriptionally silenced HBB locus (HBB BAC) or a gene desert region formed BAC arrays with noticeably more condensed structures. Manipulation of these BAC sequences revealed interesting clues to determinants of large-scale chromatin organization. For example, deleting large regions encompassing the Dhfr-Msh3 divergent promoter increased the compaction of these BAC arrays. Based on ongoing experiments, this increased compaction does not appear to be simply the consequence of decreased transcription. For example, overall transcription of the BAC array, assayed by RT-qPCR, remained high and transcriptional inhibition did not change the structure of arrays made from intact DHFR BACs. Our current working hypothesis is that these promoter regions have cis elements and bound trans factors that produce large-scale chromatin decondensation at a distance.

As another example, our work demonstrated that reporter mini-genes containing a strong housekeeping gene promoter from a gene expressed at similar levels in many cell types appeared imperious to differences in large-scale chromatin structure of these BAC arrays. Interestingly, this reporter mini-gene changed the nuclear localization of the HBB BAC transgene array from the nuclear periphery to interior, and possibly certain epigenetic marks. These results suggest an experimental path forward to identify separable pathways that control large-scale chromatin compaction versus nuclear localization.

DNA Helicase and temperature regulation of mitotic chromosome condensation.
D. Shen¹, R.V. Skibbens¹;
¹Biological Sciences, Lehigh University, Bethlehem, PA

Chl1 DNA helicase plays multi-faceted roles in sister chromatid cohesion. For instance, Chl1 associates with both the cohesion establishment acetyltransferase Eco1/Ctf7 and the DNA polymerase processivity factor PCNA that supports Eco1/Ctf7 function. Mutation in Chl1 results in precocious sister chromatid separation and cell aneuploidy, defects that arise through reduced levels of chromatin-bound cohesins which normally tether together sister chromatids. Key insight into the mechanism through which Chl1 helicase promotes the tethering of DNA segments in trans (between sister chromatids) was revealed through its role in recruiting Scc2 (cohesin deposition component) to DNA. A single report suggested that Scc2 might also direct the deposition onto DNA of the cis tethering condensin complex. Here, we developed a streamlined rDNA condensation assay and then tested the ability of Chl1 to promote cis tethering. The results reveal that chl1 mutant cells exhibit moderate condensation defects both within the rDNA locus and genome-wide. We then further assessed the roles for both Chl1 and Scc2 to promote condensin recruitment to DNA. Importantly, chl1 and scc2-4 mutant cell condensation defects appear primarily to occur through reduced chromatin binding of cohesin. Consistent with a role for Scc2 specifically in cohesin deposition, scc2-4 mutant cell condensation defects are irreversible – in contrast to prior findings that condensin-dependent condensation defects are reversible. We thus term Chl1 a novel regulator of both chromatin condensation and sister chromatid cohesion through cohesin-based mechanisms. Combined with findings that Chl1 functions during S phase and resolves DNA secondary structures, these results reveal an exciting interface between DNA structure and cohesin complex functions. Surprisingly, our streamlined condensation assay uncovered a heretofore dramatic change in rDNA conformation in response to temperature. This apparent hypercondensation occurs in wildtype cells, independent of mutation maintained at 37°C, compared with cells maintained at 23°C. Neither accelerated condensation, elevated recombination nor reduced transcription appear to promote this reduction in rDNA loop structure. This observation impacts current views of chromatin structure based on conditional mutant gene analyses and significantly extends our understanding of physiologic changes in chromatin architecture in response to hyperthermia.

Genome organization and metastatic potential in breast cancer.
M. Gaillard¹, J. Cutler¹, T. Luperchio¹, B. Brener², P. Wu³, J. Taylor², D. Writz³, K. Reddy¹;
¹Biological Chemistry, Johns Hopkins University, School of Medicine, Center for Epigenetics, Baltimore, MD, ²Biology and Computer Science, Johns Hopkins University, Baltimore, MD, ³Chemical and Biomolecular Engineering, Johns Hopkins University, Institute for Nanobiotechnology, Baltimore, MD

The human genome exhibits a higher-order organization and architecture within the highly compartmentalized nucleus. For instance, association of chromatin with the nuclear periphery as the so-called Lamina Associated Domains (LADs) has been implicated in gene regulation, particularly correlating with gene repression. Such organization and compartmentalization is intimately associated with epigenetic modifications to both DNA and histone proteins modifications that distinguish heterochromatin from euchromatin. However, the mechanisms involved in dysregulation of chromatin and overall nuclear architecture in breast cancer remain largely unknown. Like most carcinomas, breast
cancers develop through multiple genetic and epigenetic changes that culminate in oncogenic transformation, deregulated cell growth and, for a subset of these, metastatic potential. Large changes in nuclear morphology or ‘nuclear grade’ are key criterion for pathologic diagnosis of many cancers, including breast cancer, and gross changes in nuclear morphology are generally associated with tumor progression. By using high throughput genomic data, such as DNA Adenine Methylation Identification (DamID) to identify LADs, combined with RNA-seq, we intend to decipher the inter-relationship of genome organization and dysregulation of transcription in breast cancer by comparing normal epithelial breast (MCF10A, HMECs) with -breast cancer cell lines (MCF7, MDA-MB231). We also decrypt the relationship between genome organization and metastatic potential by analyzing single colony clones (SCCs) from MDA-MB231 with different tumorigenic and metastatic potentials. Our preliminary data show that 20%-25% of up-regulated mRNAs were found in regions where LAD organization was disrupted. In particular, ESM-1 and SPANX loci were upregulated and no longer associated with the nuclear lamina in the highly metastatic clones. Intriguingly, SPANX, ESM1, and HMGA1 genes have all been linked with a highly aggressive and invasive phenotype in breast cancer. Genes not in LADs were also differentially regulated including HMGA1 (High Mobility Group protein 1) which is involved in chromatin decomposition and the formation of distorted DNA structures. These early results suggest that LADs and chromosome organization become disrupted during tumor progression, providing molecular insights into pathological findings correlating highly disorganized nuclei with poor prognosis.

Lamina associated domain dynamics during cell cycle investigated by super-resolution microscopy.
E. DeBoy¹, J. Cutler¹, M. Gaillard¹, K. Reddy¹;
¹Biological Chemistry, Johns Hopkins University School of Medicine, Baltimore, MD

3D nuclear organization and compartmentalization are important for regulation of gene expression. Lamina Associated Domains (LADS) are regions of chromatin associated with or in close proximity to the nuclear lamina. These regions are enriched in heterochromatin and genes found within them are largely inactive. Lamin A and C are hypothesized to be necessary for maintenance of this organization, at least in more differentiated cell types. Using murine fibroblast cells expressing the m6A tracer system and a GFP-coupled single chain antibody to detect LMNA/C we are able to study the dynamics of LADs and lamin protein using live cell imaging. Intriguingly, during the cell cycle we observed changes in LAD localization and organization consistent with a loss of organization during mitosis and robust reorganization in early G1. During G1 phase the LADs are organized at the periphery of the nucleus and associate with the nuclear lamina. In prophase, LADs collapse together at the periphery of the nucleus before moving to the center as full chromatin condensation occurs. LADs do not immediately return to the periphery after division but return several hours into G1 by an undetermined mechanism. Importantly, LADs maintain self-association throughout cell cycle. Imaging this system using super resolution microscopy, including the Nikon N-SIM and 3i lattice light sheet microscopes, revealed novel structural features of the LADs at a much higher resolution. Rather than appearing as a continuous layer within the nuclear lamina, the LADs form globules that associate with the lamina and each other in a dynamic fashion. These results emphasize the role of self-association in maintaining LAD organization and contribute to our overall understanding of LAD and nuclear organization.

Extracellular divalent ions rescue aberrant nuclear morphology through a novel heterochromatin formation pathway.
P.Z. Liu1, A.D. Stephens1, L.M. Almassalha2, H. Chen3,4, T. O’Halloran3,4, V. Backman2, S.A. Adam5, R.D. Goldman5, E.J. Banigan6, J.F. Marko1,6;
1Department of Molecular Biosciences, Northwestern University, Evanston, IL, 2Department of Biomedical Engineering, Northwestern University, Evanston, IL, 3Department of Chemistry and Department of Molecular Biosciences, Northwestern University, Evanston, IL, 4The Chemistry of Life Processes Institute, Northwestern University, Evanston, IL, 5Department of Cell and Molecular Biology, Northwestern University Feinberg School of Medicine, Chicago, IL, 6Department of Physics and Astronomy, Northwestern University, Evanston, IL

The nucleus is a dynamic organelle responsible for maintaining the structural and functional organization of the genome. Proper nuclear morphology is critical for gene localization, gene expression, differentiation, and cellular function. In several human diseases, including progeria, cancers, and dystrophies, nuclear morphology becomes severely altered and exhibits protrusions termed “blebs”. Nuclear blebs are associated with altered lamina content and chromatin compaction. It is widely believed that lamina perturbations are responsible for bleb formation, but the role of chromatin compaction state in this process is poorly understood. We find a novel signaling pathway through which extracellular divalent ions (Mg+2 and Ca+2) alter histone modification state, which then dictates nuclear blebbing independent of lamins. Treating mammalian cells with histone deacetylase inhibitors increases euchromatin levels and leads to nuclear blebbing without altering lamin content. Conversely, treating histone deacetylase inhibitor induced blebs with divalent ions rescues nuclear blebs in a dose dependent fashion. Immunofluorescence confocal imaging reveals that treatment with divalent ions significantly increases the heterochromatic marks H3K27me3 and H3K9me2,3. Micromanipulation force measurements of isolated nuclei also reveal that nuclear morphology is tightly coupled with chromatin-based nuclear rigidity, which is determined by histone modification state. Furthermore, divalent ions also rescue aberrant nuclear morphology associated with lamina perturbations. Nuclear blebbing associated with lamin B1 depletion as well as nuclear morphological abnormalities in Hutchinson-Gilford Progeria Syndrome caused by mutant lamin A can be rescued via treatment with extracellular divalent ions. Immunofluorescence imaging reveals that treatment with extracellular divalent ions does not alter lamin levels, but instead restores heterochromatin markers that are depleted in these cells. Interestingly, even abnormal morphology of nuclei in the breast cancer model MDA-MB-231 can be partially rescued through increased extracellular divalent ions. Therefore, chromatin compaction through histone modification state is a major determinant of nuclear morphology and presents a potential therapeutic target.

Characterization of nucleolar-localized H4 histone variant, H4G.
M. Long1, W. Shi1, X. Sun1, T. Ishibashi1;
1Life Science, The Hong Kong University of Science and Technology, HONG KONG, Hong Kong

Histone variants are the non-allelic variants of core canonical histones. Numerous studies have showed their diverse roles in chromatin regulation. The most studied histone variants are those of H3 and H2A. Compared to H1, H2A, H2B and H3, histone H4 is considered to be the only one without histone
variants. We identified a primate-specific histone H4 variant HIST1H4G (H4G). The H4G protein has 85% protein sequence identity with canonical H4. We detected H4G RNA expression in malignant breast cancer cell lines MCF7, MCF7/LCC1 and MCF7/LCC2 but not in benign breast epithelial cell line MCF10a. Immunostaining of tagged-H4G shows its subcellular localization in nucleolus and cytoplasm whereas canonical H4 localizes in the nucleus. We further identified that amino acids in the third alpha helix of globular domain are responsible for H4G nucleolar distribution. In addition, we found that a nucleolar protein nucleophosmin1 (NPM1) interaction with H4G through the third alpha helix leads to H4G nucleolar localization. In conclusion, our research has characterized a new nucleolus localized histone variant H4G and identified NPM1 as a chaperone targeting H4G to nucleolus.

Hippocampal Neuron Stimulation Promotes Intracellular Tip60 HAT Dynamics with Concomitant Genome Reorganization and Synaptic Gene Activation.

A.M. Karnay¹, F. Elefant²;

¹Neurobiology and Anatomy, Drexel University, Philadelphia, PA, ²Biology, Drexel University, Philadelphia, PA

Coordinated transcription of genes within mammalian nuclei in response to external stimuli is a highly orchestrated process involving the interplay between epigenetics-mediated chromatin remodeling and RNA polymerase-mediated transcription. Recently, the emergence of the concept of transcription factories (TFs), characterized as specialized nuclear subcompartments enriched in hyperphosphorylated RNAPII and transcriptional regulatory proteins, suggests the potential for an additional mechanism directing coordinated and efficient gene transcription. While these nuclear transcriptional ‘hot spots’ have been implicated in the transcriptional co-regulation of partner genes in other cell types, its presence in hippocampal neurons and its role in activity-dependent transcriptional control within the brain remains relatively unexplored. Furthermore, while previous findings indicate a functional relevance of histone acetylation in activity-dependent gene expression, the full array of histone acetyltransferases (HATs) involved in this process remain to be determined. Our findings reveal that the HAT Tip60 shuttles into the nucleus following extracellular stimulation of rat hippocampal neurons and by utilizing chromatin immunoprecipitation (ChIP), further show that Tip60 binding patterns on activity-dependent synaptic plasticity genes are altered in response to extracellular stimulation. Combining immunocytochemistry with DNA fluorescent in situ hybridization, we show that neuronal stimulation alters the localization of these genes within the nucleus, corresponding to the mobilization of these co-regulated genes to RNAPII-rich TFs. Lastly, we show that Tip60 is found within the same TFs as the co-regulated synaptic plasticity genes following neuronal stimulation. Taken together, these data suggest that specific, directed compartmentalization of target genes, HATs and transcription machinery within hippocampal nuclei occurs following the introduction of external stimuli thereby enabling efficient, coordinated gene transcription. Our findings provide insights into a fundamental physiological gene expression paradigm governing transcriptional activation of co-regulated genes in response to external stimuli in hippocampal neurons.

β-actin dependent global chromatin organization and gene expression programs control cellular identity.
X. Xie², B. Almuzaini², N. Drou¹, S. Kremb⁵, A. Yousif¹, A. Ostlund Farrants³, K. Gunsalus¹,⁴, P. Percipalle¹,³; ¹Biology Program, New York University - Abu Dhabi, Abu Dhabi, United Arab Emirates, ²Department of Medical Genomic, King Abdullah International Medical Research Center, Ryad, Saudi Arabia, ³Molecular Biosciences, The Wenner-Gren Institute, Stockholm University, Stockholm, Sweden, ⁴Center for Genomics and Systems Biology and Department of Biology, New York University, New York, United States

During differentiation and development, cell fate and identity are established by waves of genetic reprogramming. Although the mechanisms are largely unknown, during these events dynamic chromatin reorganization likely functions to ensure that multiple genes involved in the same cellular processes are co-regulated depending on the nuclear environment. Emerging evidence suggests that changes in chromatin dynamics and genome organization may be dependent on nuclear actin and its function as part of chromatin remodeling complexes. In this study we determined the functional impact of β-actin on genome organization and gene activity. Using high content profiling of embryonic fibroblasts from a β-actin knockout mouse, we report major chromatin rearrangements and changes in histone modifications such as methylated H3K9. Genome-wide H3K9Me3 landscape changes correlate with gene up-regulation and down-regulation in β-actin knockouts. As part of the BAF complex, β-actin regulates the ATPase subunit Brg1. Compatible with this findings, we found a general loss of chromatin association at multiple genomic sites by the BAF chromatin remodeling complex subunit Brg1 in the absence of β-actin. Transcriptional profiling by RNA-seq revealed that actin-dependent chromatin reorganization was concomitant with the up-regulation of sets of genes involved in angiogenesis, cytoskeletal organization and myofibroblast features in β-actin knockouts. Some of these genes and phenotypes were gained in a β-actin dosage-dependent manner. Moreover, reintroducing an NLS-containing β-actin in the knockout cells affected nuclear features and gene expression. Collectively our results suggest that, by affecting the genome wide organization of heterochromatin through the chromatin-binding activity of the BAF complex, β-actin plays an essential role in the determination of gene expression programs and cellular identity.

PRC2-Ezh1 mediates transcription of hippocampal genes.
M.A. Saez¹, B. Van Zundert¹, M. Montecino¹; ¹Center for Biomedical Research, Andres Bello University, Santiago, Chile

Methylation in lysine 27 of histone H3 (H3K27me3) is mainly known as a critical component of gene silencing mechanisms during cell differentiation. This methylation is mediated by the widely-distributed Polycomb Repressive Complex 2 (PRC2). PRC2 methylase activity lays in both Ezh1 and Ezh2 catalytic subunits. Ezh1 is the main form in postmitotic cells, exhibits lower enzymatic efficiency, and has been also found associated with transcriptionally active promoters. Here, we have analyzed global profiles of H3K27me3 and H3K27Ac enrichments using publicly-available ChIP-seq data (http://www.ncbi.nlm.nih.gov/gds) from mouse hippocampal tissue. Ezh1 genomic distribution in hippocampi as well as in FACS-purified hippocampal neural nuclei was also assessed by Chip-seq. The data were clustered according to the expression profiles of putative targets. Our results indicate that
Ezh1 isoforms are differentially partitioned within nuclear compartments, with a distribution profile that changes during neuronal maturation. Ezh1 is found enriched at transcriptionally active gene promoters and enhancers and poorly associated with H3K27me3-marked genomic regions. Co-immunoprecipitation analyses show an association between soluble Ezh1 and RNA-Pol II. Together, our results provide a new layer of complexity among the epigenetic mechanisms that control genes associated with hippocampal neuronal function. We propose that PRC2-Ezh1 contributes to transcriptional activity of a selected group of neural genes by interacting, together with RNA Polymerase II, with their promoters and enhancers. Chromatin dependent glucocorticoid receptor plasticity within the cancer genome.
1Epigenetics and Stem Cell Biology Laboratory, National Institute of Environmental Health Sciences, Research Triangle Park, NC

Upon hormone stimulus, type I nuclear receptors (NRs) bind to their hormone ligand, enter the nucleus, and interact with regulatory elements in the DNA to elicit changes in transcriptional activity. NRs are required throughout development and in adult life, and NR activities are frequently targeted in the treatment of human diseases. Activation of Glucocorticoid Receptor (GR) with the synthetic corticosteroid dexamethasone is commonly used to promote fetal lung development and to combat auto-immune and inflammatory disorders. Elucidating the genetic and transcriptional mechanisms by which GR and other NRs perform their myriad functions is critical for human health and disease treatment.

Brg1, the catalytic ATPase of the human SWI/SNF complex, is critical for hormone-induced transcriptional regulation by GR. Previous studies from our lab demonstrated that upon DNA-binding, GR recruits Brg1 to remodel the local chromatin architecture to alter transcriptional output. Our work significantly expands this model and suggests that Brg1 may act on hormone-regulated genes prior to hormone stimulus and GR binding. Using ChIP-seq, we have generated a genome-wide map of Brg1 and GR chromatin interactions in untreated and dexamethasone-treated cells. We show that Brg1 interacts with many GR binding sites in untreated cells and is present at these sites upon dexamethasone treatment and subsequent GR binding. Using these and other data sets, we have identified three classes of GR binding sites that are differentially associated with hormone-dependent transcriptional events. These classes of binding site showed distinct patterns of chromatin accessibility, histone modification, and transcription factor binding. Examination of GR binding in Brg1-deficient cells revealed that disruption and restoration of Brg1 expression selectively alters the chromatin environment at these classes of GR binding sites. Taken together, these data suggest that GR elicits the transcriptional response to hormone via multiple distinct mechanisms that are dependent on specialized chromatin environments. Our classification of these genomic environments provides a more profound understanding of nuclear receptor function that will allow new approaches in drug development and disease treatment.
Tissue specific gene expression plays a critical role in regulating energy metabolism, and understanding the transcriptional mechanisms by which metabolically active tissues such as liver and adipose respond to caloric imbalance holds the key to better treatments for diseases such as obesity and diabetes. In order to better elucidate the transcriptional circuitry underlying these diseases, we set out to map the enhancer proteome in liver tissue, naive mesenchymal stem cells, and differentiating adipocytes using ChIP with selective isolation of chromatin-associated proteins (ChIP-SICAP). ChIP-SICAP targeting of H3K27ac, a well-characterized histone mark of active enhancers, uncovered roughly 500 proteins including sequence-specific transcription factors (TFs) and numerous members of co-activator and co-repressor complexes that define the landscape of active chromatin in hepatocytes and differentiating adipocytes. This analysis revealed a pivotal role for CEBP TFs in establishing enhancers in both settings. Strikingly in liver, both CEBPalpha and CEBPbeta rank within the top-five proteins enriched over IgG control, and they are the top-ranked TFs. To gain further insight into the roles of CEBPs, we performed ChIP-SICAP for CEBPbeta and identified a subset of the proteins comprising the H3K27ac proteome. Interestingly, although CEBP-bound chromatin is enriched for both the nuclear receptor GR and the bZip protein NFIL3 in both liver and differentiating adipocytes, other co-distributing TFs, such as TEADs and HNF1a, show strict tissue-specificity. Moreover, we observe that chromatin remodelers and transcriptional co-activators such as BRD2 and MED8 are dynamically recruited to CEBP-bound chromatin during the course of adipogenic differentiation, suggesting these factors may play important roles in the establishment of active chromatin at sites of CEBP binding. In contrast, repressor proteins such as transducin-like beta 1 X proteins and HDACs appear to be more constitutively associated with CEBP-bound chromatin in both liver and differentiating hMSCs. Together the enhancer proteomes revealed by ChIP-SICAP analyses suggesting novel insights into the establishment of tissue-specific gene expression programs.

Mutations in CDCA7, the SWI2/SNF2 family protein HILLS (LSH), or the DNA methyltransferase DNMT3b, cause Immunodeficiency–Centromeric instability–Facial anomalies (ICF) syndrome. While DNA methylation defects presumably cause this disease, little is known about the molecular function of CDCA7 and its functional relationship to HILLS and DNMT3b. Systematic analysis of how the cell cycle, H3K9 methylation, and the mitotic kinase Aurora B affect chromatin in Xenopus egg extracts revealed that HILLS and CDCA7 comprise a complex whose chromatin binding is inhibited by Aurora B. Although
HELLS alone fails to remodel nucleosomes, we demonstrate that the HHELLS-CDC7 complex possesses nucleosome remodeling activity. Furthermore, CDC7 is essential for loading HHELLS on chromatin, and CDC7 harboring patient ICF mutations fails to recruit the complex to chromatin. Together, our study identifies a unique bipartite nucleosome remodeling complex where the functional remodeling activity is split between two proteins, delineating the pathway defective in ICF syndrome.

**Measuring DNA Methyltransferase Activity in Breast Cancer Cells.**

M. Muyalde\(^1\), L.A. Duran\(^1\), L. Delgado-Cruzado\(^1\);

\(^1\)Program for Research Initiatives in Science and Math, John Jay College of Criminal Justice, New York, NY

Epigenetics is the study of “heritable changes in gene expression not attributed to DNA sequence,” or as Adrian Bird described: “inheritance, but not as we know it” (Bird, 2007). The epigenetic mechanism of DNA methylation, or the addition of a methyl groups to the promoter regions of genes, is mediated in humans by the the DNMT1 enzyme. Abnormal methylation patterns influenced by DNMT1, such as the hypermethylation of tumor suppressing genes (TSGs) and/or hypomethylation of cancer-causing genes (oncogenes), can lead to carcinogenesis and cancer progression. Abnormal methylation is also a hallmark of breast cancer, a leading cause of death among women worldwide. The exact activities and functions of DNMT1 in breast cancer are not clearly understood. In this work, the activity and function of DNMT1 in the MCF-7 breast cancer cell line will be studied. We hypothesize that DNMT1 activity will be increased in MCF-7s in comparison to normal breast cancer cells. To date, standard curves using Bovine Serum Albumin (BSA) protein have been generated to define a linear range of 0-50 ug for quantifying protein in MCF-7 nuclear extracts. Furthermore, we have observed lower DNMT1 activity in MCF-7 nuclear extracts compared to commercially-provided pure DNMT1 with the use of an Enzyme-Linked Immunosorbent assay kit (ELISA). Future work will be done to observe DNMT1 activity in MCF-7s treated with varying concentrations of 5-azacytidine, a known DNA methylation inhibitor, with respect to normal breast cancer cells. This work holds importance in establishing DNMT1 as a potential therapeutic target for breast cancer treatment.

**Dissecting the synthetic lethality between htz1Δ and RPB2-2<sup>5L</sup>: the interplay between RNA Pol II and the nucleosome dynamics.**

M.S. Santisteban\(^1\), C.L. Bright\(^1\), E.G. Gerges\(^1\);

\(^1\)Biology, University of North Carolina at Pembroke, Pembroke, NC

Histone H2A.Z, coded for by the HTZ1 gene in *Saccharomyces cerevisiae*, is a highly conserved variant of histone H2A with many reported important roles in chromosome segregation, transcription regulation, maintenance of heterochromatin-euchromatin boundaries, DNA repair, cell cycle control and resistance to genotoxic stress, among others. Unlike its homologues in other species, the protein is not essential in yeast, as deletion of this gene is not lethal. We previously reported that Htz1 has a role in transcription elongation, but the mechanism of this is not yet understood. We uncovered a synthetic lethality between a HTZ1 null (htz1Δ) and a mutation in the second largest subunit of the RNA pol II (rp2-2). That is, either mutant is viable individually but the combination is lethal suggesting that Htz1 and Rpb2 work together to facilitate an essential function. Moreover, the synthetic lethal phenotype is dominant, i.e. an extra wild type copy of the *RPB2* gene in the *rp2-2* mutant does not alleviate the dependence on

**Monday-226**
Htz1, suggesting that rpb2-2 could stall on the elongation template in the absence of Htz1. In order to study the mechanism of the Htz1 role in transcription elongation, we have focused our efforts on the \(htz1Δrpb2-2^{SL}\) synthetic lethality. A second site suppressor analysis of the \(htz1Δrpb2-2^{SL}\) synthetic lethal uncovered links to \(set2\), which encodes a protein that methylates H3K36 in RNA polymerase II transcribed regions of the genome. It has been shown that in cells lacking Set2, initiation of RNA pol II transcription occurs inappropriately within the protein-coding regions of genes, rather than in the proximal promoter regions; a phenotype that has been referred to as “cryptic” initiation. It is thought that chromatin integrity in the wake of the polymerase passage is compromised in the absence of me-H3K36 and downstream modifications. We tested our strains for cryptic initiation phenotypes and have found that \(htz1Δ\) cells exhibit a mild cryptic initiation phenotype and \(rpb2-2\) has a strong phenotype. A plausible explanation for these results is that the Rpb2-2 mutant polymerase is particularly prone to aberrant transcription initiation and when nucleosome dynamics is altered in the absence of Htz1, the effect is exacerbated.

Investigating the role of NuA4 and Swr1 in regulating RNA splicing in \(Saccharomyces cerevisiae\).
T.S. Gunning\(^1\), L.M. Palfini\(^1\), R.S. Maisner\(^1\), X. Cheng\(^2\), J. Cote\(^1\), T.L. Kress\(^1\);
\(^1\)Biology, The College of New Jersey, Ewing, NJ, \(^2\)St-Patrick Research Group in Basic Oncology, Laval University Cancer Research Center, Quebec City, Canada

Eukaryotes undergo transcription and splicing simultaneously, allowing for coordination and regulation of these two processes. Currently, there are a few known connections between chromatin modification, which regulates transcription, and splicing found in yeast and metazoan, yet there is still much to study. The NuA4 histone acetyltransferase works with Swr1 chromatin remodeling enzyme to promote transcription. First, NuA4 acetylates histone H4, which is recognized by Swr1. Next, Swr1 inserts the histone variant H2A.Z, which is subsequently acetylated by NuA4. Interestingly, in \(Saccharomyces cerevisiae\), both NuA4 and Swr1 play a key role in the transcription of the ribosomal protein genes, which make up a large fraction of the intron containing genes. Thus, NuA4, Swr1, and H2A.Z are excellent candidates for coordinating transcription and splicing. Indeed, a role for H2A.Z in splicing was recently identified. Previous experiments from our lab revealed genetic interactions between genes encoding splicing factors and \(NUA4\) and \(SWR1\). Additionally, we found that deletion of the \(NUA4\) and \(SWR1\) proteins impact the splicing of mRNA. We are now testing whether NuA4 acetyltransferase activity is important for RNA splicing. We generated double mutants that contained a deletion of a splicing factor gene, as well as a point mutation in the catalytic domain of gene encoding the Esa1 subunit of NuA4, and showed that \(ESA1\) shows multiple genetic interactions with various splicing factor genes. We are now utilizing these strains to further elucidate the impact of NuA4 on splicing. Moreover, using a directed genetic screen, we show that mutations that alter the catalytic activity of NuA4 display genetic interactions with \(SWR1\), supporting the possibility of independent functions of each complex in RNA splicing. Together, our data implicate both NuA4 and Swr1 in regulating RNA splicing, and our future work will focus on investigating the specific mechanism(s) by which NuA4 and Swr1 impact splicing.

Elucidating the function of histone H4 acetylation in RNA splicing in *Saccharomyces cerevisiae*. A.G. Mendizabal¹, J.S. Kopew¹, N. Paripati¹, T.L. Kress¹; ¹Biology, The College of New Jersey, Ewing, NJ

The ability of RNA splicing and transcription to take place simultaneously allows for efficient coordination and regulation within cells. Few known connections exist between chromatin modifications, which regulate transcription, and RNA splicing in the yeast *Saccharomyces cerevisiae*, as well as in metazoa, leaving much to explore. Our previous research has shown that genetic interactions exist between splicing protein genes and the NuA4 complex genes in *S. cerevisiae*. In addition, we found that deletion or mutation of these NuA4 complex genes have impact RNA splicing. NuA4 plays a key role in regulating transcription by acetylating histone H4; following this, the Swr1 chromatin remodeling complex is recruited to the acetylated histone and ultimately deposits H2A.Z in place of H2A, allowing for transcriptional activity. Given these findings, our current research is focused on elucidating whether specific acetylation of histone H4 is required for coordinating splicing with transcription. We constructed an array of double mutant yeast strains comprising a deletion of an essential splicing factor gene and a point mutation in either H4K5, H4K8, H4K12, or H4K16 preventing chemical modification and conducted genetic interaction studies to identify synthetic sick/lethal, or suppressive genetic interactions between the two genes. The majority of the double mutant growth phenotypes reveal synthetic sick/lethal interactions when compared to their single mutant parent strains, suggesting a functional link between H4 acetylation and RNA splicing. RT-qPCR was used to determine whether the mutation of H4 resulted in different levels of pre-mRNA splicing. Our data show that there is generally higher accumulation of pre-mRNA in the histone point mutant strains when compared to the wild type, and that this trend is most pronounced in the H4K12 and H4K16 point mutants. In addition, mutation of H4 worsens splicing defects observed in splicing factor deletion strains, consistent with the genetic interactions observed. Our future research will focus on identifying the specific mechanism by which the histone H4 acetylation is functioning to regulate RNA splicing.

Age-related changes in diurnal non-coding RNA correlates with changes in genome-wide facultative heterochromatin. J. Park¹, W. Belden¹; ¹Animal Sciences Department, Rutgers University, The State University of New Jersey, New Brunswick, NJ

The circadian rhythm controls timed choreography of gene expression to maintain normal cell physiology and metabolism. The predominant regulatory mechanism of the circadian rhythm is a transcriptional negative feedback loop that facilitates, and is facilitate by circadian-regulated facultative heterochromatin. The long-term consequence of disrupted diurnal rhythm, or mutations in core clock genes, cause accelerated aging and an increased incidence in age-related diseases. To understand the mechanisms underlying age-related changes to circadian transcription, we performed a combined RNA-seq and ChIP-seq at two diurnal time-points for three different age groups. Our analysis revealed that the core clock genes remain rhythmic expression regardless of age, but circadian output, including numerous ncRNAs, changes dramatically with age. In addition, there is both diurnal and age-related change in Histone H3 lysine 9 trimethylation (H3K9me3) that correlates with the changes in gene...
expression. Collectively, the data suggest a model where age-related changes in diurnal gene expression occur, in part, due to age-related redistribution of rhythmic facultative heterochromatin. The age-related redistribution of rhythmic facultative heterochromatin is potentially mediated by changes in diurnal lncRNA expression creating an interlocked circadian-chromatin regulatory network that undergoes age-dependent metamorphosis.

Neurodegenerative Disease Proteinopathies Are Connected To Distinct Histone Post-Translational Modifications.
M.P. Torrente;
1Chemistry, Brooklyn College- City University of New York, Brooklyn, NY

Amyotrophic Lateral Sclerosis (ALS) and Parkinson’s disease (PD) are devastating neurodegenerative diseases involving the progressive degeneration of neurons. No cure is available for patients diagnosed with these diseases. A prominent feature for both ALS and PD is the accumulation of protein inclusions in the cytoplasm of degenerating neurons; however, the particular protein comprising these inclusions varies. The RNA-binding proteins TDP-43 and FUS are most notable in ALS, while α-synuclein aggregates into Lewy bodies in PD. In both diseases, genetic causes fail to explain the occurrence of a large proportion of cases and, thus, both are considered mostly sporadic. We aim to understand the role of epigenetics in ALS and PD. In particular, we are interested in delineating histone post-translational modification profiles in both yeast and human ALS and PD models. Histones from cell models recapitulating FUS, TDP-43, and α-synuclein proteinopathies are probed for different histone modifications. Remarkably, we find distinctive changes in histone modification profiles for each proteinopathy model. We detect the most striking changes in the context of FUS aggregation: changes in several histone marks support a global decrease in gene transcription. We also detect more modest changes in cells overexpressing TDP-43 and α-synuclein. Our results highlight a great need for the inclusion of epigenetic mechanisms in the study of neurodegenerative disease. We hope our work will pave the way for discovery of more effective therapies to treat patients suffering from ALS, PD, and other neurodegenerative diseases.

Nuclear Envelope As A Physical Barrier In Electrotransfection.
L.D. Cervia1, L. Wang1, C. Chang1, M. Mao1, F. Yuan1;
1Biomedical Engineering, Duke University, Durham, NC

Electrotransfection is one of the widely used gene delivery approaches because it is simple to use, safe, and can result in successful delivery to difficult-to-transfect cells. The main limitation of this technology is low efficiency for some types of cells, compared to viral gene delivery approaches. This is caused partly by a lack of understanding of how plasmid DNA (pDNA) enters cells and travels to the nucleus for successful transgene expression. For exogenous molecules, such as pDNA, to enter the nucleus of a mammalian cell, they must overcome three physical barriers: (1) plasma membrane, (2) cytoplasm, and (3) nuclear envelope. Among them, the last one is probably the strongest barrier to gene transfer. To understand mechanisms of nuclear entry of electrotransfected pDNA, the current study investigated
effects of nuclear envelope break down (NEBD) on electrotransfection efficiency (eTE). The NEBD occurs when cells enter the M phase of the cell cycle. COS7 and HCT116 cells were synchronized in G2-M phase through treatment with nocodazole or released from double thymidine block for eight hours prior to electrotransfection. As a result, a large fraction of cells entered the M phase when electrotransfection was performed. The dissolution of the nuclear membrane was visualized after 30 minute treatment with FM64 dye, which binds to lipids that localize to the nuclear membrane via diffusion and membrane trafficking during this timeframe. Additionally, overexpression of Lamin A fusion protein, which is in direct contact with the inner nuclear membrane, was used to visualize the NEBD. Results from the study showed that both nocodazole treatment and eight-hour release from double thymidine block synchronized cells to G2-M phase. NEBD was observed prior to electrotransfection. The eTE was greatly enhanced by the treatments. These results indicated that eTE depended on the percentage of cells in the M phase within a period after electric pulse application, or the percent of cells that can be successfully transfected may be critically limited by the number of cells in a mitotic state where the nuclear membrane is dissolved. This study confirmed that the nuclear membrane was a critical barrier in delivery of pDNA via electrotransfection, and that dissolution of this barrier could significantly increase transfection efficiency. The significance of the study is two-fold. One is that the study provides new insight on mechanisms of nuclear entry of genes delivered by electrotransfection. The second is that results from the study can be used to develop novel strategies for significantly improving efficiency of electrotransfection, which could make electrotransfection a more competitive method for gene delivery in the clinic.

Characterizing mRNA export at high resolution in individual nuclear pores in single cells.
R. Ben-Yisahy1, A. Ashkenazy1, A. Mor1, A. Shraga1, Y. Garini2, Y. Shav-Tal1;
1Faculty of Life Sciences, Bar-Ilan University, Ramat Gan, Israel, 2Department of Physics, Bar-Ilan University, Ramat Gan, Israel

The export of mRNA from the cell nucleus is one of the pillars of the gene expression pathway in eukaryotes. Conventional light microscopy does not allow high resolution analysis of specific and functional interactions that exported mRNA molecules undergo as they pass from the nuclear side of the nuclear pore complex (NPC), through the inner channel of the pore, and then out to the cytoplasmic side. Such limitations hinder our understanding of the biology of mRNA export within the context of gene expression and its regulation, and require the innovation of new approaches. We set out to characterize interactions involved in the various stages of mRNA transition through the nuclear pore at the level of individual NPCs. Using different types of mRNA export blocks together with single-molecule mRNA tracking in living human cells we could detect the regions of the NPC at which the mRNAs were stuck. Treatments that led to mRNA export blockage were the addition of wheat germ agglutinin (WGA), knockdown of the mRNA export factor NXF1/Tap (Mex67 in yeast), knockdown of Nup153, and the use of a dominant negative Dbp5 helicase. Our results suggest that the initial mRNA binding to the NPC does not require NXF1/Tap, whereas mRNA passage through NPC and release into the cytoplasm does. In accordance, super-resolution microscopy showed that NXF1/Tap is consistently occupying positions within the cytoplasmic side of the NPC. Measurements performed within individual nuclear pores using super-resolution STED microscopy, showed the positioning of NXF1/Tap in individual pores during regular and export blockage conditions. We then could further pinpoint these interactions with specific nucleoporins using a FLIM-FRET approach for measuring protein-protein interactions inside single NPCs. Altogether, these approaches have allowed the detection and measurements in intact cells, of specific interactions taking place between NXF1/Tap and mRNAs, and between NXF1/Tap and proteins within...
the NPCs. We have found that specific interactions at the cytoplasmic side of the NPC are crucial for the release of the mRNA to the cytoplasm, and have identified positions within the NPC that are mechanistically fundamental for the directional flow of mRNA and NXF1/Tap from the nucleus into the cytoplasm.

**Identification of a small, PH domain-embedded region responsible for the nuclear-cytoplasmic distribution of RGNEF.**

M. Tavolieri¹, C. Droppelmann², D. Campos-Melo², K. Volkening¹, M. Strong¹;

¹Department of Clinical Neurological Sciences, Schulich School of Medicine Dentistry, Western University, London, ON, ²Molecular Medicine Group, Robarts Research Institute, London, ON

Rho Guanine Nucleotide Exchange factor (RGNEF) is a 190 kDa protein implicated in both cancer and amyotrophic lateral sclerosis (ALS) pathologies. One area of interest in cancer research – and increasingly in ALS research – is the role nuclear-cytoplasmic shuttling plays in the disease mechanism. RGNEF has previously been reported to localize at low levels to the nucleus despite its large molecular weight, suggesting active transport likely plays a role. Here we have identified a 23 amino acid region composed of both a nuclear localization signal (NLS) and nuclear export signal (NES) that is capable of regulating RGNEF nuclear-cytoplasmic distribution.

We created a series of mutant constructs and observed their localization using confocal microscopy. First, deletion of the Pleckstrin Homology (PH) domain of RGNEF was sufficient to eliminate nuclear localization of the endogenous protein. In silico analysis was used to identify two clusters of basic residues that were located on the exterior of the PH domain and were accessible for karyopherin interaction. We predicted this region would constitute a bipartite NLS. Site-directed mutagenesis in three different constructs – endogenous RGNEF, a vector designed to exclude the fusion protein from the nucleus (pHM830), and a vector designed to direct the fusion protein to the nucleus (pHM840) – all consistently showed that these residues were both necessary and sufficient for nuclear localization of a protein of 160 kDa or greater molecular weight.

We were able to extrapolate from this set of data the presence of an NES. Expression of the PH domain in the pHM840 vector was sufficient to significantly reduce nuclear localization of the fusion protein compared to empty vector. We found that the linker region of the bipartite NLS contained a large cluster of hydrophobic residues, which were also accessible for karyopherin interaction. When considered as a linear amino acid sequence the NES is flanked by the NLS, though molecular modeling shows us that the two signals are independent of one another. We confirmed that the region promotes nuclear export in an exportin-1 dependent manner by treating cells with leptomycin B (LMB) and observing accumulation of the fusion protein in the nucleus.

To date, this is the first time a NES has been described embedded within a NLS. Given the role it plays in determining the nuclear localization of the protein we have termed this 23 amino acid region the multisignal transport (MT) region. As an RNA binding partner, the nuclear-cytoplasmic distribution of RGNEF may have profound effect on ALS and particularly cancer pathology. Future directions should focus on how the dual, opposing roles of this region are regulated to maintain healthy nuclear-cytoplasmic balance.

The role of specific sequence patterns of FG Nups on transport through the NPC.
M. Peyro1, V.S. Nibber1, M. Soheilypour1, M. Mofrad1;  
1Bionengineering and Mechanical Engineering, University of California Berkeley, Berkeley, CA

Nuclear Pore Complex (NPC) is the largest protein complex inside the cell that is responsible for bidirectional transport of cargo through the nuclear envelope. It is made up of ~30 different types of proteins that are called nucleoporins (Nups). Nups can be categorized into two major groups, FG Nups and non-FG Nups. FG Nups are disordered proteins that are rich in Phenylalanine-Glycine repeats and are major role players in nucleocytoplasmic transport. While it is commonly believed that the FG Nups enable transport process through transient and weak interactions with cargo complex, the mechanism by which the FG Nups enable fast yet selective transport has remained unknown. This question has motivated recent bioinformatics and computational biology studies on sequence features of FG Nups that may help understand the underlying reason for FG Nups’ specific function. We previously showed that there are evolutionarily conserved features in sequences of FG Nups that affects their conformation and dynamics in the NPC. These sequence patterns are long regions in the disordered region of FG Nups that only contain positively charged residues. These regions are low in charge density, and are located toward the N terminus of FG Nups. We called these patterns Like Charge Regions (LCRs). In our recent study, using bioinformatics techniques and in-house codes, we compared FG Nups with other disordered protein datasets, namely Disprot, IDEAL and MobiDB-Lite disorder predictions of Uniprot database, and showed that LCRs are specific to FG Nups, and are not found in other disordered proteins. These new results highlight the possible role of LCRs in transport process. In our last study, by using a previously developed coarse-grained molecular dynamics model we studied the role of LCRs in the conformation of FG Nups. In our current study, we added a representation of cargo complex to the system, and repeated the study. In this coarse-grained model, FG Nups are modeled as chains of beads with one-bead-per-amino acid and the cargo complex has been roughly modeled as a sphere with hydrophobic patches on it. Our results show that presence of LCRs is effective in the location of cargo inside different cross sections of NPC. Mutating the positive charges in LCRs to Alanine causes the cargo to move differently in the NPC and cover a different amount of volume inside the NPC. The difference in the mutated and wildtype results is dependent on the type of Nup that is being simulated. In conclusion, our results suggest that LCRs are evolutionarily conserved patterns that can be found only in sequences of FG Nups, and are important both in the conformation of FG Nups in the NPC and in the dynamics of cargo complex in the NPC.

Quantitative analysis of nuclear translocation of ERK by using a novel single molecule technique.
K. Mouri1, Y. Okada1,2;  
1QBIC, RIKEN, Osaka, Japan, 2Grad. Sch. Sci., Dept. Phys., Univ. Tokyo, Tokyo, Japan

Nuclear translocation of ERK is a key process in the signal transduction of MAP-kinase pathway. It has been shown to be the rate-limiting step and its non-linear kinetics has suggested to be essential to trigger digital response of cell fate decision from the analog input of growth factor signal (Y. Shindo, K. Iwamoto, K. Mouri, et. al., Nat. Commun., 2016). The observed non-linear kinetics suggests underlying positive-feedback mechanisms, but the molecular mechanisms still remain unclear. To elucidate the
mechanism, we wanted to build quantitative models of this process, which requires to measure parameters such as concentration of ERK in cytoplasm and nucleoplasm, diffusion coefficient, binding frequency of ERK to a nuclear pore, and the import and export rates through the nuclear pore. Fluorescent correlation spectroscopy or FCS has been used for the measurement of the concentration and the diffusion coefficient of protein in cytoplasm, but the signal from only a single point in the sample is measured at once. However, it would be beneficial to make simultaneously in the cytoplasm and in the nucleoplasm of the same cell for the analysis of the nuclear transport. Here we report the development of a new multi-point FCS method using laser scanning confocal microscope. Line scan image sequence is taken at high frequency by using the resonant scanner. Thus, the autocorrelation is calculated for each pixel, yielding the concentration and the diffusion coefficients for the diffraction limited spots along the line. In this presentation, we will first describe the principle of this method, and its validity compared with conventional single point FCS and raster scan image correlation spectroscopy (RICS). Finally, we will discuss on the latest results on the quantitative parameters of ERK translocation measured by this method, and the extension to the FCCS (fluorescent cross correlation spectroscopy) for the quantitative measurement of protein-protein interaction.

Super-resolution microscopy reveals the transport route of transmembrane proteins into the nucleus.
K.C. Mudumbi\textsuperscript{1}, R. Czapiewski\textsuperscript{2}, W. Luo\textsuperscript{1}, E. Schirmer\textsuperscript{2}, W. Yang\textsuperscript{1};
\textsuperscript{1}Biology, Temple University, Philadelphia, PA, \textsuperscript{2}The Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

The transport routes and mechanisms used by transmembrane proteins to reach the nucleus across the nuclear envelope remains in dispute. Using high-speed super-resolution microscopy, we have solved the dispute by identifying two distinct transport routes for different membrane proteins as they transport through the peripheral or central channels of the nuclear pore complexes.

High nuclear export efficiency and conformational changes of pre-ribosomal subunits revealed by high-speed super-resolution microscopy.
J. Kelich\textsuperscript{1}, A. Goryaynov\textsuperscript{3}, K. Herbine\textsuperscript{1}, W. Yang\textsuperscript{1};
\textsuperscript{1}Biology, Temple University, Philadelphia, PA

The nuclear envelope (NE) in eukaryotic cells provides a barrier separating nascent pre-ribosomal subunits assembled in the nucleus from matured ribosomes translating proteins in cytoplasm. Nuclear pore complexes (NPCs) embedded in the NE function as the sole gatekeepers for pre-ribosomal subunits exiting the nucleus. However, the basic nuclear export mechanism for pre-ribosomal subunits through the NPCs remains obscure. Here we combined a high-speed super-resolution microscopy with Förster resonance energy transfer (FRET) to obtain real-time single-molecule trajectories for pre-60S and pre-40S through the NPCs in live HeLa cells. Remarkably, we found that approximately two thirds of all NPC-interacting pre-ribosomal subunits successfully reach the cytoplasm during their export time of $\sim$14 ms for pre-60S and $\sim$8 ms for pre-40S. Moreover, the unexpectedly high nuclear export efficiency, about two-fold over that of message RNAs, may be enhanced by multiple species of transport receptor recruited for pre-ribosomal subunits. Finally, dual-channel single-molecule FRET tracking provides
evidence that both pre-ribosomal particles undergo conformational changes during their export through the NPCs.

Karyopherins regulate nuclear pore complex barrier and transport function.
L.E. Kapinos1, B. Huang1, C. Rencurel1, R.Y. Lim1;
1Biozentrum, University of Basel, Basel, Switzerland

Nucleocytoplasmic transport of nuclear localization signal (NLS)-specific cargos involves karyopherin receptors (e.g., Kapα and Kapβ1), a RanGTP gradient, and nuclear pore complexes (NPCs) that perforate the nuclear envelope (NE). Kapβ1 binds specifically to intrinsically disordered proteins called Phe-Gly nucleoporins (FG Nups) within each NPC to facilitate this selective transport. Otherwise, the FG Nups are widely accepted to form a permeability barrier that hinders the passage of non-specific macromolecules. However, because Kapβ1 also binds Kapα in the cytosol to ferry NLS-cargoes and RanGTP in the nucleus to deliver the cargo, the binding of one partner may functionally impact on another to orchestrate the entire transport continuum. To this end, NPC barrier selectivity, Kap traffic and NLS-cargo release are inexplicably linked yet how they are simultaneously regulated under equilibrium conditions remains incoherent and poorly understood. Here, we show using quantitative modelling and functional analysis of permeabilized cell assays that Kapα is essential for facilitating Kapβ1 turnover from NPCs in a RanGTP-dependent manner that is directly coupled to NLS-cargo release and NPC barrier function. This is underpinned by the binding affinity of Kapβ1 to the FG Nups, which is comparable to RanGTP-Kapβ1, but quantitatively stronger for Kapα-Kapβ1. On this basis, RanGTP is ineffective at releasing standalone Kapβ1 from NPCs. Depleting Kapα-Kapβ1 by RanGTP further abrogates NPC barrier function whereas adding back Kapβ1 rescues it. Therefore, the FG Nups are necessary but insufficient for NPC barrier function. Based on these findings, we reveal that Kapα is more than an adaptor for NLS-cargo but in fact underpins functional NPC control by mediating Kapβ1 occupancy and turnover. Thus, a deregulation of Kapα leads to defects in NCT that might result in cellular dysfunction. To conclude, Kaps constitute integral constituents of the NPC whose barrier, transport and cargo-release functionalities converge under Kap-centric control.

A novel role for the Calcineurin phosphatase at the nuclear pore.
C.P. Wigington1, J. Roy1, N.P. Damle1, I. Ulengin-Talkish1, S. Ei Cho1, N.E. Davey2, Y. Ivarsson3, C.J. Wong4, A. Gingras5, M.S. Cyert1;
1Biology, Stanford University, Stanford, CA, 2Conway Institute of Bimolecular and Biomedical Research, University College Dublin, Dublin, Republic of Ireland, 3Chemistry-BMC, Uppsala University, Uppsala, Sweden, 4Lunenfeld-Tanenbaum Research Institute at Mount Sinai Hospital, University of Toronto, Toronto, Canada

Calcineurin (CN) is the Ca2+/Calmodulin-activated serine/threonine protein phosphatase with a well-defined role in immune cell activation as well as critical roles in the brain, heart, and other tissues. CN-substrate engagement is mediated via conserved docking surfaces on CN that bind to Short Linear Motifs (SLiMs), termed PxxiIT and LxVP, in substrate proteins. Recent work in our lab has employed SLiM-directed approaches to identify the spectrum of CN substrates and interactors, thereby mapping the human CN signaling network and expanding our understanding of CN-dependent processes in...
human cells. Using Proteomic Peptide Phage Display analysis (ProP-PD), which directly selects for CN-binding SLIms from the human proteome, we identified many novel PxlIT- and LxVP-containing peptides from a diverse group of proteins that were not previously known to be regulated by CN. One such sequence is a PxlIT-containing peptide from NUP153, a peripheral nucleoporin that comprises part of the nuclear basket of the nuclear pore complex (NPC). Using in vitro and in vivo binding assays, we have shown that this conserved, novel PxlIT sequence is required for the interaction between CN and NUP153. The NUP153 PxlIT sequence lies within a heavily phosphorylated region of NUP153 that mediates many protein-protein interactions which are important for proper nuclear transport. Building upon previous studies demonstrating ERK phosphorylation of this region of NUP153, we have shown that CN dephosphorylates these ERK phosphosites on NUP153 in a PxlIT-dependent manner in vitro and that a NUP153 PxlIT mutant shows altered dephosphorylation in vivo. Together, these data suggest that NUP153 is a bona fide substrate of CN and establishes a role for CN dephosphorylation at the nuclear pore. In addition to our ProP-PD analyses, we have also employed computational and BioID/MS approaches to identify hundreds of novel CN substrates and interactors. These analyses have uncovered many additional CN-binding nucleoporins and nuclear transport factors, such as NUP50, another nuclear basket-associated nucleoporin that binds to CN via a conserved PxlIT sequence. Consistent with these observations as well as previous studies that demonstrate a role for Ca\(^{2+}\) in nuclear transport, we observe co-localization of CN to the nuclear rim as well as CN-dependent changes in nuclear transport of a GFP reporter. Altogether, these data demonstrate a novel point of regulation for CN in human cells and suggest a broader and previously uncharacterized role for CN in regulating nuclear transport.

Transport of the human immunodeficiency virus type 1 (HIV-1) pre-integration complex (PIC) through the nuclear pore complex (NPC) is prerequisite to virus replication. The viral capsid protein (CA), a PIC component, directly interacts with specific nucleoporins (Nups), including the phenylalanine-glycine (FG) rich Nup153. N74D mutation of CA reduces Nup153 binding and HIV-1 dependence while increasing reliance on Nup155, indicating an ability to exploit secondary nuclear transport routes. Here we find that CA extends this discrimination to Nup35 and POM121, with the loss of either impairing infection under conditions where Nup153 is also utilized. The coordinate requirement of Nup35, Nup153, and POM121 enabled the investigation of controlling mechanisms. We show HIV-1 use of Nup35, Nup153, and POM121 is regulated by CPSF6 and cyclophilin A (CypA) interaction with CA. Both factors show a differential concentration gradient in cells with CypA enriched at the cytoplasmic face of the nuclear membrane, and CPSF6 predominantly localized to the nucleus. CypA binding in particular directs HIV-1 toward the Nup153-dependent nuclear entry pathway, whereas HIV-1 switches to a Nup155-dependent pathway in the absence of this interaction. This dual tropism in the utilization of nuclear entry pathways likely reflects the challenges of transporting a megadalton protein and nucleic acid complex that is susceptible to binding of competing factors in the cytoplasm prior to docking at the NPC. We propose that the HIV-1 core, comprised of multimeric CA in association with the viral nucleic acid and enzymatic proteins, directly functions as a nuclear transport receptor and exploits successive FG interactions to achieve transfer through the NPC. Notably, soluble non-karyopherin factors are key regulators of this process.

Monday-235
The Ran (Ras-related nuclear protein) GTPase plays critical roles in multiple cellular processes, including nucleocytoplasmic transport, nuclear envelope (NE) assembly and mitotic spindle assembly. During interphase, high levels of GTP-bound Ran (Ran-GTP) within nuclei and of GDP-bound Ran (Ran-GDP) in cytosol determine the direction of transport to and from the nucleus. After mitotic NE breakdown, Ran-GTP is concentrated near mitotic chromatin while Ran-GDP is more abundant distal to chromosomes. This pattern is essential because it spatially controls spindle assembly. RanBP1 and RanBP3 are conserved Ran-GTP binding proteins that can form complexes containing RCC1 (Regulator of chromatin condensation 1). RCC1 is a chromatin bound protein that is the sole exchange guanine nucleotide factor for Ran, converting Ran-GDP to Ran-GTP. RanBP1 and RanBP3 have also been implicated in transport cargo loading and unloading from nuclear transport receptors of the karyopherin family. The in vivo functions of these proteins remain somewhat enigmatic, particularly for RanBP1 because knockout mice lacking this protein are viable, albeit with male infertility. To test the role of RanBP1 and RanBP3 in shaping Ran-GTP gradients in somatic cells, we have employed CRISPR/Cas9 to insert sequences encoding an auxin-induced degron (AID) into the RanBP1 and RanBP3 genes of DLD-1 human cells that stably express the Transport Inhibitor Response 1 (TIR1) protein. Auxin family hormones bind TIR and promote its interaction with AID domain. TIR acts as a substrate recognition subunit for SCF-mediated ubiquitination, resulting in rapid auxin-dependent proteasomal degradation of AID-tagged substrates in a manner that is reversible and tunable. AID-tagged RanBP1 or RanBP3 can be rapidly degraded in a regulated fashion. This system allows us to test the influence of RanBP1 and RanBP3 on Ran gradients using previously developed Förster (fluorescence) resonance energy transfer (FRET)-based assays, to assess their influence RCC1 dynamics quantitatively, and to determine the extent of disruption in interphase nuclear trafficking and mitotic progression in their acute absence.

Nuclear transport factors NTF2 and importin α regulate nuclear size in Xenopus. In general, importin α levels positively regulate nuclear size, while increased NTF2 concentrations decrease nuclear size. Comparing melanoma cell lines that represent different stages of disease, we found that NTF2 expression levels inversely correlate with nuclear size. Consistent with this trend, normal melanocytes exhibited the highest levels of NTF2 and smallest nuclei. Based on transient transfections of different melanoma cell lines, as well as HeLa and MRC5 cells, we find that increased NTF2 expression leads to reduced nuclear size. We have generated a stable WM983B melanoma cell line that allows for titratable doxycycline-induced expression of NTF2. The largest reduction in nuclear cross sectional area (~10%) was observed with 20 ng/ml doxycycline which causes a 5-fold increase in NTF2 levels. These cells
showed downregulation of TSG101, which was performed using bafilomycin, leading to the degradation of vesicles. To begin to understand the mechanism of action of NTF2 in these assays, we performed RNAseq to determine how nuclear size impacts gene expression. These results will be presented and used for future FISH studies to examine how nuclear size affects gene position of differently-expressed genes.

We have also performed in vivo experiments in which NTF2-inducible WM983B melanoma cells were injected subcutaneously or intravenously into RAG2 and NSG mice. Tail vein injected RAG2 mice exhibited fewer lung metastases when treated with doxycycline, indicating that in vivo metastatic potential is reduced upon NTF2 overexpression. We are now planning to test a combination therapy in which we reduce nuclear size and treat with the well-established melanoma drug vemurafenib. Most melanoma patients with BRAF mutations show a good response to this drug, however relapse often occurs with drug-resistant melanoma cells expressing high levels of the cancer stem cell markers JARID1B, CD271, and fibronectin. According to our RNAseq data, cells expressing higher levels of NTF2 show reduced gene expression of JARID1B and fibronectin. Thus increasing NTF2 expression in drug-resistant tumors may improve prognosis and survival time.

Mechanistic Study of the Attenuation of Androgen Receptor Expression Level by TSG101-ART27 Interaction.
Y. Lin¹, P. Ouyang¹;
¹Anatomy, Chang Gung University, Taoyuan, Taiwan

The androgen receptor (AR) signaling pathway plays a vital role in the normal development and function of male reproductive organs. Dysregulation of the AR signaling pathway have been linked to diseases such as prostate cancer. Here, we demonstrate that tumor susceptibility gene 101 (TSG101) regulates AR transactivation via interacting with ART-27 protein, an AR interaction partner. In LNCaP cells, TSG101 overexpression recruits ART-27 to TSG101-decorated cytoplasmic vesicles and leads endogenous AR to TSG101-containing vesicles, resulting in reduced AR protein level and AR transactivation activity downregulation. Immunofluorescence microscopy demonstrated that TSG101-decorated cytoplasmic vesicles were associated with late endosomes or lysosomes and AR could be found within the Lamp2 positive TSG101 vesicles upon lysosomal protease inhibitor treatment. Furthermore, chloroquine or bafilomycin A1 treatment was able to restore TSG101-mediated AR expression reduction and depletion of ART-27 expression compromising AR co-localization in TSG101 vesicles. Based on this data, we conclude that the localization of AR to TSG101-containing cytoplasmic vesicles is mediated by ART-27, and TSG101-induced downregulation of AR expression associated with the late endosome/lysosome degradation pathway.

Structural determinants of Dnase1L3 that alter its localization during inflammation.
J.J. McCord1,2, F. Harsini3, K.N. Abbott4, S. Chebrolu5, R. Sutton5,6, P.A. Keyel7;
1Biological Sciences, Texas Tech University, Lubbock, TX, 2Cell Physiology and Molecular Biophysics, Texas Tech University Health Science Center, Lubbock, TX, 3Center for Membrane Protein Research, Texas Tech University Health Sciences Center, Lubbock, TX

One debilitating autoimmune disease that affects about 1.5 million Americans is Systemic Lupus Erythematosus (SLE). Although SLE is a multifactorial disease, one cause of SLE in humans and mice is disruption of Dnase1L3. Dnase1L3 is a secreted endonuclease that degrades chromatin in apoptotic microparticles. However, Dnase1L3 can also act intracellularly to promote inflammation. Dnase1L3 switches from extracellular to intracellular localization, and what domains are necessary for intracellular activity are unknown. To understand how this secreted protein functions intracellularly, we expressed Dnase1L3 both as a tdTomato fusion in mammalian cells to study trafficking and in bacteria to solve the structure. We found that lipopolysaccharide increased the nuclear localization of tdTomato-Dnase1L3, suggesting that inflammation can alter the nuclease trafficking. To purify recombinant Dnase1L3, we generated a His6-Maltose Binding Protein-Dnase1L3 fusion protein. We compared expression of this fusion between E. coli BL-21, and E. coli Rosetta-gami cells, and purification between either Nickel-NTA beads or amylose affinity resin. We found optimal expression using E. coli Rosetta-gami cells and purified the fusion protein to 97.89% purity using amylose resin, compared to 1.87% purity using Nickel-NTA beads. We removed the His6 tag and Maltose Binding Protein using Tobacco Etch Virus (TEV) protease and further purified Dnase1L3 using S-resin and size exclusion chromatography. Purified Dnase1L3 was active, based on nuclease assays. We confirmed the identity and size of Dnase1L3 by Western blot. Overall, we developed a purification method to generate high-purity Dnase1L3. We also found that inflammation perturbs the trafficking of tdTomato-Dnase1L3. Our combined structure-function approach will enable us to relate disease causing mutations in Dnase1L3 to the intracellular trafficking and structure of Dnase1L3. The structural information may provide key binding site information that will facilitate a greater understanding into the mechanisms behind SLE and characterize Dnase1L3 prior to use in SLE treatment.

Tau protein, which normally functions to stabilize microtubules, is the major constituent of neurofibrillary tangles in Alzheimer’s disease (AD). The accumulation of tau in neuronal soma correlates with neuronal loss. However, the mechanism underlying tau associated neurodegeneration remains unclear. We now show that hyperphosphorylated tau can interact with nucleoporins (nups), protein constituents of the nuclear pore complex (NPC) and affect its functional integrity. Pathological tau leads to disruption of nuclear pore complex proteins, reduction of NPC complexes, cytoplasmic mislocalization of nups, and impairs nuclear export and import, in vitro, in tau overexpressing transgenic mouse models.
and in human Alzheimer tissue. Correspondingly, nuclear pore component, Nup98, surprisingly colocalizes with neurofibrillary tangles in neuronal soma, and both in vivo and in vitro directly interacts with tau and facilitates its aggregation. These data support the hypothesis that phospho-tau directly interacts with nuclear pore complex constituents, leading to their mislocalization and to disruption of nuclear pore function, raising the possibility that nuclear pore dysfunction contributes to tau induced neurotoxicity in Alzheimer’s disease.

ROCK-dependent phosphorylation of NUP62 regulates p63 nuclear transport in squamous cell carcinoma.
M. Hazawa¹, A. Kobayashi¹, R. Wong¹;
¹Institute for Frontier Science Initiative, Kanazawa University, Kanazawa, Japan

p63, more specifically its Np63 isoform, plays essential roles in squamous cell carcinomas (SCCs); yet the mechanisms controlling its nuclear transport remain unknown. Nucleoporins (NUPs) are a family of proteins building nuclear pore complex (NPC) and mediating nuclear transport across the nuclear envelope. Recent evidence suggests a cell-type-specific function for certain NUPs; however, the significance of NUPs in SCC biology remains unknown. In this study, we report that nucleoparin 62 (NUP62) is highly expressed in stratified squamous epithelia, which is further elevated in SCCs. Depletion of NUP62 inhibited the proliferation potential and augmented differentiation of SCC cells. This loss of dedifferentiation was associated with defects in Np63 nuclear transport. We further found that differentiation inducible Rho kinase reduced an interaction between NUP62 and Np63 by phosphorylation of phenylalanine-glycine regions of NUP62, resulting in attenuated Np63 nuclear import. Our results characterize NUP62 as a key gatekeeper for Np63 and uncover its lineage-specific function to control cell fate through regulation of Np63 nuclear transport in SCC.

A nuclear localization signal is sufficient to target membrane proteins to the nuclear envelope in plants.
N.R. Groves¹, J.F. McKenna², I. Meier¹³;
¹Molecular Genetics, The Ohio State University, Columbus, OH, ²Biological and Medical Sciences, Oxford Brookes University, Oxford, United Kingdom, ³Center for RNA Biology, The Ohio State University, Columbus, OH

Among protein targeting pathways, the journey of a transmembrane protein to the inner nuclear membrane (INM) is likely the least understood. However, understanding trafficking to the INM has increased in importance, as many INM proteins have been identified with roles in chromatin organization, nuclear morphology, meiosis, and nuclear movement, and have further been implicated in human disease. Two primary theories of how proteins reach the INM have been described, both with experimentally demonstrated backing: a. passive lateral diffusion coupled with local nucleoplasmic retention, and b. signal-driven nuclear import. In some cases of signal-driven import, nuclear localization signals (NLSs) have been implicated. All currently available data on INM targeting stem from the

Monday-239
eukaryotic supergroup Opisthokonta (including animals and fungi). Here, we ask if an NLS-driven pathway for INM protein targeting exists in another supergroup, the Archaeplastida (plants). The SV40 Large T Antigen NLS was fused to the Arabidopsis thaliana ER tail-anchored protein PICL tagged with GFP (“NLS-PICL”). Subcellular targeting of fusion proteins was assessed after transient transformation of Nicotiana benthamiana leaf epidermal cells and the enrichment of the protein at the NE compared to the ER was quantified. Addition of this NLS was sufficient to enrich PICL at the NE. To differentiate between association with the outer versus inner nuclear membrane, we applied high-resolution Airyscan confocal microscopy. NLS-PICL displayed a localization indistinguishable from an INM or INM-associated protein, indicating that addition of an NLS is sufficient to target a tail-anchored ER membrane protein to the INM.

Alternative NLSs- five monopartite and four bipartite- were then tested for their ability to enrich chimeric membrane proteins at the NE. NLS fusions resulted in various degrees of NE enrichment. Based on these data, the NE enrichment of one monopartite and one bipartite NLS were analyzed by Airyscan confocal microscopy. Chimeric membrane proteins fused with either NLS localized to the INM.

Dependence of INM targeting on the spacing between NLS and TMD is currently being tested. Rules for plant INM targeting thus defined will be used to (a) artificially target novel functions to the plant INM, and (b) generate bioinformatic search criteria to identify unknown plant INM proteins.

**Biochemical fractionation of Xenopus extract to identify components limiting for nuclear growth,**

P. Chen¹, K. Nelson², M. Tomschik¹, J.C. Gatlin¹, J.S. Oakley², D.L. Levy¹;

¹Molecular Biology, University of Wyoming, LARAMIE, WY, ²Chemical Petroleum Engineering, University of Wyoming, LARAMIE, WY

Nuclear size dramatically reduces during early *Xenopus laevis* embryogenesis. From fertilization to gastrulation (stages 10-12), there is a ~16-fold reduction in the volume of individual nuclei. The regulatory mechanisms responsible for these nuclear size reductions have not been fully elucidated. We are interested in the contribution of cytoplasmic volume to the regulation of nuclear size during early embryogenesis. We use microfluidic devices to encapsulate *X. laevis* stage 10 embryo extracts, generating cytoplasmic droplets of defined size and shape. Nuclei in droplets expand to a new steady-state size after ~3 hours. We find that nuclei exhibit similar growth trends in spherical and flattened droplets of comparable volume, indicating droplet shape minimally affects nuclear growth. Additionally, nuclear volume increases by 1.4- to 3-fold in droplets ranging in volume from 0.02 nL - 0.5 nL, with larger increases occurring in larger droplets. These data indicate that the volume of embryonic cytoplasm is limiting for nuclear growth. However, in larger than ~0.5 nL droplets, the increase in nuclear volume reaches a threshold of ~3-fold. Compared to stage 8 blastomeres (~0.8 nL) in vivo, final nuclear volume in ~0.8 nL droplets is two times less than for nuclei in stage 8 embryos. Furthermore, when gastrula-stage nuclei are treated with stage 5 embryo extract and encapsulated in gastrula-cell-sized droplets (~0.08 nL), the average nuclear volume increases ~3-fold more than in gastrula-stage embryo extract droplets. These results suggest that both cytoplasmic composition and volume contribute to nuclear size scaling. We are now testing the hypothesis that limiting components in later stage embryo extract contribute to nuclear size scaling. We developed an in vitro assay in which clarified cytosol from egg extract causes stage 10 nuclei to grow. The cytosolic nuclear growth activity is heat-sensitive and dependent on importin alpha-mediated nuclear import, and we have ruled out several potential candidates, including nuclear lamins. Fractionation of cytosol through gel filtration and anion
exchange chromatography results in two active fractions, and proteomic analysis of these fractions has generated a list of candidate proteins that are limiting for nuclear growth in our assay. We are currently testing these putative nuclear size regulators both in vitro and in vivo.

SPOP regulates the levels of the nuclear pore protein NupJ.
J. Ong¹, J.Z. Torres¹;
¹Department of Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA

Cell processes like growth and division are tightly regulated. One such mechanism of regulation is ubiquitination. Ubiquitination can change a protein’s localization or activity, or it can mark the protein for degradation by the ubiquitin proteasome system. The final step of ubiquitination, transferring ubiquitin to the target protein, is mediated by E3 ligases and their substrate adaptors, proteins that allow E3 ligases to be selective in choosing their targets. Understanding the targets of E3 ligases and substrate adaptors, then, is crucial to understanding cell regulation and disease mechanisms linked to misregulation of protein levels and activity. SPOP is a Cul3 E3 ligase substrate adaptor whose targets, such as c-Myc, DAXX, and ERG, are crucial for cell cycle progression and proliferation. Through a mass spectrometry screen, we identified SPOP as a potential regulator of NupJ, a nuclear pore protein. Knockdown of SPOP via siRNA in HeLa cells leads to increased protein levels of NupJ via immunoblotting, and SPOP and NupJ both co-localize at the nuclear membrane via immunofluorescence microscopy. Moreover, co-immunoprecipitation assays demonstrate that SPOP and NupJ bind to each other in vitro. Similar to overexpression of NupJ, siRNA against SPOP leads to an increase in the number of nuclear envelope defects. Our results suggest that SPOP targets NupJ for ubiquitin-mediated proteasomal degradation.

Actin facilitates nuclear envelope breakdown by separating nuclear membranes from the lamina in starfish oocytes.
N. Wesolowska², P. Machado², M. Mori³, U. Matti¹, Y. Schwab¹, P. Lénárt¹;
¹Cell Biology and Biophysics, European Molecular Biology Laboratory, Heidelberg, Germany, ²Electron Microscopy Core Facility, European Molecular Biology Laboratory, Heidelberg, Germany, ³Center of Developmental Biology, Riken, Japan

In Metazoa, the nuclear envelope (NE) disassembles and reassembles in every division. This requires a concerted disruption of links between the NE components: the nuclear membranes, their resident proteins, nuclear pores (NPCs) and the underlying lamina, an intermediate filament scaffold stabilizing the NE. A phase of sudden and complete rupture of the NE appears to be a conserved feature of NEBD across animal species. This sudden rupture, which is crucial to the timely capture of chromosomes by spindle microtubules, appears to involve mechanical forces that in cultured mammalian cells are generated by microtubules tearing the NE – although the exact way the force is transduced and the type of membrane rearrangements brought about, remain completely unknown.

We have recently uncovered that in the starfish oocyte it is rather a transient Arp2/3 nucleated F-actin shell assembling on the inner side of the NE that drives rapid rupture of the large oocyte nucleus during meiosis (Mori et al. 2014). Through immunostaining and live cell imaging, we have found that this transient cortex-like structure assembles within the lamina and sprouts dynamic spike-like protrusions
towards the nuclear membranes. As consequence, the nuclear membranes appear to separate from the underlying lamina, which at this time are still intact and maintain a tight-knit network, as confirmed by super resolution microscopy (SMLM). We used a correlative light-electron-microscopy (CLEM) approach to gain more insight into the morphological changes within the nuclear membranes that might transpire from the observed separation of NE layers. To this end, we used fluorescence imaging to capture oocytes at the moment of shell formation, just prior to NE rupture, a time-window of ~1-2 minutes. These correlative EM micrographs reveal the morphology of NE membranes at the exact sites of destabilization. We observe fibrous spikes (presumably F-actin) underlying protrusions in the NE membrane. Moreover, we find that these protrusions are in areas devoid of NPCs, in contrast to adjoining stretches of the NE, which are packed with pores. Based on these data, we propose that F-actin shell with its spikes puts force on the weakened NE areas – presumably stripped of nuclear pores prior to this stage of NEBD – and as a consequence separates the membranes from lamina. This in turn leads to destabilization of the NE and results in breaks. Thereby, our data for the first time provide detailed characterization of the dramatic reshaping of the NE during its breakdown.

Mixing of parental genomes after fertilization in C. elegans involves fusion and fenestration of pronuclear membranes.
M.M. Rahman¹, I. Chang², A.S. Harned², K. Narayan², O. Cohen-Fix¹;
¹Laboratory of Cell Molecular Biology, National Institute of Diabetes Digestive Kidney Diseases, Bethesda, MD, ²Center for Molecular Microscopy, Frederick National Laboratories for Cancer Research, Frederick, MD

In a fertilized embryo, the nuclear envelopes (NEs) of the maternal and paternal pronuclei must disassemble to allow mixing of two haploid genomes, leading to the formation of a single diploid nucleus in the zygote. The regulation and mechanics of this process are poorly understood but they are clearly important as premature or delayed disassembly could result in failure to incorporate chromosomes in a zygotic nucleus. It is assumed that NEBD occurs once the two pronuclei are in close apposition, but the precise order of events, and in particular the architecture of the pronuclear membranes, is unclear. To address this, we used the C. elegans embryo and followed NE dynamics and architecture using two orthogonal techniques, live cell fluorescence microscopy and 3D electron microscopy, specifically Focused Ion Beam - Scanning Electron Microscopy (FIB-SEM). After fertilization, the maternal and paternal pronuclei migrate towards each other and form a stable interface where NEs are closely juxtaposed. The NE between maternal and paternal pronuclei is breached via a membrane fenestration in the vicinity of the chromosomes only after the maternal and paternal chromosomes have aligned on their respective metaphase plates. This membrane gap then expanded as chromosomes moved in opposite directions in anaphase. Using FIB-SEM we visualized the 3D architecture of the NE fenestration through the four juxtaposed pronuclear membranes. We found that breaching the nuclear membranes between the two pronuclei involves the formation of membrane gaps that span all four membranes, the most prominent of which is in the vicinity of the aligned chromosomes. Moreover, we detected multiple sites where the membranes of the two pronuclei physically interact, forming membrane junctions. Our preliminary data suggest that NE fenestration involves membrane fusion between the two pronuclei at multiple sites, leading to the formation of gaps across all four membranes. We further speculate that the presence of the chromosomes, and perhaps signals emanating therefrom, contribute to the expansion of NE gaps in the vicinity of the chromosomes.
We previously reported that inactivation of the conserved Polo-like kinase 1 (PLK1) results in a failure in pronuclear membrane fenestration and inhibition of parental chromosome mixing in the *C. elegans* zygote (Rahman et al., MBoC 2015). Recently we identified five additional genes that upon down-regulation by RNAi fail to fenestrate the pronuclear membranes. We are currently investigating how these genes contribute to the timely NEBD after fertilization in the *C. elegans* embryo.

Exchange of molecules between the cytoplasm and the nucleus occurs through conduits called nuclear pore complexes (NPCs). NPCs consist of roughly 30 distinct proteins (nucleoporins), forming a central channel with filaments extending into the nucleus and cytoplasm. Besides macromolecular trafficking, nucleoporins participate in the control of gene expression, chromatin maintenance and mitotic progression. In particular, Nup153, Tpr, and Nup50 localize to nucleoplasmic filaments, and they are collectively called the basket nucleoporins. The nucleoplasmic filaments have been proposed to serve as a platform for RNA modification and export, as well as for chromatin remodeling. Their action in these processes offers a rich variety of possible mechanisms for biological regulation via nucleoporins and for coordination amongst cellular functions. However, understanding the roles of individual basket nucleoporins in vertebrate cells is difficult because their depletion by RNAi requires an extended incubation, during which the all processes may be increasingly disrupted, potentially resulting in a highly pleiotropic phenotypes, many of which are secondary consequences of nucleoporin loss. To circumvent this problem, we created CRISPR/Cas9-targeted cell lines, where the basket nucleoporins Nup50, Nup153, and Tpr are endogenously targeted with Auxin Inducible Degron (AID) tags. The AID-tagged nucleoporins localize correctly, are functional within NPCs and are rapidly degraded upon Auxin addition (<2 hours). To assess the role of each nucleoporin, we followed cell growth in the absence and presence of Auxin, as well as nuclear trafficking and the immediate response in gene expression profile (RNA-sequencing). Moreover, we assessed the interdependence of the basket components, and associated with the basket proteins (SENP1, SENP2, MAD1) on each other, on the stability of the assembled nuclear pore, and ability to reform the nuclear pore post mitosis. Overall, our data indicate that basket nucleoporins play distinct, individual roles in nuclear function and gene expression. This system will allow us to dissect their roles at a molecular level.

The nuclear pore complex (NPC) acts as a conduit for transport between the interphase cytoplasm and nucleus. NPCs consist of roughly 30 distinct proteins (nucleoporins), forming a channel through the nuclear envelope. The central domain of NPCs consists of three co-axial rings that each display a lattice-
like arrangement, and that are called the cytoplasmic ring, inner ring, and nucleoplasmic ring, respectively. The Nup107-160 complex contains nine core nucleoporins (Nup37, Nup85, Seh1, Sec13, Nup96, Nup107, Nup133 and Nup160), with a tenth subunit called ELYS required for chromatin recruitment. The Nup107-160 complex forms the scaffold underlying the cytoplasmic and nuclear rings. Due to this major structural role, Nup107-160 complex organization has been intensely studied. Interestingly, the Nup107-160 complex also associates with kinesinocores in metazoan mitosis, where it plays a transport-independent role in spindle assembly and chromosome segregation.

In vivo analysis of individual vertebrate Nup107-160 complex members during interphase and mitosis has been problematic because their abundance and stability makes them difficult to manipulate with standard methods (e.g., RNAi). The extended time required for depletion causes progressive defects in both interphase and mitotic functions that can produce adverse secondary consequences. Moreover, the levels of non-targeted subunits decrease during extended RNAi depletion, possibly suggesting that they become unstable when the larger complex is absent. To address this problem, we have used CRISPR/Cas9 to add Auxin-Induced Degron (AID) tags along the genomic locus of the individual subunits in human DLD-1 cells. AID-tagged nucleoporins assemble into functional NPCs, and they are degraded rapidly (<4 hours) after auxin addition, with minimal impact on the stability of other Nup107-160 complex members. We are currently using these cells to analyze the in vivo functions of Nup107-160 complex components. We have assessed the roles of Nup107-160 complex subunits in nuclear trafficking through comparison of nuclear import and export in the absence and presence of auxin. We will also discuss how individual complex members contribute to the structural stability of NPCs, and the inter-dependence between subunits for Nup107-160 complex persistence at existing NPCs, as well as for spindle function and post-mitotic NPC assembly.

¹NICHD, National Institutes of Health, Bethesda, MD

Nuclear pore complexes (NPCs) are essential in eukaryotes, and they facilitate gated transport of macromolecules between the interphase cytoplasm and nucleus. NPCs consist of roughly 30 distinct proteins called nucleoporins (Nups), forming a channel through the nuclear envelope. The barrier function of NPCs is established by a subset of nucleoporins (FG Nups) that possess tandem repeats of motifs based on a Phe-Gly core. These FG repeats also enable selective nuclear-cytoplasmic trafficking through binding to karyopherins, a family of Ran-GTP binding receptors that mediate nuclear import and export of cargo proteins and RNAs. Karyopherins form multiple low-affinity hydrophobic interactions with FG Nups, allowing them to selectively traverse NPCs. An intriguing possibility is that specific karyopherin-Nup interactions give rise to distinct import pathways. However, it has been technically difficult to examine the requirements of individual vertebrate Nups for particular karyopherin transport events in vivo. The abundance and stability of Nups makes them problematic to manipulate with standard methods (e.g., RNAi): The extended time required for depletion causes progressive defects in both interphase and mitotic functions that can produce adverse secondary consequences, as well as disrupt the localization and stability of other Nups over time. To address this problem, we have used CRISPR/Cas9 to add Auxin-Inducible Degron (AID) tags at the genomic loci encoding individual Nups in human DLD-1 cells. We find that AID-tagged Nups assemble into functional NPCs, and they are degraded rapidly after Auxin addition. Here, we examine the localization and dynamics of karyopherins within cells after Auxin-induced depletion of individual Nups, in order to establish the distinct impacts of Nup loss.

Monday-244
on different transport pathways. In particular, we focus on the evolutionarily conserved, essential karyopherins, Importin-β, Transportin, RanBP5, Crm1, and CAS which are mediators of major cellular import and export pathways. We have quantified the relative nuclear-cytoplasmic distributions of these receptors in fixed control and Nup-depleted cells by immunofluorescence, as well as mCherry-tagged karyopherin relocalization by live cell imaging before and after Nup degradation. Additionally, we are exploring changes in steady state dynamics of karyopherins following Nup-degradation using Fluorescence Recovery After Photobleaching. Depletion of a subset of Nups results in altered karyopherin transport dynamics, suggesting a specific requirement of karyopherins for these Nups during import and export. Together, these data provide useful insights into the specific relationship between individual Nups and specific import and export pathways.

Nuclear Pore Complexes (NPCs) mediate bidirectional transport of molecules between the cytoplasm and nucleus. NPCs consist of around 30 distinct proteins (nucleoporins) that form a channel through the nuclear envelope, with filaments extending into the nucleus and cytoplasm. Nucleoporins associated with the cytoplasmic filaments (CFs) include RanBP2 (also known as Nup358), Nup214, Nup88 and Aladin. RanBP2 binds the SUMO1-modified form of the Ran GTPase activating protein (RanGAP1•SUMO1), and the SUMO conjugating enzyme Ubc9 in a stable complex (RRSU complex). CFs interact with transport complexes as they enter and exit the nucleus, and CFs interact with components of the microtubule cytoskeleton. During mitosis, some CF components localize on mitotic spindles and play important roles in spindle assembly or function. In particular, the RRSU complex associates to mitotic kinetochores in a Crm1- and Ran-dependent manner, and this recruitment is important for the formation of spindle-kinetochore attachments. Nup214 and Nup88 have likewise been reported to have important mitotic roles. It is difficult to assess the functions of individual vertebrate nucleoporins using conventional gene knockdown or knockout systems because they are abundant and highly stable proteins, because they have important roles in both interphase and mitosis, and because they are often encoded by essential genes. To circumvent these problems, we are using CRISPR/Cas9 to biallelically insert an auxin-induced degron (AID) tag into CF nucleoporins genes in DLD-1 cells. AID-tagged CF nucleoporins correctly local in functional NPCs. Upon auxin treatment, they are rapidly and specifically degraded, allowing us to assay changes in cellular functions. We are particularly investigating nuclear transport, gene regulation, mitotic progression, and post-mitotic nuclear envelope and NPC re-assembly. Our results will be discussed in comparison to earlier reports, and we will discuss how these proteins individually contribute to NPC function during the cell cycle in higher eukaryotes.

Torsin A expression in budding yeast reveals a connection to conserved lumenal domains of the nuclear pore complex.
M. Chalfant\textsuperscript{1}, C. Zhao\textsuperscript{2}, S. Borah\textsuperscript{1}, K.W. Barber\textsuperscript{3}, C.D. Schlieker\textsuperscript{1,2}, P. Lusk\textsuperscript{1};
\textsuperscript{1}Department of Cell Biology, Yale School of Medicine, New Haven, CT, \textsuperscript{2}Department of Molecular Biophysics and Biochemistry, Yale University, New Haven, CT, \textsuperscript{3}Department of Cellular and Molecular Physiology, Yale School of Medicine, New Haven, CT

Early onset hereditary dystonia is a neurodegenerative disease caused by a 3 bp (ΔE) deletion in the DYT1 gene, which encodes the AAA+ ATPase TorsinA (TorA). TorA is an atypical ATPase that localizes to the endoplasmic reticulum/nuclear envelope lumen: its ATPase activity is stimulated by binding to the lumenal domains of either the integral inner nuclear membrane protein LAP1 or the resident ER protein, LULL1; however, its substrates and function remain ill defined. Accumulating evidence supports that TorA functions at the nuclear envelope, perhaps during nuclear pore complex (NPC) biogenesis: expression of TorA-ΔE in developing neurons and the knockout of all Torsin alleles in cell culture results in the formation of nuclear envelope herniations over NPC-like structures. As the NPC biogenesis pathway is thought to be well conserved, we hypothesized that the machinery that Torsin acts on is likely also present in budding yeast: morphologically similar nuclear envelope herniations have long been observed upon perturbing NPC biogenesis in this organism. We therefore expressed TorA-GFP and TorA-ΔE-GFP in S. cerevisiae and observed a discrete accumulation of these fusion proteins at the nuclear envelope, likely at spindle pole bodies. Consistent with the idea that TorA impacts nuclear envelope function, genetic backgrounds with deletions of conserved integral nuclear envelope proteins were sensitive to TorA or TorA-ΔE overexpression. Most remarkably, an unbiased affinity purification strategy revealed that TorA-GFP interacts with Pom152, a transmembrane domain-containing nucleoporin that possesses a well conserved cadherin-like lumenal domain. As TorA-ΔE-GFP failed to interact with Pom152, our data are consistent with a model in which TorA-ΔE-linked nuclear envelope herniations might be a result of an inability of TorA to interact productively with the NPC biogenesis machinery. Our data therefore provide new avenues to interrogate the dystonia-disease mechanism while further suggesting the existence of structural motifs that have been well maintained through evolution.

Chm7/CHMP7 is recruited to nuclear envelope herniations through the winged helix domain of Heh1/LEM2.
D.J. Thaller\textsuperscript{1}, S. Borah\textsuperscript{1}, M. Allegretti\textsuperscript{2}, P. Ronchi\textsuperscript{1}, M. Beck\textsuperscript{2}, P. Lusk\textsuperscript{1};
\textsuperscript{1}Cell Biology, Yale School of Medicine, New Haven, CT, \textsuperscript{2}Structural and Computational Biology Unit, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, \textsuperscript{3}Electron Microscopy Core Facility, European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

The endosomal sorting complexes for transport (ESCRT) are recruited to the nuclear envelope upon the imposition of genetic nuclear pore complex (NPC) assembly blocks (Webster et al. Cell. 2014; Webster, Thaller et al. EMBO. 2016). In particular, yeast strains with nuclear envelope herniations (Wente and Blobel, JCB. 1993; Scarcelli et al. JCB. 2007) exhibit a striking accumulation of the ESCRT Chm7/CHMP7 suggesting that ESCRTs might seal off defective NPCs in a quality control mechanism that remains to be fully elucidated. It is unclear, for example, whether Chm7 is even recruited to NE herniations let alone...
whether it plays a direct role in their biogenesis or resolution. Here, we take advantage of correlative light electron microscopy to show that a gain of function mutant of Chm7 (chm7\textsuperscript{OPEN}) accumulates at nuclear envelope herniations. Affinity purification of chm7\textsuperscript{OPEN} further confirms the importance of the Lap2-emerin-MAN1 (LEM) domain integral inner nuclear membrane protein, Heh1, and specific nucleoporins, as physical interactors. We also further refine the molecular determinants of Chm7 recruitment to conserved amino acid residues in the C-terminal winged helix domain of Heh1, which are also required to support viability of CHM7-dependent genetic backgrounds. Ongoing efforts are examining the morphology of the nuclear envelope in strains lacking CHM7, which show discontinuities consistent with ruptures. These data suggest an emerging relationship between herniations and loss of nuclear envelope integrity.

Towards defining the interactome of LEM-domain proteins and ESCRTs during nuclear pore complex biogenesis.

S. Borah\textsuperscript{1}, D.J. Thaller\textsuperscript{1}, Z. Hakhverdyan\textsuperscript{2}, M.P. Rout\textsuperscript{2}, P. Lusk\textsuperscript{1};

\textsuperscript{1}Department of Cell Biology, Yale University, New Haven, CT, \textsuperscript{2}Laboratory of Cellular and Structural Biology, The Rockefeller University, New York, NY

The biochemical interactions that contribute to de novo nuclear pore complex (NPC) assembly and endosomal sorting complexes required for transport (ESCRT)-mediated NPC assembly-surveillance remain ill defined. For example, in previous work, we determined that the budding yeast Lap2-emerin-MAN1 (LEM)-domain containing integral inner nuclear membrane proteins, Heh1 and Heh2, recruit the ESCRTs to the nuclear envelope, likely to sites of NPC assembly (or misassembly) (1, 2). However, the mechanism by which the LEM domain proteins and/or the ESCRTs identify de novo NPC assembly sites remains unknown. To shed light on this question, we have used an affinity-pulldown strategy to isolate native complexes of Heh1, Heh2 and the nuclear envelope-specific ESCRT, Chm7/CHMP7 from both wildtype cells and those where NPC assembly is genetically inhibited. These experiments show that Heh2 stably interacts with either a subset of NPCs and/or intermediates in the NPC assembly process whereas the interaction between Chm7, Heh1 and nuclear pore complex proteins (nucleoporins/nups) can be stimulated by imposing NPC assembly blocks. These data provide a foundation to identify the molecular mechanism that trigger ESCRT-recruitment to the nuclear envelope.

College London, London, United Kingdom

The Nuclear Pore Complex (NPC) is the major conduit of macromolecular transport between the nucleus and cytoplasm. At the core of this massive protein complex is a central channel filled with intrinsically disordered proteins rich in Phe-Gly (FG) amino acid residues in repetitive motifs. A clear understanding of the mechanisms underlying the NPC’s selective permeability properties remain to be fully defined and are likely dependent on the collective properties of these “FG-nups”. Here, we use a technique called DNA-origami to generate a ring-like scaffold with dimensions that mimic the native NPC central channel. By engineering “anchor points” with 8-fold radial symmetries for recombinantly produced FG-nups, these Nucleoporins Organized by DNA” or “NuPODs allow the systematic examination of the collective properties of FG-nups within relevant 3D architectures, with precise stoichiometries and spatial positioning. So far, we have successfully assembled up to 48 copies of either the FxFG nup, Nsp1, or the GLFG nup, Nup100. Using transmission electron and super-resolution microscopy, these FG-nups exhibit unique morphologies; high speed atomic force microscopy shows that both FG-nups exhibit remarkable mobility within the DNA rings. We will ultimately utilize NuPODs as a platform for investigating increasingly complex networks of FG-nups and their ability to function as a permeability barrier.

Nuclear pore complexes (NPCs) are the sole gates embedded in the nuclear envelope (NE), acting as a key regulator of transport between the cytosol and the nucleus. NPCs consist of ∼30 proteins, termed nucleoporins. About one-third of nucleoporins harbor unstructured, intrinsically disordered phenylalanine-glycine repeats (FG-Nups), which involved in transport selectivity. Because the barriers insert deeply in the NPC, they are nearly inaccessible. Several in vitro barrier models have been proposed; however, the dynamic FG-Nups protein molecules themselves are imperceptible in vivo. We show here that high-speed atomic force microscopy (HS-AFM) is a potential tool to visualize nanotopographical changes of the nuclear pore central channel in colorectal cancer cells. Furthermore, using MLN8237/alisertib, an apoptotic and autophagic inducer currently being tested in relapsed cancer clinical trials, we showed the functional loss of nucleoporins, particularly the deformation of the FG-Nups barrier, in dying cancer cells. We propose that the loss of this nanoscopic resilience is an irreversible dying code. These findings not only illuminate the potential application of HS-AFM as an intracellular nanoendoscopy but also might aid in the design of future nuclear envelope-targeted nanodrug delivery tailored to the individual patient.

Complete 3D mapping of FG domains for all eleven FG-Nups in living cell NPCs using super-resolution microscopy.
J. Yu¹, J. Kelich¹, Y. Li¹, J. Kim¹, N. Guessaymi¹, M. Klein¹, W. Yang¹; ¹Biology, Temple University, Philadelphia, PA

Nuclear Pore Complexes (NPCs) are large macromolecular gateways that serve to regulate the passage of particles between the nucleus and cytoplasm of eukaryotic cells. The two primary components of the NPC are the structural scaffold nucleoporins and the phenylalanine-glycine (FG) motif containing nucleoporins (FG-Nups). While the former has been well studied with electron microscopy to reveal their spatial positions and structure, FG nups, however, due to their dynamic nature and lack of secondary structure, have thus far not been individually mapped in their native environment: a living cells NPC. These FG-Nups compose the NPCs permeability barrier. Here we present a complete three-dimensional mapping of the FG domains for all known FG-Nups in living cells obtained through super-resolution microscopy for the first time. Dynamical ranges of motion for FG-Nups within native NPCs are also revealed.

Correlative Light and Electron Microscopy at the Nuclear Envelope Herniations.
M. Allegretti¹, D.J. Thaller², P. Ronchi³, Y. Schwab³⁴, P. Lusk³, M. Beck¹⁴; ¹Structural and Computational Biology Unit, European Molecular Biology Laboratory, Heidelberg, Germany, ²Department of Cell Biology, Yale School of Medicine, New haven, CT, ³Electron Microscopy Core Facility, European Molecular Biology Laboratory, Heidelberg, Germany, ⁴Cell Biology and Biophysics Unit, European Molecular Biology Laboratory, Heidelberg, Germany

Nuclear envelope herniae (herniations) are protrusions of the outer and inner nuclear membrane that enclose nuclear pore complexes (NPCs). They have been observed as a result of genetic manipulation of nuclear envelope associated proteins and nucleoporins in both yeast (Wente and Blobel, 1993; Scarcelli et al, 1996; Murphy et al, 1996) and human cells (Laudermilch et al, 2016). More recently, ESCRT components have been found to play a major role in the surveillance of nuclear envelope integrity, including the formation of herniae (Webster et al, 2014; Webster, Thaller et al, 2016). Nevertheless the exact origin and potential physiological role of nuclear envelope herniations remains unknown.
We have used correlative light and electron microscopy CLEM (Kukulski et al, 2011) to understand the fate of the herniae in various yeast strains and under conditions of impaired NPC assembly. We show that anchor away (Haruki et al, 2008; Colombi et al, 2013) of the newly synthesized nuclear pore proteins Nup192 (inner ring complex) and Nup84 (Y-complex) induce herniae formation after 3-5 hours. We show that FG-nucleoporins of the inner ring are present at the herniae sites. Prospectively, we will structurally analyze herniations by cryo-electron tomography and subtomogram averaging to address if the underlying NPC is fully or partially assembled.

Opening windows into the Cell: taking the next step in Structural Biology.
G. Heiss¹, A. Rigort¹, D. Rossum¹;
¹Analytical Instruments, Thermo Fisher Scientific, Eindhoven, Netherlands

Studying the molecular machinery of cells with molecular detail in the cellular context is a great challenge for cell and structural biology. It requires the integration of dynamic and structural information coming from different ranges of spatial resolution and imaging modalities. In order to do so, a comprehensive workflow is needed covering live-cell imaging, vitreous freezing, cryo-fluorescence microscopy, sample thinning and high-resolution electron cryo-tomography.

As most cell types (and particular the nuclear region) are too thick to be studied in the cryo-TEM the sample needs to be thinned in order to render it accessible to cryo-TEM imaging. Thinning by mechanical means has been notoriously difficult and artifact prone in the past why we follow the approach to apply cryo focused-ion-beam (cryo-FIB) milling to thin vitreously frozen specimens. Using a FEI DualBeam™ microscope, regions of interest are thinned down to the appropriate thickness of 200-300 nm while maintaining cryogenic conditions. The thinned cellular sample is then transferred to an automated, high-throughput cryo-TEM for high-resolution imaging by electron cryo-tomography

On the micro rheology of the Nuclear Pore Complex: Nature evolved a novel super nanopore.
R. Moussavi-Baygi¹, M. Mofrad¹;
¹Applied Science Technology, UC Berkeley, Berkeley, CA

The nuclear pore complex is the unique gateway to the cell nucleus and is allegedly filled with intrinsically disordered proteins (IDPs) rich in Phe-Gly repeat domains. While the microdynamics of these IDPs is under debate and there are several groups actively involved in the field, there is no information and/or consensus about their micro rheology. Here, unprecedentedly, we deep dive into the micro rheology of IDPs confined inside the NPC. Our results indicate that the IDPs rich in FG repeat domains show an intriguing rheological behavior, which uniquely stems from the interplay of biophysical factors including hydrophobicity, charge, the ratios of positive and negative charge content to hydrophobicity content, geometrical confinement, chains' lengths, channel wall permeability, and the
chains’ end-tethering. It appears that among these factors, the latter plays the dominant role in shaping the mechanical spectrum of FG-meshwork, particularly in low-frequency domains. The frequency-dependent viscosity of the FG-meshwork is reminiscent of pseudo-plasticity, and thus, the FG-repeats form a shear-thinning polymeric meshwork. The meshwork poses a super-viscous environment to the inert (non-specific) cargos while behaving like less viscous liquid for nuclear-transport-factor-bound cargos.

Genome-wide screen indicates that the spatial organization of genomes is dynamically regulated by transcription factors.

D.G. Brickner¹, J.H. Brickner¹;

¹Molecular Biosciences, Northwestern University, Evanston, IL

Hundreds of genes physically interact with the nuclear pore complex (NPC) and many inducible genes reposition to the nuclear periphery when they are activated. In budding yeast, interaction with the NPC is controlled by cis-acting targeting elements (or “DNA zip codes”) and requires both NPC proteins and transcription factors (TFs). Here, we describe the mechanistic dissection of the function of TFs and transcriptional regulators/mRNA export factors in mediating targeting to the nuclear periphery. Further, we have performed a global screen of all ~200 yeast transcription factors to test the generality of this phenomenon. Each TF was tagged with the DNA binding domain from LexA and crossed against a strain having the LexA binding site integrated at a locus that normally localizes to the nucleoplasm. The position of this locus with respect to the nuclear envelope was scored using confocal microscopy. Approximately 50% of the tested transcription factors were sufficient to cause localization to the nuclear periphery. The major pathway by which this targeting was mediated required the NPC; CRISPR-mediated mutations in the NPC protein Nup2 blocked peripheral targeting by >95% of these TFs. This suggests that controlling gene positioning within the nucleus is an important and unappreciated function of TFs and that interaction with the NPC is the major pathway by which genes localize at the nuclear periphery. The TFs identified in the screen regulate over 1000 genes, including housekeeping genes as well environmentally or developmentally regulated genes. The TFs are found in all transcription factor families in budding yeast and a large subset (50%) of the transcription factors identified have human homologs. A human TF was able to mediate targeting to the nuclear periphery in yeast, suggesting that the molecular mechanism of gene recruitment to the NPC has been deeply conserved and likely plays a fundamental role in genome organization.

Sphingolipid homeostasis is critical for nuclear envelope integrity.

S. Hwang¹, E.M. Torres¹;

¹Molecular, Cell and Cancer Biology, UMass Medical School, Worcester, MA

The structure and integrity of the nuclear envelope depends on complex interactions between a diverse group of nuclear envelope proteins, the nucleoplasm and cytoplasm. However, the roles that specific lipid molecules play in the formation and integrity of the nuclear envelope remain poorly understood. Here we show that inhibition of de novo synthesis of sphingolipids leads to abnormal nuclear envelope morphology in *Saccharomyces cerevisiae*. Moreover, we find that in human cells, inhibition of sphingolipid synthesis not only affects nuclear envelope structure but also promotes the formation of
micronuclei and increases genomic instability. Our studies reveal an important role for sphingolipids in regulating nuclear envelope integrity, and also suggest a possible mechanism for how downregulation of sphingolipids may promote tumorigenesis as a result of increased genomic instability.

Nuclear envelope defects on S. japonicus lagging chromosomes.
I. Lee\textsuperscript{1,3}, E. Stokasimov\textsuperscript{1,2}, D. Pellman\textsuperscript{1,2,3},
\textsuperscript{1}Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, \textsuperscript{2}Cell Biology, Harvard Medical School, Boston, MA, \textsuperscript{3}Howard Hughes Medical Institution, Chevy Chase, MD

The nuclear envelope (NE) is a highly organized membrane structure separating chromosomes from the cytoplasm in eukaryotes. In metazoans, the NE disassembles in mitotic prophase, and reassembles in late anaphase/telophase. If a lagging chromosome persists until telophase, NE assembly on the lagging chromosome can lead to the formation of an aberrant nuclear structure called a micronucleus. Micronuclei are prone to disrupt the NE, which can result in massive localized DNA rearrangements termed chromothripsis. This highlights the importance of understanding NE assembly on lagging chromosomes, which would be greatly facilitated by studies in a facile model system. However, NE disassembly and reassembly do not occur in organisms that undergo closed-mitosis, such as S. cerevisiae and S. pombe, making it difficult to utilize them in aforementioned studies. Here we use S. japonicus, the dimorphic yeast that undergoes semi-open mitosis, to investigate the NE on lagging chromosomes. We found that although lagging chromosomes were enclosed by NE components, they could not assemble a functional NE, and would spontaneously lose NE components over time. We are testing several possible mechanisms underlying this instability. One possibility is that NE sealing could be defective on lagging chromosomes. Recent studies suggested that Chmp7, a protein likely to be a fusion of ESCRT-II and ESCRT-III proteins, directs the assembly of ESCRT-III filaments on chromatin to seal the newly assembled NE after DNA segregation. We found that deletion of S. japonicus chmp7 impaired the import of NLS-GFP, suggesting that the function of Chmp7 in NE integrity may be conserved. Interestingly, chmp7\textsuperscript{-}\textDelta cells were viable. In addition to investigating how Chmp7 might affect NE sealing around lagging chromosomes, we have also isolated suppressors of chmp7\textsuperscript{-}\textDelta to define parallel NE sealing mechanisms.

Although Gp210 was the first nuclear pore complex (NPC) protein identified 35 years ago, a role in supporting nucleocyttoplasmic transfer has remained elusive. Despite being one of the few transmembrane NPC proteins, a number of studies suggest that Gp210 is not required for assembly or localization of the NPC, consistent with observations that not all cells express Gp210. Recent inquiries into Gp210 function have uncovered roles in a variety of cellular processes including regulation of gene specific transcription in muscle cells, maintenance of ER homeostasis and in cellular differentiation. A particularly interesting and surprising finding is that some functions of Gp210 do not require the protein to be localized to the NPC. We present an in-depth study of Gp210 function in Drosophila melanogaster, reporting on gp210 mutant phenotypes in multiple tissues and cell types during various stages of the Drosophila life cycle.
Our initial investigation takes advantage of two existing P-element insertions into the gp210 locus which significantly decrease transcript and protein levels. Despite strong knock-down from these hypomorphic mutations, both alleles are surprisingly viable and fertile as homozygotes, and do not have a decreased lifespan. Moreover, preliminary studies indicate that these two gp210 alleles display age dependent loss of motor function similar to wild-type animals. We are currently generating a null allele and tissue specific knock downs of Gp210 function using transgenic CRISPR/Cas9 approaches. Our preliminary results have also led to the interesting discovery that Gp210 mutants have an increase in Nuclear Envelope Budding (NEB) events, however it is unclear if this phenotype is due to increasing or blocking of this process. During NEB, large granules containing RNA presumably bud through the nuclear envelope in a process akin to the nuclear egress of Herpesviridae nucelocapsids, however, the cellular function of this pathway is still enigmatic. We are testing a number of possibilities to determine the mechanisms underlying the apparent increase in NEB events in gp210 mutants. Additionally, we find that mutant animals display altered movement behavior, and in accordance with other studies, loss of Gp210 function does not grossly alter the localization of the NPC but does lead to elevated levels of ER stress in some cell types. Ultimately, these in-vivo studies will add to our understanding of this enigmatic NPC protein.

Aurora B-mediated exclusion of HP1α from late-segregating chromatin prevents formation of micronuclei.
B. Warecki1, W. Sullivan1;
1MCD Biology, UC Santa Cruz, Santa Cruz, CA

In Drosophila neuroblasts, late-segregating acentric chromosome fragments that would otherwise form micronuclei are instead incorporated into telophase daughter nuclei by passing through Aurora B kinase-dependent channels in the nuclear envelope. However, the mechanism by which Aurora B kinase activity mediates channel formation remains unknown. Here, we show that localized concentrations of Aurora B preferentially phosphorylate H3(S10) on acentrics and their associated DNA tethers to exclude association with the heterochromatin component HP1α. Additionally, we show that Aurora B-mediated exclusion of HP1α from endonuclease- and irradiation-induced acentrics results in localized inhibition of nuclear envelope reassembly both on acentrics and on the main daughter nuclei at the sites of acentric entry. These data suggest a model in which Aurora B-mediated phosphorylation of H3(S10) on acentrics and their associated tethers prevents HP1α recruitment and subsequent nuclear envelope reassembly on the lagging acentrics and their tethers. This ultimately results in nuclear envelope channel formation and reintegration of the late-segregating acentrics into the main nuclei, avoiding micronucleation. In support of this model, we find that HP1α also plays a role in global nuclear envelope dynamics by specifying the site of initiation of nuclear envelope reassembly. Taken together, these results demonstrate that mitotic HP1α-chromatin interactions influence nuclear envelope reassembly and maintain genome integrity in response to endonuclease- or irradiation-induced chromosome fragments that would otherwise form micronuclei.

The Structural Basis of an ESCRT-III Membrane Assembly.
H.C. Nguyen1, N. Talledge1,2, J. McCullough2, D.M. Wenzel2, J.J. Skalicky2, W.I. Sundquist2, A. Frost1,2,3;1Department of Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA, 2Department of Biochemistry, University of Utah, Salt Lake City, UT, 3Chan Zuckerberg Biohub, San Francisco, CA

The Endosomal Sorting Complexes Required for Transport (ESCRT) mediate critical membrane remodeling events throughout the mammalian cell cycle, including HIV budding, cytokinetic abscission, and sealing of the nuclear envelope, among other roles. ESCRT-III proteins assemble into membrane-binding filaments to catalyze these reactions, but the structures and functions of these assemblies remain poorly understood. Our collaborative team recently determined the first atomic-resolution structure of an ESCRT-III filament – a hetero-polymer consisting of CHMP1B and IST1/CHMP8. Our previous structure demonstrated how one of these ESCRT-III subunits, CHMP1B, transitions from a “closed” to an “open” state to form an interlocked and domain-swapped filament. Moreover, we and others have shown that the CHMP1B-CHMP8 copolymer participates in non-canonical, positive-curvature membrane fission pathways. Very recent work on other ESCRT-III proteins indicated that the mechanisms of opening and assembly we reported are conserved, but also raised questions regarding membrane binding and remodeling activities, as well as and the generality of hetero-polymerization. To address these gaps in our understanding, we have determined the high-resolution structure of a membrane-bound CHMP1B-CHMP8 assembly by cryo electron microscopy (cryoEM). We find that CHMP1B induces a high degree of curvature alone, and that deposition of the CHMP8 strand further constricts the membrane tubule by more than 2-fold – almost to the fission point. Notably, the distance between outer leaflet lipid headgroups is ~10 nm and the distance between inner leaflet lipid headgroups is reduced to only ~4 nm. Conserved residues along helix α1 of CHMP1B serve as the major membrane binding surface and exploit both electrostatic as well as hydrophobic interactions with the convex leaflet of the membrane tubule. Our atomic-resolution cryoEM study reveals the structural mechanisms governing ESCRT-III assembly, membrane-binding, and positive-curvature membrane deforming activities. By analogy with the structural features of other ESCRT-III proteins, we propose general rules for membrane-shaping by the ESCRT-III family.

A new model for COPII-mediated cargo export from the endoplasmic reticulum.
O. Shorn1, I. Nevo-Yassa2, T. Aviad1, J. Shepchelovich1, Y. Yaffe1, E. Perlson3, A. Yeheskel3, M. Pasmanik-Chor3, G.H. Patterson4, C. Kaether5, K. Hirschberg1;1Pathology, Tel Aviv University, Tel Aviv, Israel, 2Physiology and Pharmacology, Tel Aviv University, Tel Aviv, Israel, 3Bioinformatics Unit, G.S.W. Faculty of Life Sciences, Tel Aviv University, Tel Aviv, Israel, 4Section on Biophotonics, NIBIB, National Institutes of Health, Bethesda, MD, 5Leibniz Institute for Age Research, Fritz Lipmann Institute, Jena, Germany

Both COPII and COPI are considered as analogous sets of coat protein complexes mediating the formation of membrane vesicles translocating in opposite directions to different destinations within the secretory pathway. Here we provide evidence for a fundamentally different model for the function of
the COPII coat during protein export from the endoplasmic reticulum (ER). We used live cell microscopy combined with a range of well-defined pharmaceutical and genetic perturbations of ER-Golgi transport. Primarily, ER to Golgi transport of a cargo membrane protein was visualized in living intact cells coexpressing fluorescently tagged Sec24 isoforms. Further COPII localization and function were analyzed and characterized in living intact cells by uncoupling vesicle fission from the preceding cargo sorting and accumulation processes in ERESs (using BFA and Nocodazole treatment). Finally, perturbation at the interface of COPII-cargo using mutagenesis of Sec24 was applied resulting in cargo accumulation in the ER, functionally establishing the localization of COPII at the ER-ERES boundary. Together, these data support the hypothesis that rather than generating coated vesicles, COPII mediates the sorting of transport-competent proteins by dynamic binding to stable elongated membranes that comprise the ER-ERES boundary. The finding that COPII is absent from nascent vesicles and thus does not limit carrier size or shape, resolves the dispute of how large cargo molecules or complexes can be accommodated in ER-derived vesicle. We propose that cargo sorting and concentration is driven by ER to ERES-directed treadmilling of the membrane bound COPII coat-cargo complex. This treadmilling movement is generated by restricting COPII recruitment to the ER side of the boundary by the activated GTP-bound ER-localized Sar1 GTPase. Cargo-protein interaction with its neighboring membrane environment contributes to direct this process. These findings transform our understanding of the role of coat proteins in ER to Golgi transport.

Dynamin is a mechanochemical GTPase essential for membrane fission during clathrin mediated endocytosis. Dynamin forms washer ring-shaped/helical complexes at the neck of endocytic pits and their structural changes coupled with GTP hydrolysis drive membrane fission. Dynamin and its binding protein amphiphysin cooperatively regulates membrane remodeling during fission (Yoshida et al., EMBOJ 2004), but its precise mechanism remains elusive. In this study, we analyzed structural changes of dynamin-amphiphysin complexes during membrane fission using electron microscopy and high-speed atomic force microscopy (HS-AFM). In vitro incubation of liposomes with recombinant human dynamin 1 and amphiphysin resulted in the formation of membrane tubules decorated with dynamin 1-amphiphysin ring complexes. The addition of GTP to the membrane tubules lead to the formation of multiple constriction sites within 30 sec., then eventually the membrane fission occurred and numerous vesicles were formed within 1min. Interestingly, dynamin 1-amphiphysin ring complexes were transiently formed clusters prior to membrane fission. HS-AFM analyses clarified that regularly spaced dynamin-amphiphysin rings were dynamically rearranged to form clusters upon GTP hydrolysis and membrane constriction occurred at protein-uncoated regions between the clusters. Furthermore, we found a novel function of amphiphysin in size control of the dynamin 1-amphiphysin clusters to enhance biogenesis of endocytic vesicles. Our new approaches using combination of EM and HS-AFM clearly demonstrates dynamics of dynamin-amphiphysin complexes during membrane fission suggesting a novel “clusterase” model of dynamin-mediated membrane fission.

Structural Basis of Mitochondrial Receptor Binding and GTP-Driven Conformational Constriction by Dynamin-Related Protein 1.
R. Kalia1,2, R.Y. Wang1, A. Yusuf1, P.V. Thomas1, D.A. Agard1, J.M. Shaw2, A. Frost1,2; 1Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA, 2Biochemistry, University of Utah, Salt Lake City, UT

Mitochondrial inheritance, genome maintenance, and metabolic adaptation all depend on organelle fission by Dynamin-Related Protein 1 (DRP1) and its mitochondrial receptors. DRP1 receptors include the paralogs Mitochondrial Dynamics 49 and 51 (MID49/MID51) and Mitochondrial Fission Factor (MFF), but the mechanisms by which these proteins recruit DRP1 and regulate its activities are unknown. Here we present a cryoEM structure of human, full-length DRP1 bound to MID49 and an analysis of structure-and disease-based mutations. We report that GTP binding allosterically induces a remarkable elongation and rotation of the G-domain, Bundle-Signaling Element (BSE) and connecting hinge loops of DRP1. In this nucleotide-bound conformation, a distributed network of multivalent interactions promotes DRP1 copolymerization into a linear filament with MID49, MID51 or both. Subsequent GTP hydrolysis and exchange within the filament leads to receptor dissociation, shortening through disassembly, and concomitant curling of DRP1 oligomers into closed rings. The dimensions of the closed DRP1 rings are consistent with DRP1-constricted mitochondrial tubules observed in human cells. These structures are the first views of full-length, receptor- and nucleotide-bound dynamin-family GTPases and—in comparison with nucleotide-free crystal structures—teach us how these molecular machines perform mechanical work through nucleotide-driven allostery.

Escaping the bar: modulating dynamin function and T-tubule maintenance through SH3-PRD domain interaction.
J. Laiman1, Y. Liu1; 1Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan

Eukaryotic cells harness multiple endocytosis pathways to regulate cell signaling and nutrient uptake to cope with different physiological demands. Among those different endocytic machineries, a membrane fission GTPase dynamin has been demonstrated to be a key regulator for several endocytic routes. However, fission activity of dynamin-2, a ubiquitously expressed isoform of dynamin, is curvature sensitive. In muscle cells, invagination of cell membrane forms highly curved T-tubules that are enriched in phosphatidylinositol-4,5-bisphosphate (PI4,5P2), a phospholipid that is strongly bound by PH domain of dynamin-2. The muscle-specific form of BIN1/Amphiphysin 2, a Bin/Amphiphysin/Rvs (BAR) domain containing protein, is highly expressed in T-tubule and is important for its biogenesis. BIN1 could bind to dynamin-2 PRD domain through its SH3 domain. These criteria make T-tubule a perfect platform for dynamin-2 scission. We previously discovered that Centronuclear myopathy-associated dynamin-2 mutants could indeed induce T-tubule fragmentation. Yet T-tubule integrity is preserved in physiologically normal cells, suggesting that there must be a mechanism to regulate dynamin function. Despite its membrane-curvature-generation ability, we find that BIN1 would actually inhibit dynamin function in mediating membrane fission in vitro. This inhibition is due to SH3-PRD domain interaction, as truncated BIN1 lacking the SH3 domain would cause opposite result; it promotes GTP-dependent
membrane scission of dynamin. In turns, membrane tubulation by BIN1 is inhibited in the presence of dynamin. This reciprocal inhibition happens through regulation of protein assembly on the membrane. We propose that phosphorylation in PRD domain of dynamin-2 would serve as a mechanism to modulate SH3-PRD domain inhibition. We generate dynamin-2 phosphomimetic mutant with lower binding affinity to SH3 domain of BIN1 and show that this mutant could partially relieve inhibition of both dynamin-mediated membrane fission and BIN1 membrane tubulation caused by SH3-PRD domain interaction. Together, our results provide a new insight into the regulation mechanism between dynamin and its binding partners via binding affinity alteration. Our next step is to observe whether dynamin function in other endocytic pathways is controlled through similar mechanism, particularly clathrin-mediated endocytosis (CME) which happens generally in all cells and GLUT4 endocytosis that is specifically expressed only in muscle and fat cells.

Identification of cargoes trafficked by the retromer and CCC complexes using quantitative proteomics.
S. Swarup1, C. Bell1, J.A. Paulo1, S.P. Gygi1, J.W. Harper1;
1Department of Cell Biology, Harvard Medical School, Boston, MA

The retromer (VPS35-VPS29-VPS26) and CCC (CCDC22-CCDC93-COMMD) complexes function at endosomes to sort and traffic cargoes along specific intracellular routes. Cargoes regulated by these complexes include sorting receptors, ion transporters, and signaling receptors, that are directed either to the plasma membrane via the recycling pathway or the Golgi via the retrograde pathway. The precise delivery of cargoes to their appropriate destinations is critical for normal cellular function, and aberrant retromer- or CCC-mediated sorting results in cargoes mistrafficked to the lysosome and abnormal cellular function. In fact, VPS35 and CCDC22 have been identified as genetic risk factors of Parkinson’s disease and X-linked intellectual disability, respectively, where the incorrect trafficking of yet unknown cargoes due to compromised function of the retromer and CCC complexes contributes to the cellular physiology of these disease states.

In this study, we used an organelle enrichment strategy in combination with multiplexed tandem mass tag (TMT)-based quantitative proteomics to systematically profile retromer and CCC cargoes. Plasma membrane proteins were isolated using selective cell surface biotinylation followed by streptavidin enrichment, while Golgi and lysosome fractions were isolated by sequential density ultracentrifugation. The isolated organelle protein fractions were digested using Lys-C and trypsin, and the resulting peptide fragments were labeled with isobaric TMT and subjected to multi-notch mass spectrometry. Through the comparison of the proteomes of the plasma membrane, Golgi, and lysosome in control versus VPS35 or CCDC22 null cells, we have identified a comprehensive set of cargoes that are trafficked by the retromer and CCC complexes in the recycling and retrograde pathways. Our proteomic dataset includes several previously unidentified cargoes of the retromer and CCC complexes such as members of the GOLGIN family of tethering factors of the Golgi and the plasma membrane transporter SLC7A1, respectively. We are in the process of expanding our proteomic analyses to include mutated variants of VPS35 and CCDC22 to identify which cargoes, if any, are mistrafficked to the plasma membrane or Golgi in disease states. Our study has provided a high confidence set of retromer and CCC cargoes that facilitates our understanding of the biology of these sorting complexes, how their perturbation disrupts cellular function, and provides novel targets for therapeutic intervention in disease states.

A Rab32 trafficking pathway that prevents bacterial infections.
M. Baldassarre1, V. Solano-Collado1, D. Mancuso1, S. Spano1;
1Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom

Host defense mechanisms protect complex organisms against the attack of microbes. Intracellular bacterial pathogens such as Salmonella, evolved sophisticated, often redundant, strategies to overcome host defense and cause infection. Despite sharing many strategies to overcome host defense, different Salmonella serovars show different pathogenic behaviors, suggesting the existence of unknown bacterial killing mechanisms. We previously identified a host trafficking pathway to the bacterial intracellular vacuole that prevents the human-restricted bacterial pathogen Salmonella Typhi from surviving in mouse macrophages and therefore infecting mice. This pathway depends on the host GTPase Rab32 and its guanine nucleotide exchange factor BLOC-3. We showed that in contrast to Salmonella Typhi, the broad-host pathogen Salmonella Typhimurium infect mice by counteracting the Rab32 trafficking pathway through the delivery of two type-III-secretion effectors: GtgE, which is a specific protease cleaving Rab32; and SopD2, which is a Rab GTPase activating protein (GAP). A Salmonella Typhimurium strain deficient for both of these effectors is unable to infect mice, yet it is fully virulent in BLOC-3 deficient mice. Therefore, the Salmonella Typhimurium effectors GtgE and SopD2 act redundantly to neutralize a powerful host defense pathway that can prevent bacterial infections. However, the Rab32-dependent mechanisms directly involved in bacterial killing are still unknown. Our new results indicate that Salmonella is not the only pathogen susceptible to this pathway and suggest that other intracellular pathogens have to counteract this host-defense pathway to be able to survive inside the host cell and to cause infection.

Regulation of connecdenn/DENND1 guanine nucleotide exchange factor activity by Arf5.
G. Kulasekaran1, M. Girard1, M. Fotouhi1, P.S. McPherson1;
1Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, QC

The DENN (differentially expressed in normal and neoplastic cells) domain is an evolutionary conserved protein module found in all eukaryotes and serves as a GEF (guanine nucleotide exchange factor) for Rab GTPases to regulate diverse cellular functions. Connecdenn 1/2 are DENN domain-containing proteins known to act as GEFs for Rab35. Disruption of connecdenn/Rab35 activity causes alterations in endosomal trafficking including defects in the recycling of multiple cargo proteins from early endosomes to the plasma membrane and an enlargement of early endosomes. These alterations lead to important changes in cellular function, and yet our understanding of the regulation of connecdenn GEF activity is incomplete. Here, we have discovered a novel interaction between the DENN domain of connecdenn 1/2 and Arf5, a class II Arf GTPases. Remarkably, while the DENN domain has no GEF activity towards Arf5, the binding of Arf5 to the DENN domain greatly enhances the GEF activity towards Rab35. Moreover Arf5 knockdown decreases the activity of Rab35 in cells with subsequent enlargement of early endosomes. This study reveals an unanticipated regulatory mechanism of connecdenn GEF activity towards Rab35 and provides an unprecedented link between Rabs and Arfs.

Arf6 is a negative regulator of axonal elongation in cultured rat hippocampal neurons.

S. Alvarez1,2, F. Bodaleo1,2, M. Fukuda1, C.E. Gonzalez-Billault1,2;  
1Biology, Universidad de Chile, Santiago, Chile, 2Geroscience Center for Brain Health and Metabolism, Santiago, Chile, 3Tohoku University, Sendai, Japan

The axonal elongation is a critical process for neuronal development that involves many cellular events, such as endosome recycling, membrane trafficking and cytoskeletal remodeling. Members of several families of GTPases act as regulators of these processes. Previous work from our group has identified the small GTPase Rab35 as a positive regulator of axonal elongation, through a mechanism dependent on Map1b. Additionally, it has been reported that there exists an interplay between the small GTPases Rab35 and Arf6 acting in cellular events such as cytokinesis, phagocytosis and the coordination of adhesion and migration. Therefore, in this work, we studied the effect of dominant negative (DN) and constitutively active (CA) forms of Arf6 upon axonal outgrowth in cultured rat hippocampal neurons. We also used SecinH3, a pharmacological inhibitor that targets the cytohesin family of Arf-GEFs, to evaluate its effect on axonal elongation. Overexpression of Arf6-DN and treatments with SecinH3 induced a phenotype on cultured neurons that resembled the effect of Rab35 upon axonal growth. Treatment with SecinH3 is also capable of rescuing the phenotype observed after Map1b knockdown. Additionally, either the overexpression of Arf6-CA or Epi64B, a Rab35 GAP that interacts with Arf6-GTP induced significantly shorter axons. Finally, co-transfection of wild type Rab35 and Arf6 produced a phenotype indistinguishable from control neurons. These results suggest that active Arf6 acts as a negative signal for axonal elongation, possibly through interactions with Rab35 regulators and point to a balance between the functions of Arf6 and Rab35 during axonal outgrowth.

Cdk5-dependent phosphorylation of GRAB, a guanine nucleotide exchange factor for Rab8, regulates neuronal migration in the developing cerebral cortex.

K. Furusawa1, A. Asada1, C. Gonzalez-Billaut2,3, M. Fukuda1, S. Hisanaga1;  
1Biological Sciences, Tokyo Metropolitan University, Minami-Osawa, Japan, 2Biology, Universidad de Chile, Las Palmas, Chile, 3FONDAP Geroscience Center for Brain Health and Metabolism, Santiago, Chile, 4Developmental Biology and Neurosciences, Tohoku University, Sendai, Japan

The migration of newborn neurons from their birthplace to their final destination is critical for the construction of brain structure. Recently, it is demonstrated that the migration of developing cortical neurons is precisely regulated under the membrane traffic. Rab GTPases are major regulators of the membrane trafficking. There are more than 60 members in Rab family, each of which is localized to distinct membrane components in promoting respective membrane traffic. However, it is not fully understood how these Rabs act cooperatively in migrating neurons during corticogenesis. Cyclin-dependent kinase 5 (Cdk5) is a neuron specific Ser/Thr protein kinase that is activated by binding either p35 or p39 regulatory subunit. It plays an important role in a variety of neuronal functions including neuronal migration during brain development. Cdk5-p35 is also involved in membrane traffic, but it is unknown whether Cdk5-p35 regulates membrane traffic in migrating neurons. Recently, we have shown that Cdk5-p35 phosphorylates GRAB, a guanine nucleotide exchange factor for Rab8, at Ser169 and...
Ser180, and this phosphorylation regulates the Rab11-Rab8 cascade. Because Rab11 is involved in cortical neuronal migration, we hypothesized that Cdk5-p35 regulates neuronal migration via GRAB activity by phosphorylation. Herein, we examined and found that GRAB is a novel regulator of neuronal migration in developing cerebral cortex. In utero electroporation studies revealed that GRAB knockdown arrested most neurons in intermediate zone of cerebral cortex. The knockdown of Rab8A/B or Rab11A/B showed similar phenotypes to the GRAB knockdown, suggested that GRAB regulates neuronal migration through the cascade of Rab8A/B and Rab11A/B. We examined the role of Cdk5-dependent phosphorylation of GRAB by introduction of wild-type GRAB (WT GRAB), non-phosphorylatable GRAB mutant S169/180A (2A GRAB), or phospho-mimic GRAB mutant S169/180D (2D GRAB) in migrating neurons together with GRAB-knockdown vector. The expression of WT GRAB fully restored neuronal migration in GRAB knockdown cortices, whereas 2A or 2D GRAB could not. These results suggested that GRAB regulates neuronal migration in developing cerebral cortex via Rab8 and Rab11 in a Cdk5-dependent manner.

Disruption of Rab8a and Rab11a causes formation of basolateral microvilli in neonatal enteropathy.
Q. Feng1, E.M. Bonder1, A.C. Engevik2, L. Zhang1,3,4, M.J. Tyska5, J.R. Goldenring2,5,6, N. Gao1,4; 1Department of Biological Sciences, Rutgers University, Newark, NJ, 2Department of Surgery, and Epithelial Biology Center, Vanderbilt University School of Medicine, Nashville, TN, 3Department of Pathology, University Medical Center of Princeton, Plainsboro, NJ, 4Rutgers Cancer Institute of New Jersey, Piscataway, NJ, 5Department of Cell Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN, 6Nashville VA Medical Center, Nashville, TN

Misplaced formation of microvilli to basolateral domains and intracellular inclusions in enterocytes are pathognomonic features in congenital enteropathy associated with STX3 mutation. While the demonstrated binding of Myo5b to the Rab8a and Rab11a small GTPases in vitro implicates cytoskeleton-dependent membrane sorting, the mechanisms underlying the microvillar location defect remain unclear. By selective or combinatorial disruption of Rab8a and Rab11a membrane traffic in vivo, we demonstrate that transport of distinct cargo to the apical brush-border rely on either individual or both Rab regulators, whereas certain basolateral cargos are redundantly transported by both factors. Enterocyte-specific Rab8a and Rab11a double knockout mouse neonates showed immediate postnatal lethality and more severe enteropathy than single knockouts, with extensive formation of microvilli along basolateral surfaces. Notably, following an inducible Rab11a deletion from neonatal enterocytes, basolateral microvilli were induced within 3 days. These data identify a potentially important and distinct mechanism for a characteristic microvillus defect exhibited by enterocytes of patients with neonatal enteropathy.

Intracellular logistics of LIS1, cytoplasmic dynein, and unconventional microtubules.
M. Yamada1; 1Cell Biology Biochemistry, University of Fukui, Yoshida-Gun, Fukui Prefecture, Japan

Lissencephaly is a devastating serious neurological disorder caused by defective neuronal migration. The LIS1 (platelet-activating factor acetylhydrolase, isoform 1b, subunit 1; official symbol PAFAH1B1, for
platelet-activating factor acetylhydrolase, isoform 1b, subunit 1) gene was identified as the gene mutated in individuals with lissencephaly. LIS1 was also found to regulate cytoplasmic dynein function and localization. Cytoplasmic dynein drives the movement of a wide range of various cargoes towards the minus ends of microtubules. LIS1 is known to be required for the dynein activity, but the underlying mechanism is poorly understood. We have previously already reported that the following; 1) that LIS1 mediates anterograde transport of cytoplasmic dynein to the plus end of cytoskeletal microtubules (MTs) as a LIS1-cytoplasmic dynein complex on unconventional microtubules (we call them transportable microtubules, t-MTs) in a kinesin-1-dependent manner. LIS1 forms an idling complex with cytoplasmic dynein, which is transported to the plus ends of cytoskeletal MTs by kinesin motors. We have also shown that Mammalian mammalian NUDC (mNUDC) interacts with kinesin-1 and is required for the anterograde transport of the LIS1/cytoplasmic dynein/tMTs complex by kinesin-1. mNUDC is also required for anterograde transport of a dynactin (P150Glued)-containing complex. However, the cytoplasmic dynein complex and the dynactin complex are separately transported to the plus-end of cytoskeletal MTs. 3) Small GTPase Rab6a mediates LIS1 release from the LIS1—cytoplasmic dynein complex followed by dynein activation at the plus-end of cytoskeletal MTs. On the other hand, another small GTPase, ADP-ribosylation factor-like 3 (Arf3), and cytoplasmic dynein light chain DYNNL1/LC8 regulate the unloading of dynactin (P150Glued)-bound cargo from the dynein motor. On the other hand, we previously found that inhibition of calpain protects LIS1 from proteolysis, resulting in the augmentation of LIS1 amounts levels and the a functional improvement in LIS1-deficient mice, implying. This means that calpain inhibition is a potential therapeutic intervention for lissencephaly. Neuronal protein alpha-synuclein A neuronal protein alpha-synuclein has been shown to beis linked to Parkinson’s disease (PD), but their causative role in PD how synucleins play a causative role is unclear not clear. We have also have found that alpha-synuclein is required for the creation of unconventional microtubules named transportable microtubules (t-MTs), which function as carriers enabling anterograde cytoplasmic dynein transport. Live-cell imaging demonstrated the co-trans

The small GTPase Rab10 regulates the formation of tubular endosomes.
K. Etoh1, M. Fukuda1;
1Department of Developmental Biology and Neurosciences, Tohoku University, Sendai, Japan

Eukaryotic cells contain the endomembrane system, which is crucial for cellular homeostasis and various cellular events. A striking tubular-shaped organelle, so-called tubular endosome, is one of the components of the endomembrane system that is often considered to be involved in recycling of internalized proteins back to the plasma membrane. However, how the formation of tubular endosome is regulated and why its tubulation is necessary remain largely unknown. To address these issues, we focused on the small GTPase Rab, a conserved switch molecule for membrane trafficking by cycling between a GDP-bound inactive form and a GTP-bound active form. The active Rab drives a variety of membrane trafficking steps, such as vesicle budding, transport, and fusion, by recruiting its specific effector protein. Although Rab family consists of ~60 members in mammalian cells, which Rab regulates tubular endosomes is poorly understood. In this study, we performed a systematic Rab localization screening by expressing EGFP-tagged Rabs in HeLaM cells and identified Rab10 as a prime candidate for the crucial regulator of tubular endosomes. We found that knockout (KO) of Rab10 disrupts the formation of tubular endosomes and re-expression of Rab10 in Rab10-KO cells perfectly rescues the phenotype. We then performed live-cell time-lapse imaging of EGFP-tagged Rab10 and showed that EGFP-Rab10-marked tubular endosomes are highly dynamic structures, whose dynamics requires microtubules. To further determine the mechanism by which Rab10 regulates the formation of tubular
endosomes, we searched for microtubule-associated Rab10-binding proteins by using PSI-BLAST and successfully identified KIF13A/B, kinesin-3 type motors, as candidates for novel Rab10 effectors. We are now investigating whether KIF13A/B actually regulates the formation of tubular endosomes. We will discuss the possible molecular mechanisms for the formation of tubular endosomes and their physiological significance based on our findings.

Lysosomes receive and degrade extracellular and intracellular cargo delivered by endocytic, phagocytic and autophagic pathways. Recent studies have shed light on novel lysosome functions in regulating processes such as cell migration, nutrient sensing, bone remodeling, antigen presentation etc. that are regulated by lysosome positioning within the cell. The small GTPase Arl8b regulates both cargo delivery to lysosomes and lysosome distribution by recruiting its downstream effectors SKIP, PLEKHM1 and HOPS complex that mediate microtubule-dependent motility of lysosomes and fusion with late endosomes, respectively. Since the discovery of Arl8b, an ever-increasing number of its interaction partners have come into light, inclusive of RUN-domain containing proteins SKIP and PLEKHM1. Here, we identify a Rab4 and Rab14-interacting and RUN domain containing protein Rabip4’, as an interaction partner for Arl8b. Using GST-pulldown assay and purified protein interaction assay we show that RUN domain of Rabip4’ is sufficient for its interaction with GTP-bound Arl8b. Immunofluorescence studies show that Arl8b and Rabip4’ localize on LAMP1-positive endosomes as well as on mature phagosomes. Notably, Arl8b depletion led to displacement of Rabip4’ from the endosomal and phagosomal membranes, rendering it more cytosolic. The membrane localization of Rabip4’ in Arl8b depleted cells was rescued upon transfection of siRNA resistant Arl8b construct. Similar localization was also observed of the Rabip4’ mutant lacking Arl8b-binding, reinforcing that Arl8b regulates Rabip4’ membrane localization. Rabip4’ has separate binding sites for Rab4, Rab14 and Arl8b; we propose that it may act as a linker between these small GTPases as the co-expression of these proteins resulted in triple co-localization of Rab4/Rab14, Rabip4’ and Arl8b. Finally, depletion of Rabip4’ in macrophage cell line RAW264.7 impaired lysosomal membrane acquisition on latex bead containing phagosomes. LAMP1 acquisition around latex bead/bacteria (E.coli) containing phagosomes was delayed in cells depleted of Rabip4’ as compared to Control siRNA treated cells, indicating that Rabip4’ regulates phago-lysosome fusion. Together our results suggest that Rab4 and Rab14 effector, Rabip4’ interacts with Arl8b and this interaction possibly regulates cargo delivery to lysosomes.

Role of Small GTPases on differentiation of pre-adipocyte.
Y. Huang¹, M. Veisaga², M.A. Barbieri¹,²,³
¹Chemistry and Biochemistry, FIU, Miami, FL, ²Biomolecular Science Institute, FIU, Miami, FL, ³Biological Sciences, FIU, Miami, FL, ⁴International Center for Tropical Botany, FIU, Miami, FL, ⁵Fairchild Tropical Botanic Garden, Miami, FL

Awareness in adipogenesis has increased noticeably over the past few years with the emphasis on the connection between extracellular signals and the transcriptional cascade that regulate adipocyte differentiation. Differentiation of murine pre-adipocytes is a highly regulated process that requires specific and selective regulation of numerous of protein activities. As many Small GTPases, Rab5 plays a critical role in numerous signaling transduction pathways. However, the role of Rab5 in adipogenesis still remains not fully understood. In this study, we prepared 3T3-L1 mouse pre-adipocytes with Rab5-wild type (WT) and several Rab5 mutants. We found that overexpression of Rab5-WT and Rab5-Q79L, the GTPase defective mutant, inhibited adipogenesis; on the contrary, Rab5-S34N, the GTP binding defective mutant, did not inhibit adipogenesis. In concordance with these results, adipogenesis markers, such as ACC, FABP4, PPARγ and C/EBPα showed consequent results. In cells expressing Rab5-Q79L mutant, but not in cells expressing Rab5-S34N mutant, the expression of PPARγ and C/EBPα were down regulated as compared with GFP expressing cells. In addition, we observed reduced Akt and MAPK signaling in Rab5-Q79L mutant expressing cells, but increased signaling in Rab5-S34N mutant expressing cells. In conclusion, our results showed an unexpected role of Rab5-WT in pre-adipocyte differentiation, which is important in coordinating a complex network of transcription factors, cofactors and signaling intermediates from numerous pathways.

Early-sorting endosomes in cancer cells show drastically altered morphology, EGFR signaling and degradation but maintain significant organization of regulatory Rab-GTPases and recycling function.
K.E. Tubbesing¹, A. Malhotra¹, J.M. Ward ¹, A. Rudkouskaya¹, M.M. Barroso²
¹Molecular and Cellular Physiology, Albany Medical College , Albany , NY

Many promising anti-cancer therapies target membrane receptors that are endocytosed into dynamic early endosomes. These sorting organelles house signaling receptors, such as EGFR, and function as essential junctions for the endocytic recycling and lysosomal pathways. However, it remains unclear how the trafficking through these structures is modified in different forms of cancer. Using a combination of fixed and live-cell fluorescent confocal and super-resolution microscopy (3D STORM, STED, and Fast Airyscan), we studied the early-sorting endosome dynamics in the non-cancerous MCF10A cells and breast cancer cell lines (triple-negative MDAMD231 and ER positive T47D cells). We quantified transferrin (TF) recycling and the trafficking of lysosomally-destined ligands EGF and LDL by pulse-chase experiments with fluorescently labelled ligands. Quantitative 3D rendering of early-endosome antigen-1 (EEA1) endosomes indicates that MDAMD231 and T47D cells have fewer endosomes compared to MFC10A cells. However, the vesicles were significantly larger in the cancer cells, which resulted in minimal differences in the per cell endocytic volume between MCF10A and MDAMB231 cells. In all the cell lines, colocalization of early-endosome antigen 1 (EEA1) positive vesicles with the Rab5 and Rab4 GTPases was high; there was no significant colocalization of EEA1 with the late
endosome and autophagy markers Rab7 and LC3. 3D STORM imaging revealed that TF was present in recycling tubules of MCF10A cells, and similar structures were not observed in MDAMB231 or T47D cells. Live-cell super-resolution imaging showed us that TF was sorted into budding vesicles in MDAMB231 cells. The recycling rate of TF was similar between MCF10A and MDAMB231, while TF recycling was significantly delayed in T47D cells. We found EGF and LDL remained in the large EEA1 vesicles of cancer cells for prolonged periods, with EGFR signaling and MMP14 present in the MDAMB231 cells. Together, our data indicates that despite the gross morphological changes of the endocytic structures in cancer cells, many aspects of the pathway are conserved including endocytic volume per cell, endocytic recycling of TF, and the gradient of early and recycling Rab-GTPases. However, there may be differences in the mechanisms of recycling with regards to endocytic tubular formation vs. budding. Our data suggests that the adaptations of the early-endosomes in cancer may be causing delayed maturation of early-endosomes and therefore prolonged receptor signaling and delayed lysosomal degradation.

TRAPP complex substrate specificity is mediated by the Rab GTPase hypervariable domain.
L.L. Thomas¹, S. van der Vegt¹, J.C. Fromme¹;
¹Weill Institute for Cell and Molecular Biology/Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY

In eukaryotic cells virtually every step of membrane transport is coordinated by Rab GTPases, which recruit effectors that facilitate vesicle formation, transport, tethering, and fusion. Rab GTPase activity is controlled by guanine nucleotide exchange factors (GEFs), which convert inactive GDP-bound Rabs to their active GTP-bound state. In yeast the Rab GTPases Ypt1 and Ypt31/32 control entry to and exit from the Golgi complex, and thus are of critical importance to the secretory pathway. The GEFs that activate Ypt1 and Ypt31/32 are the multi-subunit complexes TRAPPIII and TRAPPII, respectively. The TRAPP complexes activate these two different Rabs through a shared active site. This indicates that these complexes use a novel mechanism for substrate specificity involving complex-specific regulatory subunits.
The C-terminal hypervariable domain (HVD) has the highest degree of sequence divergence between distinct Rab GTPases, and has been proposed to function as subcellular targeting signal through an unknown mechanism. An apparently competing hypothesis is that GEFs are responsible for subcellular targeting of Rabs via their localized activation. Using a series of Ypt1 and Ypt31/32 HVD chimeras, we have found that the Ypt1 HVD plays a significant yet non-essential role in enabling TRAPPIII catalyzed nucleotide exchange. In contrast, the more highly conserved Ypt31/32 HVD is essential for activation by TRAPPII. These findings support a unifying mechanism in which the Rab HVD functions as a targeting signal by mediating GEF substrate specificity through direct interaction between the GEF and the HVD.

The RAB2B-GARIL5 complex promotes cytosolic DNA-induced interferon responses.
M. Takahama¹, T. Saitoh¹;
¹Institute for Enzyme Research, Tokushima University, Tokushima, Japan

The innate immune system senses viral nucleic acids by pattern-recognition receptors and protects the host from viral infection. Pattern-recognition receptor, cyclic guanosine monophosphate–adenosine
monophosphate synthase (cGAS), detects viral genomic DNA in the cytosol and activates downstream signal transducer, stimulator of interferon genes (STING), to establish an antiviral state. STING is an ER-resident protein that translocates to the Golgi apparatus to induce expression of type I interferon (IFN) and IFN-inducible genes after cytosolic double-stranded DNA stimulation. Although the regulatory mechanism for the cGAS-STING signaling axis has been revealed, the positive regulator of this signaling axis that functions on the Golgi apparatus has not been identified. We show here that RAB2B, a Golgi-resident small GTPase, is involved in the cGAS-triggered innate immune response. RAB2B recruits its candidate effector molecule GARIL5 to the Golgi apparatus, where it colocalizes with STING after cytosolic dsDNA stimulation. The RAB2B-GARIL5 complex promotes expression of type I IFN and IFN-inducible genes, and limits replication of vaccinia virus, a DNA virus. The present study revealed a positive regulator of the cGAS-STING signaling axis and highlights the importance of the Golgi apparatus in the host defense response to DNA virus.

Defining the PI3Kβ-Rab5 Interface.
S.D. Heitz¹, J.M. Backer¹,², A.R. Bresnick², J. Flanagan³;
¹Molecular Pharmacology, Albert Einstein College of Medicine, Bronx, NY, ²Biochemistry, Albert Einstein College of Medicine, Bronx, NY, ³Auckland Cancer Society Research Centre, University of Auckland, Auckland, New Zealand

The class IA PI 3-kinase PI3Kβ is a heterodimer consisting of a p85 regulatory subunit and a p110β catalytic subunit. PI3Kβ has been implicated in the regulation of endocytic trafficking and macroautophagy in response to serum starvation, and binds to the endosomal small GTPase Rab5. Previous reports have suggested that the BCR domain of p85α binds Rab5GTP. However, using bacterially expressed and purified p85α, as well as p85α expressed in HEK293T cells, we could not detect p85α binding to GST-Rab5GTP. In contrast, Rab5 binding to the p110β catalytic subunit was readily detected. We have previously defined two amino acids in the helical domain of p110β, whose mutation disrupts binding to Rab5GTP. Our current studies focus on the further characterization of the p110β-Rab5 binding interface, which will provide an opportunity to develop modulators of the p110β-Rab5 interaction. We have developed an in vitro binding assay, which uses bacterially expressed and purified recombinant GST-Rab5 GTP and HEK293T cell expression of wild type or mutated p110β. We evaluated 36 mutations in the p110β helical domain, and identified 9 residues that reduced Rab5 GTP binding by more than 50%. These residues localize primarily to two α-helices in the p110β helical domain, which sit below the GBγ binding loop. This data will help to define the Rab5 interface within p110β and allow us to develop a high throughput assay to selectively screen small molecule inhibitors of Rab5-PI3Kβ binding in the future.
Epidermal growth factor (EGF)-mediated activation of EGF receptor (EGFR) leads to internalization and endosomal trafficking of the receptor. Feedback-regulated cross-talk between EGFR signaling and transport maintains cellular homeostasis; and the loss of spatiotemporal regulation of EGFR signaling leads to diseases such as cancers. However, the precise mechanism whereby ligand-dependent EGFR signaling controls individual endosomal transport steps, remains largely unknown. In this work, we integrate experimental measurements with mathematical modeling to identify key proteins mediating the coupling between ligand-concentration-dependent receptor signaling, and activities of Rab5 and Rab7 GTPases, which regulate early and late endosomal trafficking, respectively. In order to build a predictive, rule-based computational model, we experimentally measured a number of critical input parameters such as activation rates and protein copy numbers. Consistent with previous literature, we observed faster and higher levels of EGFR phosphorylation, as well as greater EGFR degradation in HeLa cells upon activation with high EGF dose (100 ng/mL), compared to low EGF dose (10 ng/mL). We measured rapid Rab5 activation in response to high EGF, mimicking EGFR phosphorylation kinetics, which was followed by robust Rab7 activation. Interestingly, Rab7 activation upon stimulation with low EGF dose was below detection. These results indicate that Rab7 activation plays a key role in shunting EGFR for degradation in response to high EGF stimulus. To probe the roles of regulatory proteins involved in Rab5-to-Rab7 conversion, we accurately measured copy numbers of GTPase activating proteins (GAPs) and Guanine nucleotide exchange factors (GEFs) controlling Rab5 and Rab7 activities using PRISM-SRM (high-pressure, high-resolution separations coupled with intelligent selection and multiplexing for selected reaction monitoring) technique. Measured protein copy numbers of Mon1A and Mon1B are almost 10-fold higher than previously reported. These new copy numbers are in line with Ccz1 copy numbers, thereby supporting Mon1 and Ccz1 forming an obligate heterodimer to act as a Rab7 GEF. Further experimental verification of model predictions regarding effects of modulating Mon1 and Ccz1 levels on EGF-mediated Rab7 activation kinetics is in progress. Proteomic analyses also revealed that while total copy numbers of two Rab5 GEFs, RIN1 and Rabex5, together are constant, the two Rab5 GEFs were differentially expressed in cells overexpressing Rab5 versus Rab7. These data suggest that the two Rab5 GEFs may have different roles in determining kinetics and route of EGFR transport. Taken together, our results demonstrate that Rab7 activation in response to stimulation with high dose of EGF drives...
All eukaryotes contain organelles that perform specialized functions essential for life. The Golgi complex, an organelle that is important for transport of cellular material, serves as the “Grand Central Station” of the cell by receiving, then sorting proteins and membranes to various locations. Many steps of vesicular trafficking at the Golgi complex are regulated by several families of small GTPases, which modulate between an active and inactive state. One particularly interesting GTPase is Rab1, which also has an established role in autophagy. Rab1 is activated by a guanine nucleotide exchange factor (GEF), a process that is conserved from mammals to yeast. Discordantly, mammals contain two protein complexes named TRAPPII and TRAPPIII (transport protein particle) which activate Rab1; while in yeast, four (TRAPPI - TRAPPIV) have been implicated as GEFs in Ypt1 (Rab1 homolog) activation. Yeast TRAPP complexes share a core set of six subunits. Additional subunits are thought to regulate the complex by adding substrate and compartmental specificity. TRAPPII contains four more subunits, while TRAPPIII and TRAPPIV include one additional subunit. Importantly, the precise functions of the accessory subunits remain unclear. We demonstrate that TRAPPII and TRAPPIII are the only two complexes present in yeast cells, which is consistent with findings in mammalian cells, by quantifying isolated TRAPP complexes and simultaneously monitoring the localization of all TRAPP complexes in vivo. We also find that, using an in vitro fluorescent nucleotide exchange assay, TRAPPIII activates Ypt1 more effectively than the other complexes. Concurrently, we notice that Trs85 localizes to the Golgi complex and that Ypt1 is mislocalized in vivo in the absence of the TRAPPIII-specific subunit, Trs85. Additionally, using an in vitro membrane binding assay, we find that Trs85 has an affinity for membranes. These findings suggest that there are only two TRAPP complexes in yeast, and that TRAPPIII is involved in trafficking at the Golgi complex in addition to its established role in autophagy. Taken together, our model suggests that the main role of Trs85 in the TRAPPIII complex is to bring the catalytic core close to a membrane surface, localizing the active site to the right compartment in an orientation that facilitates localization and activation of Ypt1.

Endocytic Trafficking 1

The mechanistic target of Rapamycin complex 1(mTORC1) is an evolutionarily conserved serine/threonine kinase that controls organismal growth, and have been found deregulated in several multi-faceted diseases including cancer and neurodegeneration. Here we show that overexpression of TFEB induces cellular endocytosis and formation of endosomes carrying activated protein kinase B (pT308-Akt), the amino acid transporter SLC38A9 and the tethering molecule RagD, crucial components of the lysosomal nutrient sensing complex, which stimulates mTORC1 activity. We further observed that these TFEB-induced endosomes en route to lysosomes were required to dissociate TSC2 and tether
mTORC1 to lysosomal membranes, this way restoring its activity during prolonged starvation. Finally, we find that TFEB-triggered endocytosis is required for lysosomal biogenesis and autophagy flux. Our results identify TFEB-mediated endocytosis as a critical process to regulate mTORC1 activity, lysosomal biogenesis and sustain autophagy.

Functional analysis of PI3P effector candidate SNX in Entamoeba histolytica.
N. Watanabe1,2,3, T. Nozaki2,3, K. Nakada-Tsukui2;
1Graduate School of Life and Environmental Sciences, University of Tsukuba, Tsukuba, Japan,
2Department of Parasitology, National Institute of Infectious Diseases, Tokyo, Japan,
3Graduate School of Medicine, The University of Tokyo, Tokyo, Japan

Phagocytosis and phagosome maturation are indispensable for the parasitism and pathogenesis of Entamoeba histolytica. Phosphoinositides (PIs) are well known regulators of membrane traffic during phagocytosis and phagosome maturation in model organisms. Previously we reported that one of the PIs, phosphatidylinositol 3-phosphate (PI3P), is localized on phagosomes and involved in phagosome maturation, however, PI3P downstream effectors known from model organisms are not conserved in E. histolytica. To identify unique PI3P effectors in E. histolytica, we conducted proteomic analysis of the isolated phagosomes from the transgenic strain expressing GFP-Hrs-FYVE, which binds to and is thus expected to compete for PI3P. Compared to the phagosomes from the parental strain, recruitment of two components of the retromer complex, Vps26 and Vps35, was not detected in the GFP-Hrs-FYVE expressing strain, suggesting that retromer recruitment to phagosomes is regulated via PI3P. It is well established in other organisms that the retromer complex is composed of Vps26, Vps29, Vps35, and PI3P-binding sorting nexins (SNXs). SNXs interact with PI3P via Phox homology (PX) domain. In silico analysis of the E. histolytica genome identified two PX domain-containing proteins, which were designated as EhSNX1 and EhSNX2. Biochemical and localization studies showed that both of them specifically bound to PI3P and localized on phagosomes. However, data from immunoprecipitation analysis suggested temporal, weak, or no interaction between EhSNXs and retromer complex. To understand the role of EhSNX1 and EhSNX2, transcriptional silencing of corresponding genes is underway.

Syntaxin-6 defines a cellular compartment distinct from the trans-Golgi network that accumulates internalized somatostatin receptor 2
Walaa Alshafie, Peter S. McPherson, Thomas Stroh
Department of Neurology and Neurosurgery, Montreal Neurological Institute, McGill University, Montreal, Quebec H3A 2B4, Canada
Somatostatin receptor 2 (SSTR2) is the major receptor mediating the effects of somatostatin. Upon somatostatin binding, SSTR2 rapidly traverses the endosomal system arriving in a juxta-nuclear compartment thought to be the trans-Golgi network (TGN). Using AtT20 cells expressing endogenous
SSTR2, we now demonstrated that consistent with previous reports, activated receptor rapidly internalizes in transferrin-labeled vesicles before shifting away from transferrin-labeled endosomes and into a syntaxin-6-enriched compartment. However, both confocal and stimulated emission depletion (STED) microscopy reveal that neither internalized SSTR2 nor syntaxin-6 co-localize with the TGN markers PIST and TGN38. Furthermore, neither nocodazole treatment, which leads to dispersed Golgi ministacks, nor Brefeldin A treatment, which leads to dispersion of the TGN, have any influence on the juxtanuclear localization of SSTR2 and syntaxin-6, which remain co-localized. Both STED and electron microscopy reveal that syntaxin-6 and SSTR2 localize to tubulo-vesicular juxta-nuclear structures. Sucrose gradient fractionation confirmed that the bulk of syntaxin-6 and SSTR2 signals are overlapping and distinct from TGN38. This compartment may serve as a reservoir for SSTR2 recycling since the association of SSTR2 and syntaxin-6 is reduced when the receptor recycles back to the cell surface. Our results indicate that upon ligand binding, SSTR2 accumulates in an ill-defined syntaxin-6-enriched compartment and strongly suggest that syntaxin-6 should not be used as a marker of the TGN. The identity of this compartment will provide clues about the protein machinery involved in SSTR2 cytoplasmic retention and recycling.

Involvement of the HPV E6 protein in the trafficking of several cellular SNX27 cargoes through the PDZ binding motif.
P. Massimi¹, J. Broniarczyk¹, L. Banks¹;
¹Tumour Virology, ICGEB, Trieste, Italy

A subset of high-risk Human Papillomaviruses (HPVs) are the causative agents of a large number of human cancers, of which cervical is the most common. Two viral oncoproteins, E6 and E7, contribute directly towards the development and maintenance of malignancy. A characteristic feature of the E6 oncoproteins from cancer-causing HPV types is the presence of a PDZ binding motif (PBM) at its C-terminus, which confers interaction with cellular proteins harbouring PDZ domains. We have shown that this motif allows E6 interaction with Sorting Nexin 27 (SNX27), an essential component of endosomal recycling pathways. This interaction is highly conserved across E6 proteins from multiple high-risk HPV types and is mediated by a classical PBM-PDZ interaction but unlike many E6 targets, SNX27 is not targeted for degradation by E6. Rather, in HPV-18 positive cell lines the association of SNX27 with components of the retromer complex and the endocytic transport machinery is altered in an E6 PBM-dependent manner. Analysis of a SNX27 cargo, the glucose transporter GLUT1, reveals an E6-dependent maintenance of GLUT1 expression and alteration in its association with components of the endocytic transport machinery. Since E6 interaction with SNX27 can alter the recycling of cargo molecules, one consequence of which is modulation of nutrient availability in HPV transformed tumour cells, we decided to analyse in detail which other targets involved in the trafficking pathway could be affected by the SNX27-HPVE6 interaction. With this aim we generated a Hela cell line expressing GFP-SNX27 and analyse the SNX27 proteom interaction profile from these clones in the presence or absence of E6. Several cargoes were immunoprecipitated such as the PBM containing proteins Emilin2 and Tanc2, both involved in cell growth, migration and transformation pathways.
Microvillus Inclusion Disease (MVID) is a rare form of congenital diarrhea resulting from inactivating mutations in Myosin Vb (MYO5B). The underlying cause of MVID associated diarrhea is currently unknown. We hypothesize that loss of MYO5B results in aberrant expression of key apical enterocyte membrane transporters that promote the absorption of water. Our lab has generated a mouse model of MVID with a germline deletion of MYO5B (MYO5B KO). Duodenal tissue was collected from neonatal (3-5 day old) MYO5B KO mice and wildtype (WT) littermates. Immunofluorescence staining was performed to determine the localization of apical transporters and proteins in intestinal tissue of MYO5B KO and WT mice. Human biopsies from healthy individuals and from individuals harboring a Navajo specific mutation in MYO5B resulting in MVID were immunostained to examine the localization of brush border proteins. Transgenic mice expressing a LifeAct-EGFP peptide, labeling F-actin were crossed with MYO5B KO mice to derive MYO5B KO;LifeAct-EGFP mice. Enteroids were generated from duodenal tissue of neonatal MYO5B KO, WT, MYO5B KO;LifeAct-EGFP and LifeAct-EGFP to determine the functional capacity of CFTR in vitro. Immunostaining for phosphorylated ezrin (P-ezrin) showed numerous P-ezrin positive inclusions in the duodenum of MYO5B KO mice, no inclusions were observed in WT mice. To assess the localization of key transporters known to regulate water absorption, we performed immunofluorescence staining for the NHE3, SGLT1 and CFTR. WT mice showed apical localization of NHE3, SGLT1 and CFTR. In contrast, MYO5B KO mice showed decreased apical expression and increased subapical expression of NHE3 and SGLT1. NHE3 and SGLT1 were present in intracellular inclusions in MYO5B KO mice. MYO5B KO mice had CFTR positive inclusions, but CFTR was still present on the apical membrane of enterocytes. Measurement of luminal Cl- showed a significant increase in Cl- in intestinal flushes of MYO5B KO compared to WT mice. Consistent with these findings, MVID patient biopsies showed decreased apical expression of NHE3 but CFTR remained on the apical membrane. MYO5B KO derived enteroids had decreased apical expression of SGLT1 however CFTR was expressed on the apical membrane in MYO5B KO and WT enteroids. A forskolin swelling assay demonstrated that CFTR was functional in MYO5B KO;LifeAct-EGFP and LifeAct-EGFP derived enteroids. Collectively, these data suggest that decreased apical expression of NHE3 and SGLT1 may be responsible for the dysfunction in water absorption in individuals with MVID. Furthermore, CFTR may be trafficked and recycled predominantly through a MYO5B-independent pathway leading to exacerbated water loss by continued secretion of chloride into the intestinal lumen by apical CFTR.

Amyloid Precursor Protein (APP) undergoes complex processing involving two separate pathways. Misprocessing at the terminal step of one pathway by the gamma -secretase complex leads to the
production of different-sized versions of the peptide a-beta, which have been implicated in the onset of Alzheimer’s disease. Neither the cellular factors that may contribute to this misprocessing nor the exact cellular location where the misprocessing occurs are clearly understood, but evidence suggests that cholesterol may influence the misprocessing. Previously, we found that a phospholipase A2 plays a role in the intracellular trafficking of LDL-derived free cholesterol, and inhibition of this PLA2 with ONO RS-082 (ONO) results in the accumulation of cholesterol in the Endocytic Recycling Compartment (ERC) when cells are exposed to certain levels of LDL. Immunofluorescence microscopy with an antibody that recognizes different forms of APP revealed that treatment of cells with ONO resulted in the accumulation of APP in the ERC even when Rab11 was knocked down. Furthermore, immunoblotting showed the processing of APP was altered when cells were treated with ONO. To further investigate factors involved in the localization and processing of APP, cells were grown in fetal bovine serum containing different levels of LDL. Populations of these cells were stressed by nutrient starvation, and the localization of APP was compared to the localization of Rab11 using immunofluorescence microscopy. In stressed cells, treatment with ONO altered the distribution of APP even under conditions in which the distribution of cholesterol was not significantly altered. In stressed cells grown in LDL levels of 6 mg/dl, there was little or no colocalization between APP and Rab11, but following ONO treatment significant colocalization in a compact, juxtanuclear pattern, which was similar to the response of unstressed cells grown in 15-20 mg/dl LDL. In 15 mg/dl LDL, stressed cells exhibited partial colocalization between Rab11 and APP, but APP was also localized to the Golgi complex. When stressed cells were treated with ONO, the number of cells exhibiting a compact, juxtanuclear pattern increased. In stressed cells grown in 25mg/dl LDL, the compact pattern of colocalization was observed in control cells. After ONO treatment, this same pattern could be discerned, but the overall distribution of rab11 and APP was more diffuse, with punctate structures scattered in the cytoplasm. These results are consistent with evidence that the rab11 endosome serves as a hub for APP trafficking. They also suggest that cholesterol levels affect APP processing and that cell stress may also play a role.

Reduced expression of the Endosomal Sorting Complex Required for Transport (ESCRT)-associated factor HD-PTP/PTPN23 in mice causes reduced fat accumulation and increased mortality.
B.A. Davies¹, J.A. Payne¹, Z. He¹, S.K. Jachim¹,², S.F. Bronk³, K. Jeganathan¹,⁴, B.G. Childs¹, D.J. Baker¹,⁴, J.M. Van Deursen¹,⁴, D.J. Katzmann¹;
¹Department of Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, ²Biological Sciences Department, Virginia Tech, Blacksburg, VA, ³Division of Gastroenterology, Mayo Clinic College of Medicine, Rochester, MN, ⁴Department of Pediatric and Adolescent Medicine, Mayo Clinic College of Medicine, Rochester, MN

The Endosomal Sorting Complexes Required for Transport (ESCRTs) facilitate a unique form of membrane deformation enabling the budding of membranes away from the cytoplasm (e.g. intraluminal vesicle formation during multivesicular body sorting) or the scission of a membrane tubule from within the structure (e.g. abscession during cytokinesis). This unique machinery has been implicated in a number of cellular processes including cytokinesis, receptor down-regulation via MVB sorting, exosome biogenesis, autophagy, and plasma membrane repair. Greater understanding of the contributions of the ESCRTs to animal physiology has been confounded by the observations that multiple ESCRT knockout mouse models have exhibited embryonic lethality. The mammalian Bro1 Family proteins ALIX/PDCD6IP and HD-PTP/PTPN23 are ESCRT-associated factors that appear to exhibit
unique contributions to different ESCRT-driven processes. While the ALIX knockout mouse model was viable with a normal lifespan, the HD-PTP knockout mouse exhibited embryonic lethality, suggesting HD-PTP may play a more central role in critical ESCRT-driven processes. To gain further insights into the unique contributions of HD-PTP to mammalian physiology, a murine HD-PTP hypomorphic animal model (HD-PTP\textsuperscript{hyp/o}) was generated. This allele reduced HD-PTP expression more than 80% in both mouse embryonic stem cells and mouse embryonic fibroblasts. HD-PTP\textsuperscript{hyp/o} animals were viable but exhibited a number of unexpected phenotypes. Reduced HD-PTP expression resulted in increased mortality with 6-month survival approximately 25%. The HD-PTP\textsuperscript{hyp/o} animals were reduced in mass compared to wild-type littermates. Fat mass was particularly affected evident at 6-weeks as assessed by whole body composition analysis. Mass analyses of individual fat tissues and histological examinations supported this observation of reduced fat accumulation. Reduced vacuolization within the HD-PTP\textsuperscript{hyp/o} liver, consistent with reduced lipid accumulation, was also observed, and Oil Red O staining of isolated HD-PTP\textsuperscript{hyp/o} and wild-type hepatocytes indicated reduced lipid droplet area with reduced HD-PTP expression. Oleate loading of HD-PTP\textsuperscript{hyp/o} mouse embryonic fibroblasts similarly exhibited reduced lipid droplet area compared to wild-type cells. Reduced lipid droplet area was also evident in HD-PTP\textsuperscript{hyp/o} brown adipose tissue and inguinal white adipose tissue in vivo. These results support the conclusion that reduced HD-PTP expression perturbs lipid accumulation in multiple tissues and suggest that the defect in lipid accumulation may occur in a cell autonomous manner.

**Genome-wide siRNA screen identifies GBF1-interacting protein UNC50 as a differential regulator of Shiga toxin trafficking.**

A.S. Selyunin\textsuperscript{1}, L. Iles\textsuperscript{2}, G. Bartholomeusz\textsuperscript{2}, S. Mukhopadhyay\textsuperscript{1};

\textsuperscript{1}Pharmacology Toxicology, The University of Texas at Austin, Austin, TX, \textsuperscript{2}Experimental Therapeutics, The University of Texas MD Anderson Cancer Center, Houston, TX

Shiga toxins 1 and 2 (STx1 and STx2) are potent bacterial toxins that induce cell death by targeting ribosomal function and shutting down protein synthesis. This mechanism relies on retrograde transport to endoplasmic reticulum, from where toxin’s catalytic subunit is translocated into cytosol. During early endosome-to-Golgi transport the toxins evade the lysosomal degradation pathway. Targeting this trafficking step has therapeutic promise, but mechanisms are unclear for STx2, which is more potent and is typically associated with poor clinical prognosis. We performed a viability-based, genome-wide siRNA screen in HeLa cells to identify host factors required for early endosome-to-Golgi trafficking of STx1 or STx2. We identified S64, S35, and 196 hits that were required for toxicity induced by STx1-only, STx2-only, or both toxins, respectively. Depletion of Golgi localized UNC50 prevented early endosome-to-Golgi trafficking of STx2, in turn routing it to lysosomes for degradation. UNC50 was also required for optimal Golgi delivery of STx1. Mechanistic assays revealed that UNC50 acted by recruiting GBF1, an ADP-ribsylation factor guanine nucleotide exchange factor (ARF-GEF), to the Golgi. These findings provide new insight into STx2 intracellular transport mechanisms, and may advance efforts to generate therapeutically viable toxin trafficking inhibitors.

Interrogating the thiol-disulfide redox status of the mammalian cell surface by ratiometric fluorescence imaging.
L. Jiang1, C. Thorpe1;
1Chemistry and Biochemistry, University of Delaware, Newark, DE

The exofacial/extracellular thiol/disulfide (SH/SS) redox status has been shown to play critical roles in a range of mammalian cell behaviors, including adhesion, migration and invasion. Two proteins, whose activities potentially oppose each other, the disulfide-generating Quiescin-sulfhydryl oxidase (QSOX), and the disulfide reductase activity of protein disulfide isomerase (PDI), are believed to contribute to extracellular SH/SS status. However the range of their substrates, and the possible synergy between these oxidoreductases remain cryptic. To investigate exofacial SH/SS status in a range of mammalian cells in culture, we have developed conventional confocal and super-resolution fluorescent imaging methods that can quantitatively assess the status of cell surface proteins using impermeant fluorescent maleimide reagents and selective reduction of exofacial disulfides. Using these approaches, effects of extracellular QSOX and PDI on surface SH/SS can be observed and quantitated. We will also present the impact of components of the extracellular matrix, and their in vitro mimics, on the exofacial SH/SS status of a range of mammalian cell types.

PI4K2A controls PI4P production and Rab7-cycling in late endosomal compartments.
T. Baba1, D.J. Tóth1, N. Sengupta1, T. Balla1;
1Section on Molecular Signal Transduction, Program for Developmental Neuroscience, Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

Vesicular trafficking between various organelles requires proper sorting of cargos in endocytic compartments. During this process, different Rab small G proteins mark the endosomes at different stages of their maturation. In addition, endosomes also change their phosphoinositide profiles during their conversion where both 3-phosphorylated and 4-phosphorylated inositol lipids play important roles. Type II phosphatidylinositol 4-kinases, PI4K2A and PI4K2B are localized in various endocytic compartments and have been implicated in the trafficking of various cargoes. In this study, we analyzed the effect of PI4K2A gene deletion on endosomal PI4P levels and cargo sorting. PI4K2A knockout HEK293 cells were created by CRISPR/Cas9 genome editing. PI4K2A-deficient cells showed no compensatory increase in PI4K2B and PI4KB, other PI4Ks acting on endosomes. A bioluminescence resonance energy transfer (BRET) method was developed to measure PI4P levels in different Rab-positive compartments. These measurements showed that PI4P levels were highest in Rab7-positive compartment, and PI4K2A had the biggest contribution to the PI4P in this pool. PI4K2A knockout didn’t affect the degradation of EGFR, or the endocytosis or trafficking of the transferrin receptors. PI4K2A deletion, however, caused tubulation of Rab7-positive compartments similar to those observed in cell expressing constitutively active Rab7. Current experiments are focused on understanding the mechanism by which PI4P affects the GTP-GDP status of Rab7 and how these changes affect the function(s) of late endosomes.

Regulation of membrane scission in yeast endocytosis.
D. Menon1,2, M. Kaksonen1;
1Department of Biochemistry, University of Geneva, Geneva, Switzerland, 2Cell Biology and Biophysics, EMBL, Heidelberg, Germany

Endocytosis involves rearrangement of the plasma membrane in a controlled sequence: a flat membrane forms an invagination that undergoes scission to produce a vesicle. In yeast, endocytic sites are very stereotypic, recruiting over 50 proteins, most with mammalian homologues, to effect these membrane shape-changes and produce cargo-filled vesicles. These proteins can be assigned to separable modules based on their role in the endocytic timeline. Here we study the scission module of yeast endocytosis by combining correlative light and electron microscopy with live-cell imaging of fluorescently tagged proteins in wild type and mutant cells.

A mechanistic understanding of scission remains incomplete although several hypotheses have been proposed and proteins that influence the scission process have been identified: BAR proteins interact with the invagination neck concomitant with scission, and phospholipid phosphatases are known to affect scission dynamics. We find that localization of the yeast BAR protein complex Rvs161/167 (Rvs) is influenced by an interaction of the Rvs167 SH3 domain, aside from its expected BAR-membrane interaction. The SH3 domain also affects the number of Rvs molecules at endocytic sites and progression of the invagination, suggesting that the domain is more important for the function of Rvs than has been assumed. Rvs allows invaginations to grow to around 160nm before scission, while deleting it results in either scission failure or causes scission at half that length. We thus conclude that Rvs prevents premature vesicle scission, and both BAR and SH3 domains are important for its role as a regulator of the scission machinery.

We have tested current models of membrane scission and find that although Rvs plays an important role, scission timing is independent of the number of Rvs molecules at endocytic sites, suggesting that the recently proposed mechanism of BAR-induced protein friction on the membrane is not likely to cause scission. Deleting yeast synaptojanin Inp51 or dynamin Vps1 also does not influence scission dynamics: it is likely that interfacial forces at lipid boundaries are not sufficient, and forces exerted by dynamin are not required, to produce vesicles. We propose a mechanism of membrane scission in which Rvs is recruited to endocytic sites by both BAR and SH3 domains, and the SH3 domain of Rvs167 regulates actin forces on the invagination neck, modulating scission timing.

Elucidating the Endocytosis Mechanism of Cx36.
C.G. Fisher1, M. Falk1;
1Biological Sciences, Lehigh University, Bethlehem, PA

Gap junctions are clusters of channels that directly connect the cytoplasms of apposing cells and permit the passage of hydrophilic molecules less than approximately 1.5kD in size. The channels are comprised of proteins called connexins (Cxs) which are four-pass transmembrane spanning proteins with their N- and C-termini residing in the cytoplasm. Twenty-one connexins exist in the human genome and are expressed tissue specifically.

Cx36 is of great interest to the gap junction and neuroscience fields because it is expressed in the brain where it forms electrical synapses. Furthermore, it is also expressed in the pancreas where it is needed
for the synchronous release of insulin into the blood stream from pancreatic beta-cells. A better understanding of Cx36 promises to aid in an improved understanding of endocytosis, neuron communication, and diabetes.

An important aspect of gap junction regulation involves its turnover and endocytosis. The regulation of connexin endocytosis has been shown to be critical for proper tissue function. Despite the fact that there is significant phylogenetic distance and amino acid diversity between connexins, most seem to undergo endocytosis in a similar manner. The majority of connexin endocytosis research has been conducted on Cx43, the most commonly expressed connexin, and has been shown to involve the clathrin mediated endocytosis (CME) pathway. This study addresses the turnover of Cx36, an important phylogenetically distant cousin of Cx43.

We have shown that gap junctions comprised of Cx36 form circularized Annular Gap Junctions during their endocytosis in a manner very similar to the more commonly studied Cx43. We demonstrated through cycloheximide half-life assays that Cx36-GFP exists in the membrane for approximately 2 hours. We have also shown through clathrin knockdown experiments evidence that suggests that clathrin is required for Cx36 endocytosis. Further research into the endocytosis mechanism is ongoing at this time.

NECAPs are negative regulators of the AP2 clathrin adaptor complex.
G.M. Beacham, E.A. Partlow, J.J. Lange, G. Hollopeter;
1Molecular Medicine, Cornell University, Ithaca, NY, 2Stowers Institute for Medical Research, Kansas City, MO

Eukaryotic cells internalize transmembrane receptors via clathrin-mediated endocytosis, but it remains unclear how the machinery underpinning this process is regulated. We recently discovered that membrane-associated muniscin proteins such as FCHO and SGIP initiate endocytosis by converting the AP2 clathrin adaptor complex to an open, active conformation that is then phosphorylated. Here we report that loss of ncap-1, the sole C. elegans gene encoding an adaptiN Ear-binding Coat-Associated Protein (NECAP), bypasses the requirement for FCHO-1. Biochemical analyses reveal AP2 accumulates in an open, phosphorylated state in ncap-1 mutant worms, suggesting NECAPs promote the closed, inactive conformation of AP2. Consistent with this model, NECAPs preferentially bind open and phosphorylated forms of AP2 in vitro and localize with constitutively open AP2 mutants in vivo. NECAPs do not associate with phosphorylation-defective AP2 mutants, implying that phosphorylation precedes NECAP recruitment. We propose NECAPs function late in endocytosis to inactivate AP2.

QUANTITATIVE IMAGING AND STATISTICAL ANALYSIS OF THE DYNAMICS OF CLATHRIN-DEPENDENT AND -INDEPENDENT ENDOCYTOSIS REVEALS A DIFFERENTIAL ROLE OF ENDOPHILINA2 IN DYNAMIN2 RECRUITMENT.
L. Berton, A. Grassart, T. Lagache, G. Nardi, J. Olivo-Marín, N. Sauvonnet;
1Unité de Pathogénie Microbiennne Moléculaire, Institut Pasteur, Paris, France, 2Department of Biological Sciences, Columbia University, New-York, NY, 3Unité d'Analyse d'images biologiques, Institut Pasteur, Paris, France

Eukaryotic cells internalize cargos specifically through clathrin-mediated endocytosis (CME) or clathrin-independent processes (CIE). EndophilinA2 was shown as preferentially implicated in CIE although
initially involved in CME. Here, we investigated the native interplay of endophilinA2 and dynamin2 during CME as compared to CIE. We developed an unbiased integrative approach based on genome-engineering, robust tracking methodology and advanced analytics. We statistically identified several CME and CIE subpopulations corresponding to abortive, active and static endocytic events. Depletion of dynamin2 strongly affected active CME and CIE events, whereas the absence of endophilinA2 impacted only CIE. Accordingly, we demonstrated that endophilinA2 is needed for dynamin2 recruitment during CIE, but not in CME. Despite these differences, endophilinA2 and dynamin2 acted at the latest stage of endocytosis within a similar stoichiometry in both mechanisms. Thus, we propose a conserved function of dynamin2 and endophilinA2 in vesicle scission, but a differential regulation of their recruitment during CME and CIE.

Kidney proximal epithelial cells apically express the neuronal-surface P-antigen (NSPA) cross-targeted by anti-ribosomal P antibodies from lupus patients.
M.M. Bravo-Zehnder PhD1,2, D.L. Valenzuela3, Á. Jurado3, F. Segovia Miranda PhD2, T. Toledo3, C.S. Espinoza1, F. Barake1, C. Vio PhD3, G. Méndez MD3, L. Massardo MD1,2, A. Gonzalez, MD, PhD1,2; 1Centro de Biología Celular y Biomedicina, Facultades de Medicina y Ciencia, Universidad San Sebastián, Santiago, Chile, 2Centro de Envejecimiento y Regeneración, Facultad de Ciencias Biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile, 3Departamento de Anatomía Patológica, Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile

Anti-ribosomal-P proteins (anti-P) antibodies from patients with systemic lupus erythematosus are potentially pathogenic in the brain, skin, liver and kidney epithelial cells. We recently disclosed a pathogenic mechanism in the brain involving anti-P cross-reaction with a cell surface protein of unknown function, which we called neuronal-surface P-antigen (NSPA). Because anti-P antibodies have been associated with lupus nephritis here we explore whether NSPA is an anti-P target also in the kidney. Immunoblot and RT-PCR revealed the expression of NSPA in the kidney. Histochemistry of β-galactosidase reflecting the activity of NSPA promoter in knock-in mice revealed NSPA expression mainly in the proximal epithelial tubule cells (PTEC). Immunohistochemistry showed NSPA polarized to the apical domain of PTEC. Cell surface domain-specific biotinylation assays and transfection of mCherry-NSPA showed a similar predominant apical distribution in MDCK cells. Immunization of mice with recombinant P0 ribosomal protein bearing the P-antigen generated high titers of anti-P antibodies and showed renal juxtaglomerular interstitial infiltration. These results indicate that NSPA has apical sorting information and suggest that anti-P antibodies must be filtered through the glomerulus to reach its cell surface antigen causing damage in the kidney.

TrkA signaling endosomes: Association with Rab7 and Rab11 and dynamic fusion and fission events as possible mechanisms of signaling endosome diversification.
K.A. Barford1, A. Keller3, K. McDaniel1, C. Deppmann2, B. Winckler1; 1Cell Biology, University of Virginia, Charlottesville, VA, 2Biology, University of Virginia, Charlottesville, VA

Protein trafficking is involved in all aspects of neuronal function including development, axon/dendrite growth, and synaptic function. Neurons of the peripheral nervous system in particular are in distinct
need of specialized protein transport due to the great length of their axons and need to coordinate axon growth and presynaptic development with dendritic growth. One receptor that is critical for the development of the sympathetic nervous system, TrkA, has been shown to undergo complex trafficking events. In sympathetic neurons, TrkA is expressed during development and encounters its high-affinity ligand, Nerve Growth Factor (NGF), once the axon reaches its final target tissue. TrkA binds NGF and the complex is internalized into a signaling endosome. The NGF-TrkA signaling endosome is critical in the axon for outgrowth and branching, but it is also transported retrogradely to the soma and to dendrites where it is necessary for survival signaling and synapse formation, respectively. We hypothesize that the multitude of NGF-dependent outputs, such as survival and synapse development, relies on functional and molecular diversification of the signaling endosome. We thus determined the trafficking steps and association of signaling endosomes with distinct effector proteins, especially members of the small GTPase family of Rab proteins. Indeed, we find that signaling endosomes are molecularly diversified into Rab7- and Rab11-positive populations in vitro and in vivo. This diversification happens early since retrograde axonal transport carriers can be Rab7 or Rab11 positive. Additionally, we find that signaling endosomes continue to exist in multiple distinct pools as they transport into dendrites. Surprisingly, TrkA-NGF signaling endosomes undergo dynamic sorting events, including fusion and fission in dendrites. These dynamic events might drive diversification of signaling endosomes and suggest a role for sub-populations of these endosomes to function independently in distinct signaling pathways.

ApoER2 and Its Ligand Reelin Follow a Clathrin-Independent Endocytosis.
J. Santana¹, M. Marzolo¹;
¹Cellular and Molecular Biology, Pontifical Catholic University of Chile, Santiago, Chile

Reelin is an extracellular glycoprotein with essential roles in the formation of laminated brain structures formation such as neocortex, hippocampus and cerebellum, during vertebrate embryonic development, as well with roles in learning and memory in the adult. Reelin receptors are members of the apolipoprotein E receptors and include ApoER2 and VLDLR. The disruption of ApoER2 results in cognitive and motor dysfunction, conditions that are more severe than the ones resulting from VLDLR disruption. Although, the reelin/ApoER2 signaling pathway has been widely described, little is known about its endosomal trafficking. Our laboratory has previously demonstrated that, in the absence of ligand, ApoER2 is internalized through a clathrin-dependent endocytosis (CDE) depending on the NPxY cytoplasmic motif that is recognized by the adaptor protein Dab2. Besides CDE there are clathrin-independent endocytosis (CIE) pathways, including one controlled by the small GTPase Arf6 which regulates membrane trafficking and actin cytoskeleton dynamics. Here we show for the first time that, in HeLa cells, ApoER2 and reelin are internalized using a clathrin-independent endocytosis (CIE) pathway, specifically by Arf6-pathway. In clathrin-silenced cells ApoER2 is still internalized in the presence of reelin, being the receptor able to arrive to degradative Rab7-compartment. Altogether, our results suggest that ApoER2 has at least two different routes of internalization, the already demonstrated CDE and the Arf6-pathway. We also found a similar spatial pattern of expression of endogenous ApoER2 and Arf6-overexpressed in hippocampal primary culture neurons where both proteins were found within axon dilation. Therefore, our working model is that reelin modifies ApoER2 endosomal dynamics by facilitating its traffic toward degradative pathways by Arf6-CIE. Alpha-arrestins Aly1 and Aly2 regulate trafficking of the glycerophosphoinositol transporter, Git1 and impact lipid homeostasis in cells.
B. Robinson¹, S. Anaokar¹, A. Nikiforov¹, P. Ziegler¹, J. Patton-Vogt¹, A.F. ODonnell¹;
¹Dept. of Biological Sciences , Duquesne University , Pittsburgh, PA

Cells must reorganize proteins at the plasma membrane (PM) in response to the extracellular environment in order to grow and survive. Protein trafficking adaptors that recognize select protein cargo and mark them for removal from or targeting to the PM are critical regulators of the PM proteome. A family of trafficking adaptors known as the alpha-arrestins has an emerging role in this regulation. Alpha-arrestins bind cargo proteins and recruit a ubiquitin ligase, which ubiquitinates the cargo protein to mark it for endocytosis. To date a limited number of alpha-arrestin–cargo pairs are known and the mechanisms by which alpha-arrestins control selective protein trafficking are relatively unclear. Our studies suggest a novel role for alpha-arrestins in maintaining phosphatidylinositol (PI) homeostasis. We find that alpha-arrestins Aly1 and Aly2 control endocytosis of the glycerophosphoinositol (GPI) transporter, Git1. GPI is a metabolite whose breakdown releases inositol which can be used for the synthesis of PI. Loss of Aly1 and Aly2 results in retention of Git1 at the PM, increased uptake of GPI, and sensitivity to exogenously added GPI. Aly1 and Aly2 mutants that are unable to bind the ubiquitin ligase Rsp5 fail to internalize Git1 from the PM, demonstrating that Aly1- and Aly2-mediated trafficking of Git1 requires Rsp5. Internalization of Git1 additionally requires well-established clathrin-mediated endocytic components, such as End3 and Vrp1. The AP-2 complex is also important for Git1 endocytosis; We have previously shown that Aly1 and Aly2 interact with AP-2 and we are currently assessing the role of this interaction in regulation of Git1. Interestingly, dephosphorylation of Aly1 by the protein phosphatase calcineurin, which controls other key regulators of sphingolipid homeostasis, is required for optimal Aly1-mediated trafficking of Git1. Consistent with a broader role for these alpha-arrestins in controlling sphingolipid balance in cells, loss of Aly1 and Aly2 results in sensitivity to myricin, a chemical that inhibits the first step in sphingolipid biosynthesis, and resistance to aureobasidin A, a chemical that blocks sphingolipid biosynthesis at a later step by preventing inositol-containing ceramide production. Preliminary data suggests that Aly1 and Aly2 may regulate Git1 through distinct mechanisms, with Aly1 being more important for ligand-induced endocytosis of Git1 while Aly2 is more important in the constitutive endocytosis of Git1. These findings implicate the alpha-arrestins as new players in regulating the recycling of the PI catabolite, GPI, into cellular metabolism, including PI biosynthesis, which likely impacts sphingolipid metabolism.

Screening of the ScUbl yeast deletion library for modifiers of Aly1- or Aly2-mediated resistance to rapamycin in an undergraduate lab course.
R.W. Bowman¹, M. Hall¹, A.F. ODonnell¹;
¹Dept. of Biological Sciences , Duquesne University , Pittsburgh, PA

Cells respond to cues in their extracellular environment by selectively redistributing proteins. This reorganization is imperative for cell survival and is regulated, in part, by alpha-arrestins. How then is alpha-arrestin-mediated trafficking controlled? We know that modification by ubiquitination plays a role in modifying alpha-arrestin function. To help us identify specific alpha-arrestin regulators, we generated and utilized a unique yeast gene deletion library called the Saccharomyces cerevisiae Ubiquitin

Monday-278
Interactome (ScUbl) library. ScUbl contains all the non-essential genes annotated as important for ubiquitination and ubiquitin interaction. We used this library as part of the BIOL 371w Cell & Molecular Biology laboratory course to screen for gene deletions that altered the growth phenotypes associated with over-expression of alpha-arrestins. Specifically, the undergraduates transformed the ScUbl library with plasmids over-expressing alpha-arrestins Aly1 and Aly2 and then assessed these transformants for gene deletions that either increased or decreased cells sensitivity to rapamycin, an inhibitor of TORC1 function that mimics nitrogen starvation. Three replicate screens of the ScUbl library were evaluated for changes in rapamycin sensitivity when over-expressing Aly1 or Aly2 identified 45 and 39 hits respectively as having >1 or < -1 Z-scores. Of these, 11 candidates are found in both the Aly1 and Aly2 screens. From this, Atg7 was chosen as a strong candidate and further assessed. We show that in cells lacking Atg7, Aly1 and Aly2 electrophoretic-mobility is altered, and demonstrate that this is due to a change in phosphorylation status of the alpha-arrestins. These data suggest that alpha-arrestins are regulated by changes in the autophagy pathway and we are currently working to define that role.

Systematic analysis of the molecular architecture of endocytosis reveals a nanoscale actin nucleation template that drives efficient vesicle formation.
M. Mund1, J. van der Beek1, J. Deschamps1, S. Dmitrieff1, J. Monster1, A. Picco2, F. Nedelec1, M. Kaksonen2, J. Ries1;
1Cell Biology and Biophysics, European Molecular Biology Laboratory, Heidelberg, Germany,
2Department of Biochemistry, University of Geneva, Geneva, Switzerland

Clathrin-mediated endocytosis is an essential cellular function in all eukaryotes. It is a highly efficient process that is driven by a self-assembled macromolecular machine of over 50 different proteins in tens to hundreds of copies. How so many proteins can be organized to produce endocytic vesicles with high precision and efficiency is not understood. Here, we developed high-throughput superresolution microscopy to reconstruct the nanoscale structural organization of 23 endocytic proteins from over 100,000 endocytic sites in yeast. We found that after stochastic initiation assembly proceeds by a radially ordered recruitment according to protein function. WASP family proteins formed a circular nano-scale template on the membrane to spatially control actin nucleation during vesicle formation. Mathematical modeling of actin polymerization showed that this WASP nano-template allows actin polymerization to create sufficient force for membrane invagination, and substantially increases the efficiency of the budding reaction. Such nanoscale pre-patterning of actin nucleation may represent a general design principle for force generation in other membrane remodeling processes such as cell migration and division.

NBEAL2 is required for retention of endocytosed and megakaryocyte synthesized α-granule cargo proteins.
R.W. Lo1,2, L. Li2, R. Leung2, F.G. Pluthero2, W.H. Kahr1,2,3;
1Biochemistry, University of Toronto, Toronto, ON, 2Cell Biology Pragram, The Hospital for Sick Children, Toronto, ON, 3Paediatrics, University of Toronto, Toronto, ON

Platelets are blood cells that facilitate clotting to prevent bleeding from wounds. Platelet function is linked to secretion of a wide variety of proteins carried in α-granules. Platelets and their granules are
produced by megakaryocytes, bone marrow-resident cells that can each release several hundred platelets into circulation. Most α-granule cargo is synthesized by megakaryocytes (e.g. Von Willebrand factor; VWF), but some is endocytosed from plasma, including fibrinogen. In Gray platelet syndrome (GPS), individuals lacking expression of NBEAL2 (neurobeachin-like 2) have platelets that lack α-granules and their protein cargo. The function of NBEAL2 is poorly understood. In previous studies we established Nbeal2/- mice as an animal model of GPS, and observed abnormalities in megakaryocyte development that included externalization of VWF. In this study we investigated the role of NBEAL2 in α-granule cargo protein trafficking by comparing the uptake, release and intracellular localization of labeled fibrinogen in megakaryocytes cultured from wild type (WT) and Nbeal2/- mice. While initial uptake of fluorescently-labeled fibrinogen was similar in WT and Nbeal2/- megakaryocytes, the latter showed considerably less retention of fibrinogen as assessed via flow cytometry and confocal fluorescence microscopy. Using biotinylated fibrinogen, we observed that neither WT nor Nbeal2/- megakaryocytes degraded endocytosed protein, but Nbeal2/- cells released it back to the medium much more rapidly than WT cells. Using confocal fluorescence microscopy to track fluorescently-labeled fibrinogen within megakaryocytes, we observed sequential colocalization of fibrinogen with subcellular compartments positive for RAB5, RAB7 and P-selectin in both WT and Nbeal2/- cells. In WT megakaryocytes the association of fibrinogen with the P-selectin positive compartment persisted, but this association was brief in Nbeal2/- megakaryocytes, as fibrinogen passed on to a RAB11-positive compartment and was subsequently lost from the cells. We also observed colocalization of VWF with RAB11 in Nbeal2/- megakaryocytes, indicating a common route of exit for both endocytosed and endogenously-synthesized α-granule cargo via recycling endosomes. A strong colocalization of NBEAL2 with P-selectin was observed in human megakaryocytes, supporting the conclusion that NBEAL2 associates with α-granules and/or their precursors, and is required for the proper loading and/or retention of granule cargo.

Clathrin Light Chain A is Specifically Required for Efficient Cell Spreading and Migration.

O. Tsygankova1,2, J.H. Keen1,2;

1Biochem and Mol Biol, Jefferson University, Philadelphia, PA, 2Sidney Kimmel Cancer Center, Jefferson University, Philadelphia, PA

The highly conserved clathrin heavy chain is the structural component of the clathrin triskelion. Its canonical function in membrane trafficking is well established, while additional roles have been more recently appreciated. In vertebrates, the triskelion also contains two clathrin light chains (CLCs, denoted CLCa and CLCb), each also highly conserved but with only approximately 60% identity, and with distinctive tissue distributions suggestive of exclusive functions. Yet, the few putative activities of CLCs, including coordination of actin with endocytosis, regulation of coat assembly, and G-clathrin formation and mediation of integrin recycling (PMCID: PMC4050264), appear to be shared by both CLCs. Only recently has a CLCb-specific role in regulation of endocytosis rates and dynamics been identified (PMID:28171750), while a distinct function for CLCa has remained elusive. Here we show that in detached cells, CLCa is uniquely responsible for promoting efficient cell spreading after plating, and for full mobility in subsequent cell migration. Selective depletion of CLCa using multiple siRNAs reduced spreading of HeLa, H1299 and HEK293 cells by ≥50% compared to untreated or scrambled siRNA controls. Depletion of CLCb did not inhibit spreading, and exogenous expression of siRNA-resistant CLCa but not CLCb could rescue in CLCa-depleted cells. While the initial isotropic phase of spreading is reduced in the treated cells, cell attachment is not: indeed, surface levels of active and inactive β1-integrins that largely drive attachment are unaffected by CLCa depletion. However, CLCa was required for efficient

Monday-280
integrin-mediated activation of Src and for targeting of phosphorylated FAK and paxillin to properly positioned focal adhesions. Depletion of CLCa, but not CLCb, also altered intracellular distributions of clathrin, actin, WAVE2, inactive β1-integrin, and EEA1-decorated sorting endosomes. We propose that CLCa plays key roles in targeting of endosomal components and functional actin recruitment during early phases of cell spreading, with important implications for understanding normal and neoplastic cell detachment, migration and reattachment.

Establishment and Maintenance of Polarity

Suppressors of pam-1: Uncovering the role of PAM-1 in regulation of anterior-posterior polarity in the one-cell C. elegans embryo.
R.L. Lyczak1, A. Otto1, D. Ulbel1, D. Stephens1, D.M. Saturno1, E. Jaeger1;
1Biology Dept, Ursinus College, Collegeville, PA

Anterior-posterior axis establishment occurs in the one-cell C. elegans embryo, triggered by the sperm-donated centrosome through two redundant mechanisms. First the centrosome cues rearrangement of the actin-myosin cortical cytoplasm, which reorganizes the cell contents through cortical flows. In the absence of flows, microtubules from the centrosome can cue loading of the cortical PAR-2 protein to the posterior cortex to polarize the cell. In our recent work, we have shown that the PAM-1 puromycin-sensitive aminopeptidase is required for centrosome positioning at the cortex and that sustained contact between the centrosome and the cortex enhances polarity establishment through both mechanisms. pam-1 mutants produce nonviable embryos with a sparse cortical microfilament network, compromising polarity establishment through the first pathway. Longer centrosome contact with the posterior cortex can rescue polarity by enhancing both the cortical flow and the PAR loading pathways. To learn more about PAM-1’s mechanism of action, we have identified suppressors of pam-1 that raise the hatch rate from 2% to 35-50%. By looking at the actin-myosin cytoskeleton, centrosome dynamics, and polarity landmarks in these suppressed strains, we hope to learn more about the cross-talk between these two polarity establishment pathways and the role of PAM-1 in regulation of centrosome positioning and polarity establishment.

Suppressor screening to identify new regulators of anterior-posterior axis establishment in Caenorhabditis elegans.
D. Benton1, Z. Lee4, A. Kilner4, A. Kimble1, K. Power1, E. Jaeger1, R.L. Lyczak1;
1Biology Dept, Ursinus College, Collegeville, PA

Polarity is established in the one-cell C. elegans embryo shortly after fertilization and determines the anterior-posterior body axis. This polarization is cued by the sperm-donated centrosome, which triggers changes in the posterior cortex. The PAM-1 aminopeptidase plays a role in axis polarization through regulation of the cortical cytoskeleton and centrosome positioning. PAM-1 is a highly conserved aminopeptidase that targets unknown proteins for degradation. In order to identify novel regulators of centrosome positioning and targets of the PAM-1 aminopeptidase, we took advantage of the maternal-effect embryonic-lethal phenotype of pam-1 mutants to conduct a suppressor screen. We have identified six suppressors, which significantly increase the pam-1 hatch rates from 2% to between 25-
75%. Most of the suppressors are recessive and can suppress both missense and nonsense alleles of *pam-1*. Using DIC microscopy we have found that each suppressor significantly rescues the polarity defects, such as the lack of pseudocleavage and the symmetric cleavage, found in *pam-1* mutants. Four of our suppressors have been mapped, three to different positions on chromosome I and one to chromosome II. We are currently using whole genome sequencing and RNAi to identify the suppressor mutations. Future characterization of these suppressors is likely to uncover new insights into the role of this aminopeptidase in centrosome positioning and polarity establishment and may lead to identification of targets of the aminopeptidase.

Deciphering the role of centrosomes in symmetry breaking of the *C. elegans* zygote.
K. Klinkert¹, C. Busso¹, S. Herman¹, L. von Tobel¹, P. Gόnczy¹;
¹Swiss Institute for Experimental Cancer Research (ISREC), School of Life Sciences, Swiss Federal Institute of Technology (EPFL), Lausanne, Switzerland

The newly fertilized *C. elegans* zygote exhibits uniform contractions of the acto-myosin cortical network driven by RHO-1 (RhoA). Thereafter, symmetry of the system is broken, as evidenced by the clearance of the RHO-1 guanine-nucleotide-exchange factor (GEF) ECT-2 from the cortex next to centrosomes, which results in local RHO-1 inactivation and cortical relaxation¹,². This is followed by anteriorly-directed flows of the acto-myosin cortex and segregation of anterior and posterior PAR proteins into distinct cortical domains, with PAR-6 on the anterior and PAR-2 on the posterior³. It has been shown that laser-mediated removal of centrosomes prevents polarity establishment⁴, but the mechanisms through which centrosomes instruct symmetry breaking remain to be elucidated. Intriguingly, we observed that zygotes from a mutant that lacks centrosomes undergo spontaneous symmetry breaking, leading to the formation of a PAR-2 domain either on the anterior, on the posterior or on both sides (bipolar phenotype). Analogous phenotypic manifestations have been found in embryos depleted of the centrosomal proteins SPD-2 or SPD-5⁵,⁶. Likewise, depletion of the Aurora A kinase AIR-1, which is normally recruited by SPD-2/SPD-5 during centrosome maturation, results in spontaneous symmetry breaking. Moreover, we established that AIR-1 kinase activity is essential for proper symmetry breaking. Whether this reflects merely the known role of AIR-1 in centrosome maturation or whether the kinase is required for phosphorylating a particular substrate modulating symmetry breaking remains to be determined.

Overall, our findings demonstrate that *C. elegans* zygotes possess intrinsic polarization cues that do not necessarily need mechanochemical signaling from centrosomes to be activated, and that centrosomes are critical for ensuring proper spatio-temporal regulation of these cues in an AIR-1 dependent fashion.

The epithelial membrane trafficking system is both complex and robust owing to multiple sorting mechanisms and parallel transport routes to ensure the delivery of cargo to its correct destination. Among the membrane organelles, Rab-11-enriched apical recycling endosomes (Rab-11-AREs) mediate recycling and sorting of both apically and basolaterally endocytosed membrane components, and can function as secretory transport intermediates between the Golgi complex and plasma membrane[1]. Yet, it remains an open question to elucidate the molecular networks coupling Rab-11-ARE positioning to establishment and maintenance of epithelial polarity in an epithelium in vivo.

Here, taking advantage of the powerful genetic tools available for C. elegans, using high-resolution live imaging of the C. elegans intestine, we demonstrated that the microtubule cytoskeleton and the associated minus-end motor complex, including cytoplasmic dynein and dynactin complexes, were required for the apical positioning of RAB-11-AREs. Strong basal accumulation was observed for the GFP-RAB-11 upon mirotubule or dynein-dynactin machinery disruption, while depletion of the plus-end kinesin UNC-116 caused increased apical distribution of Rab-11-AREs. Depletion of the tethering complex Exocyst components increased the apical aggregation of Rab-11-AREs more or less, suggesting a tethering problem of the AREs to the apical membrane. SEC-15, one of the exocyst components, was always perfectly located with RAB-11, which strongly suggested that SEC-15 was recruited by Rab-11 as an effector to the AREs at the quite earlier stage of AREs transport toward the apical membrane, instead of at the later stage upon Rab-11-AREs already located underneath the apical membrane. Recently, clathrin adaptor complex AP-1, instead of the epithelial-specific AP-1B, was reported to be required for the apical sorting and apicobasal polarity maintenance in the C. elegans intestine[2]. We found that depletion of AP-1 subunits resulted in the cytosol distribution of Rab-11 and SEC-15. We further determined whether these Rab-11-AREs are involved in the post-Golgi sorting or the baso-to-apical transcytotic sorting of apical membrane proteins.

In conclusion, we identified an ensemble comprising the cytoskeleton, polarity machinery and membrane traffic system that coordinates to regulate the apical sorting and apicobasal polarity maintenance in vivo.

Assessing a role for membrane trafficking in polarization of the intestinal epithelium.
M. Pickett1, J.L. Feldman3;
1Biology, Stanford University, Stanford, CA

During organogenesis, epithelial cells must become polarized to ensure proper organ function. Polarization begins with an initial symmetry breaking cue, followed by the establishment and maintenance of distinct apical and basolateral domains. While many proteins have been identified that
are required during polarity establishment and/or maintenance, far less is understood about how symmetry is initially broken in epithelial tissues in vivo, or how proteins become sorted into polarized domains. In vitro, membrane trafficking contributes to symmetry breaking, with endosomes directed to sites of cell-cell contact that define the future apical surface. Membrane trafficking has also been shown to regulate the localization of proteins to apical or basolateral domains during polarity establishment and maintenance. We are using the C. elegans embryonic intestine to investigate the role of membrane trafficking in epithelial symmetry breaking and polarity establishment in vivo. The polarizing embryonic intestine consists of 16 epithelial cells with their future apical surfaces oriented towards a central midline that will become the intestinal lumen. Prior to polarization, cells of the intestinal primordium divide parallel to the future apical surface. Proteins destined for the apical surface cluster at lateral membranes and then reposition along with centrosomes approximately ninety degrees to the presumptive apical surface. This somewhat atypical pattern of polarization makes the C. elegans intestine a good system for studying mechanistic aspects of polarization in vivo as there is a clear spatial and temporal separation between symmetry breaking and polarity establishment. Previous reports found that C. elegans intestinal cells become highly endocytic prior to the establishment of polarity and our preliminary evidence suggests that membrane trafficking is required for polarization. Therefore, we hypothesize that membrane trafficking is required in vivo for symmetry breaking, establishing a flow of proteins toward the future apical surface, which may be defined by sites of cell-cell contact. Consistent with this hypothesis, we observe that basolateral proteins first move to the apical surface of the intestine during normal polarity establishment and then become relocalized to basolateral surfaces. These data suggest that apical is the default localization pattern in polarizing intestinal cells and that the subsequent sorting of apical and basolateral proteins is a critical step in polarity establishment. As previous evidence suggests that apical endosomes are essential for maintaining polarity in the C. elegans intestine, we hypothesize that these membrane trafficking pathways are also essential for sorting of proteins during the establishment of polarity.

Induction of apically mistrafficked epieregulin is sufficient to disrupt apico-basolateral polarity in MDCK cells in 3D.
B. Singh1, G. Bogatcheva1, R.J. Coffey1,2;
1Medicine, Vanderbilt University Medical Center, Nashville, TN, 2Veterans Affairs Medical Center, Nashville, TN

Overexpression of the EGF receptor (EGFR) ligand, epieregulin (EREG), has been linked to metastasis. We previously reported that basolateral trafficking of EREG is regulated by a conserved tyrosine residue within a YXXΦ motif (Y156ERG) in its cytoplasmic domain. Constitutive overexpression of mutant (Y156A)EREG in MDCK cells resulted in its apical mistrafficking and transformation as determined by formation of invasive tumors upon subcutaneous injection into athymic nude mice (PNAS 110: 8960-5, 2013). We have also identified human cancer mutations within the trafficking motif of EREG (R147stop), which we now show leads to EREG apical mistrafficking. Using an inducible (Tet-ON) system, we have generated MDCK cells expressing wild-type and Y156A-mutant EREG. Both wild-type and mutant EREG induction increased size of MDCK cysts in 3D Matrigel cultures; however, only Y156A EREG induction in fully formed cysts led to formation of ectopic lumens and inward growth that correlates with the transformed phenotype observed in nude mouse xenografts. Furthermore, we show that EGFR activity and ligand cleavage is required for EREG mistrafficking-induced ectopic lumen formation as pre-incubation with the irreversible EGFR kinase inhibitor, EKI-785, or broad specificity metalloprotease...
inhibitors, BB94 and GM6001, abrogates formation of ectopic lumens. When observed with live cell confocal microscopy, the ectopic lumens appear to form de novo rather than budding from the central lumen. Two possible hypotheses for ectopic lumen formation are being tested and the results will be presented: 1) EREG mistrafficking compromises the fidelity of cell division and/or 2) EREG mistrafficking provides an anti-apoptotic luminal environment leading to decreased clearance of luminal cells.

Obesity is a highly prevalent and modifiable breast cancer risk factor. Chronic inflammation and elevated growth factors and cytokines are linked to tumor aggressiveness and account for poorer prognoses in breast cancer patients with high body mass index. In contrast, the mechanisms linking obesity to breast cancer initiation are poorly understood. Here, we show with a mouse model of obesity that a high fat diet leads to the mislocalization of Par3, a regulator of cellular junctional complexes defining epithelial polarity. Epithelial polarity loss is recapitulated in a 3D co-culture system combining breast acini with human mammary adipose tissues. We further establish that polarity loss results from a paracrine effect of leptin, an adipokine linked to obesity that we find elevated 2.3 fold in breast tissues from obese vs. normal weight women at high risk for breast cancer. PI3K/Akt signaling downstream the leptin receptor leads to afadin phosphorylation and relocalization away from apical polarity complexes, resulting in reduced cortical actin, reduced apical tight junctions, and increased epithelial permeability. Loss of apical polarity by leptin leads to mitotic spindle misalignment and sensitization to proliferative stimuli in epithelial cells, which are both primordial for cancer initiation. The results define a novel role for afadin in maintaining epithelial polarity and provide a molecular basis for alterations in epithelial architecture during obesity-mediated cancer initiation that may be leveraged for targeted cancer prevention approaches.

Regulation of epithelial junctions and polarity by the Scribble/SGEF/Dlg complex.
1Department of Biological Sciences, University of Toledo, Toledo, OH, 2Department of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, 3Department of Biochemistry, University of Iowa, Iowa City, IA, 4Tumour Virology Group, ICGEB, Trieste, Italy

Establishment of epithelial cell polarity is essential for growth, differentiation and morphogenesis. Conversely, loss of cell polarity is a hallmark of many disease states, including cancer. The concerted action of three conserved protein complexes – PAR, Crumbs and Scribble – controls the establishment of cell polarity. In addition, the Rho-family of small GTPases, which regulate actin dynamics, plays a key role in the development of polarity. How polarity complexes regulate Rho GTPase function remains unknown.

Monday-285
Our results show that SGEF, a RhoG-specific guanine-nucleotide exchange factor (GEF), interacts simultaneously with two members of the Scribble polarity complex – Scribble and Dlg – and functions a bridge that mediates the formation of a ternary complex. We have also identified the domains that mediate the interactions among these three proteins. SGEF binds to Scribble PDZ1 domain through a novel internal PDZ binding motif located at its N-terminus. We have solved the crystal structure of Scribble PDZ1 in complex with a peptide encoding the binding domain in SGEF. A different region in SGEF N-terminus binds to Dlg GUK domain. In addition, we found that SGEF is targeted to cell-cell junctions in both mammalian cells and Xenopus embryos, where it colocalizes with ZO-1. Silencing SGEF expression delays the formation of tight junctions and disrupt normal junction architecture. In 3D MDCK cysts, SGEF KD interferes with the establishment of polarity, with cysts showing altered lumen formation. On the other hand, SGEF overexpression alters junction architecture and dynamics, promotes apical constriction, and increases the tension at the junctions. Taken together, our results suggest that Scribble and Dlg bind to SGEF using unique interaction motifs, and that this complex by virtue of localizing RhoG activity to cell-cell junctions and modulating cell polarity is essential for the dynamic assembly and maintenance of cell-cell junctions in cells and in organisms.

Epithelial Membrane Protein 2 and Adenomatous Polyposis Coli interactions regulate apical-basal polarity.
A.C. Lesko1,2, C.G. Ahlers1,2, A.T. Lyons1,2, J.R. Prosperi1,2,3;
1Department of Biological Sciences Harper Cancer Research Institute, University of Notre Dame, Notre Dame, IN, 2College of Science, University of Notre Dame, Notre Dame, IN, 3Department of Biochemistry and Molecular Biology, Indiana University School of Medicine- South Bend, South Bend, IN

Adenomatous Polyposis Coli (APC) is a well-known negative regulator of the Wnt pathway; however, it also regulates polarity proteins, such as Dlg and Scribble. Loss of apical-basal polarity disrupts several cellular processes including epithelial structure and intracellular signaling, and is an early marker for tumor development. We previously demonstrated that APC knockdown (APC<sup>KD</sup>) in Madin-Darby Canine Kidney (MDCK) cells altered cyst size and inverted polarity in 3D culture. Through microarray analysis we made the novel observation that epithelial membrane protein 2 (EMP2) expression was increased upon APC loss. Interestingly, knockdown of EMP2 in APC<sup>KD</sup> cells decreased cyst size and restored apical polarity. These data suggest a previously unknown role for EMP2 in regulating polarity and cyst size; however, how EMP2 influences APC-mediated polarity remains unknown. In this study, we seek to investigate both the mechanism by which APC regulates EMP2 expression and the signaling modalities downstream of EMP2 that control APC-mediated polarity. First, we investigated transcriptional activation of EMP2 using bioinformatics, transcription factor DNA/protein arrays, and luciferase reporter assays. EMP2 promoter screens (ConTra v2 webserver) identified binding sites for signal transducer and activator of transcription 1 and 3 (STAT1 and 3), and E2F transcription factor 1 (E2F1). Interestingly, APC<sup>KD</sup> cells exhibited increased expression of STAT1 and E2F1 in DNA/protein arrays compared to controls. Additionally, STAT3 activation was increased in APC<sup>KD</sup> cells compared to controls in reporter assays. These studies identified STAT3, STAT1, and E2F1 as possible APC-mediated transcriptional regulators of EMP2. Future studies will continue to dissect the transcriptional mechanism of EMP2 regulation through ChIP assays and reporter assays using mutant EMP2 promoter constructs. Next, we assessed the mechanism(s) downstream of EMP2 using 2D gel analysis and mass spectrometry. Cell lysates were ran on 2D protein gels and spots that exhibited changes upon APC loss and were restored
by either EMP2 knockdown or APC reintroduction were chosen for mass spectrometry. Analysis identified the spots as filamin A, plectin isoform type 2, 3-hydroxyacyl-CoA dehydrogenase type-2, histone H3.3, and histone H2A type 1-E-like providing possible downstream pathways of APC and EMP2. Future studies will validate the 2D gel data with western blotting and investigate the signaling pathways involved in calcium/phospholipid binding and DNA binding and histone folding, processes identified with cluster analysis, as downstream mechanisms of EMP2. Understanding the interaction of APC and EMP2 and the influence on apical polarity will identify key players in APC disease progression.

Developing an assay to analyze the molecular events leading to establishment of polarity during polarized growth.
X. Cheng¹, M. Bezanilla¹;
¹Biology, Dartmouth College, Hanover, NH

Controlling the site of secretion is an essential aspect of cell biology. In walled eukaryotic cells, such as yeasts and plants, growth is dictated by secreting growth material to specific subcellular sites and thus these cell types are particularly amenable model systems to analyze the molecular basis of polarized secretion. While the mechanisms that direct the growth machinery to these specific sites have been studied in detail in fission and budding yeasts, they remain largely underexplored in many other cell types that do not have obvious homologs to the key fungal molecular players. To gain insights into this process in plants, we focused on the filamentous juvenile tissue of the moss *P. patens*, which grows via targeted secretion to the apex of the cell. While numerous cytoskeleton elements and their regulators have been identified as essential for this form of growth in moss, the exact mechanism by which the apex of the cell is selected as the site for growth has yet to be determined. The filamentous tissue of *P. patens* branches, thereby establishing new sites of polarized secretion. However, predicting when a new branch will emerge is challenging. It is known though, that *P. patens* branching is inhibited in the dark and in far red light. Upon illumination with white light, new branches emerge, thus providing a potential tool to accurately time polarity establishment. Here, we cultured and imaged *P. patens* juvenile tissue in microfluidic devices that allow long-term time-lapse recording. After a 4-day dark treatment, unbranched filaments initiate branching at 18±3.2 hrs after light exposure. Surprisingly, on a similar time scale, the majority of the previously established growing tips generate a new tip at a slightly altered angle after a short period of bulging. This phenomenon suggests that dark treatment depolarizes the original tip-growing machinery, which must then re-establish after exposure to light. Thus, dark treatment could be developed into an assay enabling visualizing of the onset of polarized growth and the recruitment of the tip-growth machinery. In future studies, known players including but not limited to actin, microtubules and cytoskeletal regulating proteins will be examined for their potential role in the initiation of tip growth.

Dissecting Roles for a Signalling Mucin and Effector Cdc42p-MAP Kinase Pathway in Polarity Establishment and Metabolic Reprogramming.

A. Prabhakar, N. Vadaie, T. Krzystek, P.J. Cullen; 1Biological Sciences, University at Buffalo, The State University of New York, Buffalo, NY, 2University of California, San Diego, San Diego, CA

In *Saccharomyces cerevisiae*, cell polarity and bud morphogenesis are multifaceted events governed by the concerted actions of key regulatory proteins. These proteins receive inputs from multiple signal transduction pathways to control morphogenesis. One such pathway that regulates the morphogenetic response to changing nutrient availability is the filamentous growth Mitogen Activated Protein Kinase (fMAPK) pathway. The fMAPK pathway is triggered by nutrient limitation and elicits a foraging-type response where ovoid yeast-form cells polarize into filaments of elongated cells. The plasma membrane regulators of fMAPK pathway include the mucin-like glycoprotein Msb2p and the tetraspan protein Sho1p. Msb2p and Sho1p’s interactions with the polarity GTPase, Cdc42p and its GEF, Cdc24p, respectively are required for the activation of fMAPK pathway. Exactly how the fMAPK pathway controls morphogenetic events is not clear. In this study, we identify new roles for the fMAPK pathway in bud emergence and metabolic reprogramming. We also show that Msb2p and Sho1p regulate aspects of filamentous growth through fMAPK-dependent and fMAPK-independent mechanisms. New Msb2p-interacting proteins were identified that might account for the how Msb2p directly impacts cellular processes during filamentous growth. Collectively, the study uncovers new functions for a signalling mucin and its cognate pathway in regulating morphogenesis and metabolism. Receptors that directly promote their cognate pathway’s goals may be a widespread biological principle.

Cellular Polarity is Directed by Electrophoresis and Electrically Driven Water Flow.

A. Sarkar, B.M. Kobylkevich, B.R. Carlberg, M.A. Messerli; 1Biology Microbiology, South Dakota State University, Brookings, SD

Weak, DC electric fields (EFs) are critical components of development, regeneration and repair. EFs direct cellular polarity and migration (galvanotaxis), giving rise to the use of externally applied EFs to manipulate cellular polarity in the applications of tissue engineering and repair of the epidermis and other soft tissues. It is not clear how cells can sense and respond to weak EFs less than 150 mV/mm, which mediate polarization of cellular structure and promote directional migration, most commonly towards the cathode. A few biophysical mechanisms have been postulated to explain the directional response observed during galvanotaxis. The predominant hypothesis involves two opposing forces exerted on the surface macromolecules in the cellular boundary layer by the EFs, electrophoresis and electro-osmosis which is electrically driven water flow towards the cathode under physiological conditions. We show that in the absence of EFs, zebrafish keratocytes migrate randomly with an asymmetric index near zero, but migrate cathodally with an asymmetric index of -0.82 in an applied EF, compared to a completely cathodal response of -1. Under similar conditions, fluorescently labelled cell surface proteins, including Concanavalin A (Con A) receptors, randomly distribute in the absence of EFs but electromigrate towards the cathode in the presence of EFs. Con A labelled receptors have 60% greater accumulation on the cathode side of cells. We are attempting to impair electro-osmosis with neutral, viscous polymers and thereby reduce cathodal electromigration of surface receptors and impair
cathode-directed migration according to our hypothesis. We are also screening known plasma membrane surface proteins with known physical characteristics that may be good candidates for the electric field receptor. Our efforts aim to bring the field closer to identifying the putative electric field receptor; a fundamental, outside-in signaling receptor that controls cellular polarity of different cell types and directs cell migration in weak EFs.

Mechanisms connecting the conserved protein kinases Kin1, Pom1, and Ssp1 in fission yeast cell polarity and division.
M. Lee*1, S.F. Rusin3, N. Jenkins1,2, A.N. Kettenbach1,2, J.B. Moseley1;
1Department of Biochemistry and Cell Biology, The Geisel School of Medicine at Dartmouth, Hanover, NH, 2Norris Cotton Cancer Center, The Geisel School of Medicine at Dartmouth, Lebanon, NH

Connections between the protein kinases that function within complex cell polarity and division networks are poorly understood. Rod-shaped fission yeast cells grow in a highly polarized manner, and genetic screens have identified multiple protein kinases required for polarized growth and cell shape in this organism. Kin1, the sole MARK/PAR-1 family kinase in fission yeast, regulates cell polarity and cytokinesis through unknown mechanisms. Here, we show that the CaMKK-like Ssp1 acts as an upstream activator of Kin1 by directly phosphorylating the Kin1 activation loop to promote cell polarity. To define the downstream targets of Ssp1-Kin1 signaling, we performed large-scale phosphoproteomics screens that identified Kin1 substrates in cells. We found that Kin1 phosphorylates itself and the endocytic adaptor protein Pal1 to promote growth at cell tips, and these proteins were interdependent for localization to growing cell tips. Additional Kin1 substrates for cell polarity and cytokinesis (Tea4, Mod5, Cdc15 and Cyk3) were also directly phosphorylated by a second cell polarity kinase, the DYRK-family member Pom1. Interestingly, Kin1 and Pom1 were enriched at opposite ends of growing cells, and they phosphorylated largely non-overlapping sites on shared substrates. Combined inhibition of both Pom1 and Kin1 led to synthetic defects in Cdc15 and Cyk3, confirming a non-redundant functional connection through shared substrates. Thus, connections between protein kinases can be direct (Kin1-Ssp1) or indirect (Kin1-Pom1), and contribute to dynamic control of robust cellular processes such as polarized growth and division. These findings identify connections between Kin1 and other conserved protein kinases in the polarity and division network, providing insights into similar mechanisms in other higher organisms.

Drosophila neural stem cells are polarised by their daughter cells.
J. Januschke1, N. Loyer1;
1Cell Developmental Biology, University of Dundee, Dundee, United Kingdom

Drosophila neural stem cells (neuroblasts) divide asymmetrically to both self-renew and generate Ganglion Mother Cells (GMCs) daughter cells. A noticeable feature of larval neuroblasts is the fact that their division orientation is maintained from one cell cycle to the next, even when isolated from their niche in neuroblast/GMCs clusters. This relies on an apical microtubule network acting as an intrinsic polarising cue which disruption, however, only partially affects division orientation maintenance. Here, we used live imaging of cultured Drosophila larval brains, genetics and laser ablation to demonstrate that the GMC acts as an additional - this time extrinsic - polarity cue also participating to neuroblasts.
division axis maintenance. We further investigated the molecular mechanism underlying this polarity cue by performing a small-scale RNAi screen and uncovered the involvement of midbody and midbody-associated structures components, which likely allow neuroblasts to distinguish their latest daughter cells from the previous ones.

Characterising the molecular mechanism of the fission yeast memory-based growth polarity landmarks Rax1 and Rax2.

H.L. Johnson¹, S. Ashraf¹, C. Spanos¹, K.E. Sawin¹;
¹Wellcome Centre Cell Biology, University of Edinburgh, Edinburgh, United Kingdom

Fission yeast are rod-shaped cells that grow in a highly polarised manner, exclusively from their cell tips. Following cytokinesis, daughter cells first grow in a monopolar fashion from their ‘old’ ends (those present in the mother cell). At a specific cell size, cells also start growing from their ‘new’ ends (those formed during cytokinesis), in a bipolar fashion. Polarity landmarks localised at the cell tips co-ordinate this growth. When the polarity landmark Tea1 is deleted, both daughter cells grow exclusively in a monopolar fashion. However, the two daughter cells have different growth patterns: one daughter cell grows from its old end, while the other daughter cell grows from its new end. The daughter cell that grows from its old end is always the cell that inherited the cell tip that was previously growing in the monopolar mother cell. This suggests that there is a memory-based landmark for cell growth. We identified the proteins Rax1 and Rax2 as being part of this landmark. In the absence of Tea1 and either Rax1 or Rax2, cells “lose memory” of past growth and are no longer able to grow from a previously growing tip. Instead, they grow exclusively from the ends formed during cytokinesis. The molecular mechanism of how the Rax1/Rax2 landmark plays a role in the re-initiation of growth at a previously growing tip is currently unknown.

We have used live-cell imaging to show that Rax1 and Rax2 are localised at the cell tips, and septum during cytokinesis, and that their localisation is co-dependent. Rax1 and Rax2 are both transmembrane proteins. Rax2 has a large extracellular domain and a small cytoplasmic tail at its C-terminus. Truncating the whole cytoplasmic tail results in loss of Rax2 localisation and function. Smaller truncations have mild effects on Rax2 localisation and function.

We fused a His-TEV-Biotin (HTB) tag to the Rax2 C-terminus and optimised cross-linking and purification of Rax2 and its interacting partners. Mass spectrometry analysis identified ~800 proteins that were detected exclusively in the cross-linked Rax2-HTB pull down. Notable identified proteins included known polarity landmarks, secretory proteins and proteins involved in cytoskeleton maintenance. To identify interacting proteins that are functionally important to the role of Rax1 and Rax2 in polarised growth, we are currently carrying out mass spectrometry in different genetic backgrounds.

MARK2 regulates directed cell migration and cytoskeleton polarization through modulation of MYPT1-Myosin II activity.
A.M. Pasapera-Limon1, T. Amos2, S.M. Heissler1, Y. Nishimura1, R.S. Fischer1, J.R. Sellers1, C.M. Waterman1;
1Cell Biology, NHLBI-NIH, Bethesda, MD, 2Molecular Physiology and Biophysics, Thomas Jefferson University, Philadelphia, PA

Directed cell migration requires establishment of cell polarity to spatially coordinate adhesion formation, to the acto-myosin cytoskeleton and microtubules to drive cell movement. MARK2 (Microtubule affinity-regulating kinase, also known as PAR1b) is well known to regulate front-back cell polarity and the microtubule cytoskeleton. However, the role of MARK2 in polarization of actin, myosin II and focal adhesions (FAs) remains less clear. A previous study from our lab using mass spectrometry identified MARK2 as a component of FAs. Thus, we hypothesized that in addition to regulating microtubules, MARK2 may promote polarity in cell migration by regulating FAs and their associated acto-myosin cytoskeleton. To test this, we analyzed GFP-MARK2 localization and the effects of its disruption or overexpression on cell polarity, FA and acto-myosin dynamics in cell migration. We found in U2OS cells that MARK2 localized at FAs and actin stress fibers, in addition to its reported association with microtubules and cell protrusions. Using siRNA and CRISPR technology, we found that MARK2 depletion increased FA size, in addition abolishing cell polarization, and slowed persistent migration. Conversely, overexpression of MARK2 resulted in smaller FAs at the cell edge, reduced cell migration and caused myosin IIA displacement from the cell edge to the center. We also found that overexpression of MARK2 induced inactivation of two key proteins in involved in myosin IIA regulation; 1) increased T696 phosphorylation of the myosin phosphatase MYPT1, and 2) increased S885 phosphorylation of GEF-H1. Using Co-immunoprecipitation experiments we found that MYPT1-MYC and MYPT1-GFP pull down endogenous MARK2 as well as MARK2-GFP. These findings indicate that MARK2 not only regulates microtubule stability through phosphorylation of MAPs as reported, but also influences the acto-myosin cytoskeleton and FAs. Our results further suggest that this effect on FAs and the cytoskeleton could possibly be achieved by inactivating GEF-H1 in the front of the cell and/or inactivating myosin phosphatase in the back of the cell, overall affecting cell polarization, FA turnover and directed cell migration.

Exploration and stabilization of Ras1 zone during fission yeast mating: a mechanism with positive and negative feedback regulation.
B. Khalili1,2, L. Merlina3, S.G. Martin1, D. Vavylonis2;
1Fundamental Microbiology, University of Lausanne, Lausanne, Switzerland, 2Physics, Lehigh University, 18015, PA

Directional cell growth or migration requires detection and interpretation of shallow chemical gradients. Recent studies in budding and fission yeasts suggest that the decoding of gradient extracellular signal happens locally through the GTPase Cdc42 polarity complex on the cell membrane. Cdc42 is a main regulator of cell polarity which prior to mating forms a dynamic polarity patch that explores the cell periphery in discrete jumps and performs a stochastic local sampling of the extracellular signal. It has been shown that upon deletion of Gap1, the GTPase-activating protein for Ras1, the lifetime of the
These constants, of occurs more 3D could we mathematical modeling to study the underlying mechanism of Ras1 patch appearance and disappearance through Gap1 inhibition. We developed a set of reaction-diffusion equations for the substrate Ras1-GDP, activator Ras1-GTP, and inhibitor Gap1. We solved the equations numerically on a 3D geometry of the fission yeast cell. We illustrated that by tuning positive and negative feedback rate constants, exploratory patch behavior can be reproduced. By locally increasing the positive feedback at the site of the gradient signal, the patch stabilizes. Our model predicts how the Ras1 patch size is regulated through positive and negative feedback.

1Department of Anatomy and Cell Biology, University of Florida, Gainesville, FL, 2Department of Neuroscience, University of Florida, Gainesville, FL, 3Center for Translational Research in Neurodegenerative Disease, University of Florida, Gainesville, FL, 4Department of Molecular Genetics and Microbiology, University of Florida, Gainesville, FL

Amyotrophic lateral sclerosis (ALS) is a progressive and fatal neurodegenerative disease characterized by motor neuron cell death. Though ALS specifically affects motor neurons, certain groups of them are more resistant to disease progression. The majority of ALS studies have focused on the cellular mechanisms that cause loss of viability, less is known about the neurons that do survive. In this study, we address the latter by culturing spinal motor neurons from adult ALS mouse models at various states of disease progression. Surprisingly, we found that in comparison to age-matched controls, motor neurons cultured from SOD1G93A ALS mouse models display increased outgrowth and branching. They also display an increase in the number and size of actin-based structures such as growth cones and filopodia. The most substantial increase in regeneration occurs in a SOD1G93A ALS mouse model with a lower copy number of the transgene that yields delayed disease onset. This phenotype occurs independently of SOD1 enzymatic activity and is cell autonomous. Further, the enhanced outgrowth occurs before the mice become symptomatic, though the effect increases with disease progression. These results indicate that the surviving motor neurons in ALS are primed for regeneration well before an individual gets sick, in response to cellular stress. Understanding this mechanism of cellular resistance could result in new therapeutic targets for the treatment of ALS.

Characterizing SMA patient-derived mutations to connect proteomic environment with disease-related phenotypes.
A.C. Raimer1, S. ten Have2, K. Gray1, A.M. Spring3, A. Lamond2, A.G. Matera1,4;
1Curriculum in Genetics and Molecular Biology, UNC Chapel Hill, Chapel Hill, NC, 2Centre for Gene Regulation Expression, University of Dundee, Dundee, United Kingdom, 3SPIRE Postdoctoral Fellowship Program, UNC Chapel Hill, Chapel Hill, NC, 4Biolog and Genetics, UNC Chapel Hill, Chapel Hill, NC
Spinal muscular atrophy (SMA) is a recessive neurodegenerative disease and the leading genetic cause of death in young children. While it is known that SMA is caused by reduced amounts of functional Survival Motor Neuron (SMN) protein, the aberrant molecular mechanisms that lead to motor neuron degeneration and muscle loss are unclear. SMN’s canonical role is in snRNP biogenesis, however it has been implicated in many other functions such as mRNA transport, cytoskeleton organization, and endocytosis.

To further elucidate the pathophysiology of SMA, our laboratory has developed an allelic series of human patient-derived Smn mutations in Drosophila. These missense mutations cover all three functional domains of SMN protein and exhibit disease-related phenotypes. Our objective is to use this model to compare disease phenotypes to proteomic environments that arise from mutations in the various domains and residues. To assess disease-related phenotypes we performed assays for viability and muscle function through locomotion.

Viability assays show that these mutant lines cover a spectrum of severities. Crawling assays also show a spectrum of locomotor defects, but they do not always correlate with viability. Using the viability and locomotion phenotypes, we have analyzed a subset of fly lines by whole proteome analysis. These lines include mutations in all three functional domains of SMN and varying severities of viability and locomotion defects. The results of this analysis are expected to provide insight into how loss of Smn function affects other proteins and pathways, and which effects depend on specific functional domains. Overall, using characterization and proteomic analysis of these patient-derived mutation lines helps us better understand how the implicated pathways and functions of SMN fit into the disease etiology, and which domains/residues are important for these functions.

Robarts Research Institute, London, ON

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease characterized by progressive loss of motor function due to loss of motor neurons. RNA metabolism has been found to play a central role in the etiology of the pathology of this disease. Specifically, RNA-binding proteins have been found to form intracellular inclusions, a key hallmark of ALS pathology. We have described a RNA-binding protein called Rho Guanine Nucleotide Exchange factor (RGNEF) that has been observed to form aggregates in the spinal cord neurons of both sporadic and familial cases of ALS. RGNEF co-localizes with other ALS-related RNA-binding proteins, including TAR DNA-binding protein 43 (TDP-43), a toxic ALS-linked RNA-binding protein with broad functions in RNA metabolism. We have determined that RGNEF is a survival factor under stress conditions. Comparison of different fragments of RGNEF revealed that its amino-terminal Leucine-rich domain plays a critical role in RGNEF’s survival activity in HEK293T cells. In MTT assays where HEK293T cells were exposed to osmotic stress, RGNEF lacking the Leucine-rich domain conferred no protection in comparison to full-length RGNEF. Additionally, we have established an in vivo model of RGNEF transgenic fly using the UAS-Gal4 expression system. This transgenic fly line was characterized through negative geotaxis (climbing assay) and lifespan. Interestingly full-length RGNEF expressed in flies produces an important improvement in their lifespan. This confirms our in vitro results showing RGNEF as a pro-survival factor and opens the door to analyze the role of the Leucine-rich domain of RGNEF in vivo exploring RGNEF as a modifier of ALS pathology.

A new genetic mouse model for SPAST-based Hereditary Spastic Paraplegia reveals the importance of toxic gain-of-function mechanisms.
L. Qiang1, E. Piermarini1, L. Leo1, H. Muralidharan1, G.M. Alexander1, L.E. Hennessy1, L.V. Zholudeva1, S. Fernandes1, W. Yu1, M.A. Lane1, T.D. Heiman-Patterson1, P.W. Baas1;
1Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA

Mutations of the SPAST gene, which encodes for the microtubule-severing protein spastin, are the most common cause of Hereditary Spastic Paraplegia (HSP), a debilitating neurological disease, typically adult-onset, in which corticospinal degeneration leads to spasticity and gait deficiencies. Haploinsufficiency is the most prevalent opinion as to the mechanism of the disease, but several lines of evidence suggest a different mechanism, namely gain-of-function toxicity of the mutant spastin proteins. SPAST has two start codons, producing a full-length isoform called M1 and a slightly shorter isoform called M87. The region specific to M1 is hydrophobic and may cause mutant or truncated forms of M1 to misfold and produce cytotoxic effects. Here we report a new genetic mouse that expresses human M1 and M87 spastins harboring a pathogenic HSP mutation (C448Y), while still also expressing endogenous rodent spastin. The particular mutation was chosen in part because previous studies indicated that the mutant spastin does not act in dominant-negative fashion to reduce endogenous spastin activity, and this conclusion was supported by observations on the mouse. For example, staining for acetylated tubulin suggest a decrease in microtubule stability, which is the opposite of the expectation of a loss-of-function mechanism. Expression of the mutant proteins was detected by Western blotting from fetus to adult, but spasticity-like tremor and gain defects were only identified in adults. No symptoms inconsistent with HSP were observed. Results of histological and tracer studies were consistent with dying back of corticospinal axons, which is characteristic of HSP. Cultured newborn cortical neurons from the mouse showed no cellular morphological defects compared to wild-type counterparts, but displayed defects in lysosome transport that were worse in homozygotes than heterozygotes and worse yet when endogenous mouse spastins was mostly depleted by siRNA. These results indicate that the toxic gain-of-function effects of the mutant spastins are present in cells long before behavioral symptoms are apparent in the animal. Interestingly, the defects in lysosome transport were not correctable when the human mutant spastins were mostly depleted by siRNA, which is consistent with previous indications that only vanishingly small amounts of the mutant protein, presumably M1, are needed to elicit the cellular pathology. We posit that the HSP phenotype in humans is produced by toxic gain-of-function mechanisms, but that haploinsufficiency can exacerbate the symptoms. The mouse will be useful for testing therapies. (LQ and EP are co-first authors. The work was supported by grants to PWB from the NIH, the Tom Wahlig Foundation, and Drexel University’s CURE program).

Expanded GGGGCC repeats in the first intron of the C9orf72 gene represent the most common cause of familial ALS, but the mechanisms underlying repeat-induced disease remain incompletely resolved. One proposed gain-of-function mechanism is that repeat-containing RNA forms aggregates that sequester RNA binding proteins, leading to altered RNA metabolism in motor neurons.

To identify new proteins associated with GGGGCC repeats, we performed RNA pulldown assays, followed by mass spectrometry and identified Zfp106 as a specific GGGGCC RNA repeat-binding protein. We found that Zfp106 binds directly to GGGGCC RNA repeats, and functionally interacts with the repeats in cultured neuronal cells. To gain additional insight into the molecular function of Zfp106, we used mass spectrometry to identify protein interactors of Zfp106. Remarkably, we found that Zfp106 interacts with multiple other RNA binding proteins, including the ALS-associated factors TDP-43 and FUS. Zfp106 is highly expressed in skeletal muscle and motor neurons, and its human ortholog ZNF106 is located at chromosome 15q15.1, a locus associated with a familial recessive form of ALS. Therefore, we genetically inactivated the Zfp106 gene in mice. Zfp106 knockout mice develop severe motor neuron degeneration, which can be suppressed by transgenic restoration of Zfp106 specifically in motor neurons.

Finally, we used Drosophila as an in vivo gain-of-function model of C9orf72 neurodegeneration to test if the interaction between Zfp106 and GGGGCC repeats had a functional consequence on neurotoxicity. Expression of Zfp106 in glutamatergic neurons suppressed the loss of larval active zones at NMJs and pupal lethality caused by expression of 30 copies of GGGGCC. Moreover, Zfp106 co-expression partially suppressed the adult locomotor defect caused by expression of C9orf72 repeats. Therefore, Zfp106 is a potent suppressor of GGGGCC repeat-mediated neurotoxicity in a Drosophila model of C9orf72 ALS.

SOD1G93A mouse model of ALS presents increased expression of NLRP1 and NLRP3 in cells from spinal cord.

R. Barboza¹, P.O. Castro¹, R.S. Lima², M.F. Ferrari²;
¹Departamento de Ciências Biológicas, Universidade Federal de Sao Paulo, Diadema, Brazil, ²Departamento de Genética e Biologia Evolutiva, Universidade de Sao Paulo, Sao Paulo, Brazil

Amyotrophic Lateral Sclerosis (ALS) is a fatal neurodegenerative disease characterized by progressive weakness, muscle atrophy with eventual paralysis and death as result of a selective loss of motor neurons. The inflammatory mechanisms involved in disease progression have not yet been fully clarified; however, evidence shows that innate immune system receptors from central and peripheral nervous system are involved in this process. Thus, in this work, we evaluate the effects of mutant
superoxide dismutase 1 (SOD1) overexpression on the gene expression of RAGE (receptor for advanced glycation end products) and NLRP1 and NLRP3 inflammasomes in the cells from motor cortex and spinal cord of mutant SOD1 (SOD1\textsuperscript{G93A}) transgenic mouse model of ALS. First, to evaluate the disease progression, we test the animals for motor coordination impairment using the rotarod performance task (once a week) for seven weeks. After four weeks, SOD1\textsuperscript{G93A} transgenic mouse began to present difficult to executing the tasks. These animals progressively presented an impaired rotarod performance when compared with a group of non-mutant SOD1 transgenic mice (Area Under the Curve = 750.20±2.09 vs. 1048.00±13.28, mutant and non-mutant mice, respectively; p<0.01). At eight week, when the SOD1\textsuperscript{G93A} transgenic mice reached its endpoint disease, that is when we observe the functional paralysis of both hind limbs, both groups of animals were euthanized. After, we analyzed the expression of RAGE, NLRP1 and NLRP3 in cells from motor cortex and spinal cord. Our results show that SOD1\textsuperscript{G93A} transgenic mice presented an increased expression of RAGE, NLRP1 and NLRP3 (1.5, 15 and 10-fold-increase, respectively) in cells from spinal cord when compared with non-mutant SOD1 transgenic. However, we do not observed differences between the groups when the same analysis was conducted in the cells from motor cortex. Together, ours results suggests the importance of RAGE, NLRP3 and NLRP1 expression in the spinal cord but not in motor cortex to the progression of murine ALS. In addition, these results highlight the role of NLRP1 as one of the main inflammasomes involved with SOD1 mouse model of ALS.

\textsuperscript{1}Neurology, Johns Hopkins School of Medicine, Baltimore, MD, \textsuperscript{2}Developmental Biology, Baylor College of Medicine, Houston, TX, \textsuperscript{3}Neuroscience, Baylor College of Medicine, Houston, TX, \textsuperscript{4}Neuroscience, Johns Hopkins School of Medicine, Baltimore, MD

A GGGGCC hexanucleotide repeat expansion (G\textsubscript{6}C\textsubscript{3} HRE) in the first intron of the C9orf72 gene has been identified as the most common genetic cause of amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD). One of the pathological hallmarks of C9-ALS is the presence of cytoplasmic protein aggregates colocalized with the autophagy receptor p62/SQSTM1. Interestingly, mutations in p62/SQSTM1 are also a rare genetic cause of ALS through an unclear mechanism. In a Drosophila model of C9-ALS expressing (G\textsubscript{6}C\textsubscript{3})\textsubscript{30}, we have found that p62 is upregulated and forms large aggregates in motor neurons. p62 plays a key role in autophagy by binding ubiquitinated proteins and delivering them to the autophagosome for degradation via the lysosome. Surprisingly, we find that knockdown of p62 rescues degeneration in the fly eye and in motor neurons. Immunofluorescence and western blot analysis of autophagy and lysosome markers demonstrates an expansion of lysosomes and decreased delivery to and digestion of autophagic cargo in the lysosome. Furthermore, we see a decrease in compartments positive for the protease CP1/Cathepsin L by immunostaining, suggesting lysosomal enzyme dysfunction. Using electron microscopy of the Drosophila eye, we observe a remarkable accumulation of expanded multilamellar bodies and autolysosomes that precedes neurodegeneration. We then tested genetic modifiers of autophagosome/lysosome function and find that mTor, Rab7, and TRPML overexpression rescue the neurodegenerative phenotypes in the Drosophila eye. Furthermore, treatment with rapamycin and trehalose, pharmacological inducers of autophagy/lysosome pathway, rescue neurodegeneration in the Drosophila eye as well as the accumulation of p62 positive aggregates. We propose that C9orf72-HRE expression causes dysregulation of protein folding and degradation leading to cytotoxic protein aggregation, and that this is rescued by aggregate clearance through genetic
and pharmacological upregulation of lysosomal function. This study suggests that drugs targeting lysosomal proteostasis pathways may have therapeutic potential for C9orf72-mediated ALS and FTD.

The expanded polyglutamine (polyQ) tract form of ataxin-1 drives disease progression in spinocerebellar ataxia type 1 (SCA1). Although polyQ-ataxin-1 is known to form distinctive intranuclear bodies, the cellular pathways and functions it influences remain poorly understood. Here, we identify direct and proximal partners constituting the interactome of ataxin-1[85Q] in Neuro-2a cells. Pathways analyses indicate a significant enrichment of essential nuclear transporters in the interactome, pointing to disruptions in nuclear transport processes in the presence of polyQ-ataxin-1. Our direct assessments of nuclear transporters and their cargos by immunofluorescence imaging and quantitative analyses reinforce these observations, revealing disrupted trafficking often with relocalisation of transporters and/or cargos to ataxin-1[85Q] nuclear bodies. Strikingly, the nucleoporin Nup98, dependent on its GLFG repeats, is recruited into polyQ-ataxin-1 nuclear bodies. Our results highlight a disruption of multiple essential nuclear protein trafficking pathways by polyQ-ataxin-1, a key contribution to furthering understanding of pathogenic mechanisms initiated by polyQ tract proteins.

Sirt1 restores proper cellular homeostasis to achieve neuroprotection in spinocerebellar ataxia type 7.
C.A. Stoyas1, D. Bushart2, J. Auwerx1, V.G. Shakkottai2, A.R. La Spada1;
1Pediatrics, University of California San Diego, La Jolla, CA, 2Neurology, University of Michigan, Ann Arbor, MI, 3Laboratory of Integrative and Systems Physiology, École Polytechnique Fédérale de Lausanne, Lausanne, Switzerland

Sirtuin 1 (Sirt1) is a NAD+-dependent protein deacetylase with established effects in countering age-related diseases, including neurodegeneration, yet the basis for Sirt1 neuroprotection remains elusive. Spinocerebellar ataxia type 7 (SCA7) is an inherited neurodegenerative disorder in which CAG-polyglutamine repeat expansions in the ataxin-7 gene produce cerebellar degeneration in affected human patients. As transcription dysregulation likely contributes to SCA7 pathogenesis, we performed transcriptome analysis on SCA7 mice, observed down-regulation of genes controlling calcium flux, and documented abnormal calcium-dependent membrane excitability in both SCA7 mouse cerebellum and SCA7 patient-derived neurons. Transcription factor binding site analysis of SCA7 down-regulated genes revealed sites for peroxisome proliferator-activated receptors, which are known Sirt1 targets, and we detected reduced Sirt1 activity in SCA7 mouse cerebellum. We then crossed Sirt1 transgenic mice with two different SCA7 mouse models, and observed amelioration of cerebellar neurodegeneration, calcium flux defects, and membrane excitability in Sirt1-SCA7 bigenic mice. These findings indicate that Sirt1
achieves neuroprotection by promoting proper calcium regulation, and reinforce an emerging view that
cerebellar ataxias exhibit altered calcium homeostasis, due to metabolic dysregulation, suggesting
shared therapy targets.

Toronto, ON, ⁵Physiology, University of Toronto, Toronto, ON

Axon degeneration is an early event and pathological in neurodegenerative conditions and nerve
injuries. To discover agents that suppress neuronal death and preceding axonal degeneration, we
performed drug screens on primary rodent neurons, and identified the pan-kinase inhibitor Foretinib
that potently rescued sympathetic, sensory, and motor wt and SOD1 mutant neurons from trophic
factor withdrawal-induced degeneration. By using primary sympathetic neurons grown in mass cultures
and Campenot chambers, we show that Foretinib protected neurons by suppressing both known
degenerative pathways, and a new pathway involving unliganded TrkA and transcriptional regulation
of the pro-apoptotic BH3 family members BimEL, Hirikiri and Puma, culminating in preservation of
mitochondria in the degenerative setting. Foretinib delayed chemotherapy-induced and Wallerian
axonal degeneration in culture by preventing axotomy-induced local energy deficit and preserving
mitochondria, and peripheral Wallerian degeneration in vivo. These findings suggest a new axon
degeneration pathway and identify a potentially clinically-useful therapeutic drug.

Post-Translational Modifications of Dipeptide Repeat Proteins in c9orf72-Associated ALS.
M. Meykler¹, M.P. Torrente¹;
¹Chemistry, CUNY Brooklyn College, Brooklyn, NY

Amyotrophic lateral sclerosis (ALS) and frontotemporal dementia (FTD) are progressive
neurodegenerative diseases associated with protein misfolding and aggregation that lead to neuronal
cell death. Chromosome 9 open reading frame 72 (c9orf72) is the most common genetic mutation
observed both in familial and sporadic cases. C9orf72 contains nucleotide repeat GGGGCC. In c9orf72
ALS/FTD patients, the nucleotide repeat may be expanded to several hundred or thousands of repeats.
By way of unconventional repeat-associated non-ATG translation, the nucleotide repeats are translated
into dipeptide repeat proteins (DPRs). Arginine-rich DPR’s, mainly Gly-Arg (GR100) and Pro-Arg (PR50)
seem to be particularly toxic and aggregation prone. The exact mechanisms linking DPR toxicity to
the development of ALS remain unknown.

Eukaryotic DNA is wrapped around an octameric histone core formed by one H3-H4 tetramer and two
H2A-H2B dimers. The N-terminal tails of histones are subject to many post-translational modifications
(PTMs). PTMs modify the interaction between the histone and DNA, either activating or suppressing
gene transcription. Saccharomyces Cerevisiae has been used as a model system for human
neurodegenerative diseases. At the cellular level, key processes are conserved between yeast and
humans, making yeast an efficient and accessible way of studying human neurodegenerative disease. Cytotoxic DPRs are overexpressed in yeast, and western blotting techniques with antibodies for specific PTMs are used to qualitatively detect changes between control yeast, and yeast overexpressing DPR. Preliminary results show no alterations in the histone modification landscape of cells displaying DPR proteinopathy. We are currently conducting additional trials for other PTMs. Elucidating the epigenetic mechanisms that associate with DPR toxicity will allow us to test compounds that can reverse these PTMs, reverse DPR toxicity and prevent neuronal cell death in ALS.

Intra-Axonal Translational Control Mechanisms for ER Chaperone Protein mRNAs.
A. Pacheco¹, J.L. Twiss², G. Gallo¹;
¹Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA, ²Dept of Biological Sciences, University South Carolina, Columbia, SC

Transport of neuronal mRNAs into distal nerve terminals and growth cones allows axonal processes to generate proteins autonomously from the cell body. Sensory neurons transport a complex population of mRNAs into their axons, including several encoding ER chaperone proteins. It remains largely unknown how specificity is provided to the localized translational apparatus. For calreticulin mRNA, one of its two 3’ UTR elements can drive its localization to axons but its 5’UTR was shown to confer translational control through a mechanism that requires phosphorylation of eIF2α in axons after stimulation of ER stress with LPA. Interestingly, the proximal 3’UTR localization element in calreticulin mRNA is essential for this phospho-eIF2α-dependent translational control. Thus, 5’ and 3’ UTRs can perform concerted roles to achieve specificity for axonally localized mRNA translation. We show that PERK (protein kinase RNA-like endoplasmic reticulum kinase) is required for the increase of calreticulin translation in response to ER stress. Since PERK has been detected in DRG axons and LPA triggers ER Ca²⁺ release, a Ca²⁺-dependent activation of axonal PERK likely leads to axonal calreticulin translation. Calcium influx in the axoplasm represents a fast signaling event in response to injury that is able to trigger several mechanisms connected to axonal growth. We have seen an increase in the phosphorylation of eIF2α after 20 min of axotomy and axotomized DRG axons undergo a local calreticulin translation through the 3’UTR proximal element. PERK is required for this translational regulation since its inhibition impaired calreticulin translational increase. Similar to LPA results, eIF2α phosphorylation could be a common signaling mechanism mediating axonal calreticulin translational in response to injury. Our static imaging experiments have shown a decrease in the total axonal length of calreticulin depleted DRG neurons suggesting that axonal calreticulin translation could mean a fast triggered response to injury. Further experiments are being performed to understand this mechanism.

The adaptor protein FEZ1 links metabotropic glutamate receptors to the autophagy pathway.
M. Donoso¹, M. Kalinowska², C. Castillo¹, A. Francesconi¹;
¹Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Group I metabotropic glutamate receptors (mGlu1 and mGlu5) are G protein-coupled receptors (GPCRs) enriched at excitatory synapses throughout the brain where they act both pre- and postsynaptically to
regulate glutamatergic neurotransmission. Signaling by group I mGluRs is critical to formation and maintenance of brain circuitry and activity-dependent synaptic plasticity, a cellular substrate of learning and memory. Recessive mutations in the gene encoding mGlu1 (GRM1) in patients with congenital ataxia and intellectual disability give rise to aberrant mRNA transcripts that produce receptors with abnormal intracellular carboxyl-tails, indicating that this domain is critical to receptor physiopathological functions. Using genetic, biochemical and imaging approaches we found that mGlu1 interacts via its carboxyl-tail with the adaptor protein Fasciculation and Elongation Protein Zeta-1 (FEZ1). FEZ1 was recently shown to participate to the regulation of macroautophagy, a catabolic process critical to neuronal homeostasis and survival throughout organism lifespan. Our findings indicate that mGlu1 receptors function via FEZ1 to regulate autophagy in neurons, a mechanism through which metabotropic signaling may contribute to maintaining neuronal homeostasis.

A pair of E3 ubiquitin ligases coordinate responses of DCC to its ligand, netrin-1.
C. Monkiewicz1, N. Boyer3, S. Menon1, S.L. Gupton1,3;
1Cell Biology and Physiology, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC, 2Neurobiology Curriculum, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC, 3Neuroscience Center, University of North Carolina at Chapel Hill, School of Medicine, Chapel Hill, NC

Fidelity in axon guidance and axon branching are critical to appropriate wiring of the nervous system. Although the guidance cues and receptors that direct axonal extension have been identified, the complex underlying molecular pathways, and in particular how extracellular guidance cues modulate the receptors that initiate neuronal morphogenesis, have been relatively unexplored. Netrin-1 is a secreted guidance cue, originally considered a soluble, chemotactic cue that functions in axon attraction, axon repulsion, and axon branching. Recently netrin-1 has been found to adhere to the extracellular environment and function as a haptotactic cue. Our work has identified a pair of closely related, brain-enriched E3 ubiquitin ligases, TRIM9 and TRIM67, as critical links between the netrin receptor DCC and the signaling pathways and cytoskeletal responses critical to axonal morphogenesis. In this study, we utilize two purification protocols to separate soluble, non-adhesive netrin-1 and adhesive netrin-1, to determine how responses to these two forms of netrin differ and are modulated by TRIM9 and TRIM67. We use TIRF microscopy to reveal the spatiotemporal clustering of DCC in response to netrin. We have found that low concentrations of soluble netrin-1 promote attractive axonal responses and DCC clustering, whereas high doses of soluble netrin-1 promote repulsive axonal responses without DCC clustering at the cell periphery. Interestingly individual deletion of Trim9 or Trim67 disrupts a unique subset of these responses. We are exploiting a newly-developed FRET-based DCC tension sensor to define how mechanotransduction differs in these netrin regimes in wildtype, Trim9+/−, Trim67+/−, and Trim9−/−/Trim67−/− neurons. Although TRIM9 and TRIM67 share high sequence similarity and binding partners, including DCC, their expression patterns are distinct and the phenotypes associated with their individual deletion or combined deletion are all surprisingly divergent in vitro and in vivo. Published work indicates that TRIM9 is required for attractive growth cone responses to netrin-1. Here we show that TRIM67 is required for both attractive and repulsive responses to netrin-1, and that Trim9−/−/Trim67−/− have additional, unique phenotypes. Our previous work has identified neuroanatomical defects and behavioral deficits in Trim9−/− mice. Here we show distinct neuroanatomical and behavioral deficits occur in the absence of Trim67 in vivo.

**CHL1 and SLIT1 Colocalize in the Intermediate Zone During Embryonic Development.**  
C. Levinger\(^1\), P. Tran\(^1\), A.G. Wright\(^1\);  
\(^1\)Biology and Physical Sciences, Marymount University, Arlington, VA

Axons are an integral part of a neuron responsible for transmitting electrical signals within the brain. It is important to understand the mechanics of axon growth, including how growth cones function and which proteins are involved in axon migration and how they co-exist with other proteins. This hierarchy of information is essential to combat certain types of cancers and neurological disorders such as Alzheimer’s disease. We currently know of several families of proteins that play major roles in regulating axon guidance. Two such families are neural cell adhesion molecules (NCAMs) of the immunoglobulin superfamily (Maness and Schachner, 2007) and the family of SLIT proteins (Andrews, et al., 2007). Close Homolog of L1 (CHL1), a NCAM, is part of the mammalian L1 family, which is known to play a role in axon growth and migration of developing neurons (Wright, et al., 2007). Roundabout1 (ROBO1), also a member of the immunoglobulin super family, plays a role in axon guidance in the developing forebrain by serving as a receptor for the guidance cue, SLIT1 (Andrews, et al., 2007). Our objective in this study is to investigate a potential interaction between CHL1 and SLIT1. We hypothesize that these two proteins function together to regulate SLIT-mediated axon guidance in developing neurons. The first step in our investigation involved the use of co-immunofluorescence staining to visualize CHL1 and SLIT1 colocalization. We demonstrate here that CHL1 and SLIT1 do colocalize in the intermediate zone of the cerebral cortex during axonal targeting (E16). We also demonstrate that CHL1 and ROBO1, the receptor for SLIT1, are coordinately expressed during this same period but do not colocalize. This data suggests an interaction between CHL1 and SLIT1 and a cooperation between CHL1 and ROBO1 that may help control axon guidance to regulate proper neuronal topographic mapping.

\(^1\)Laboratory of Developmental Genetics, The Rockefeller University, New York, NY

Faithful assembly of neural circuits requires a complex array of cellular interactions and molecular pathways guiding axon navigation. Circuit assembly begins when early neuronal processes extend over non-neuronal cells to form tracts that guide follower axons. Although axon guidance has been intensely studied for decades, major open questions remain. Among these are the molecular properties of pioneer axons, and the guidance interactions between pioneer axons and glia, which appose pioneer bundles. To determine how neurons and glia interact during CNS formation, we studied assembly of the C. elegans nerve ring (NR), a brain-like neuropil consisting of ~180 axons, and enveloped by four astrocyte-like CEPsh glia.

Using time-lapse embryonic imaging, genetics, protein-interaction, cell ablations and functional studies, we uncovered the early events of NR assembly. We showed that the NR is populated in an orderly manner, with CEPsh glia playing key roles in assembly initiation. We identified a set of ~10 pioneer neurons, with unique cellular, molecular, and growth properties that cooperate with glia to guide follower axons of diverse groups. Importantly, we demonstrate that CEPsh glia regulate pioneer and
follower axon guidance using distinct signals, and identify a network of guidance cues acting in glia and pioneer neurons to drive assembly.

From a genetic screen, we isolated a novel mutant that spares axon-outgrowth initiation, but severely disrupts axon guidance, with more than 70% of axons of different subtypes failing to incorporate into the NR. Two mutations, in a Chimaerin (GTPase regulator) and a Furin (pro-hormone convertase), are causal for the mutant defects. These proteins act non-canonically in glia for pioneer-axon guidance and in both glia and pioneer neurons for follower-axon navigation. Importantly, we show that they together regulate guidance-cue trafficking. Single Chimaerin or Furin mutants, or in other axon guidance genes exhibit only mild defects in NR assembly, suggesting redundancy, a problem that has plagued genetic analysis of axon guidance in vertebrate and invertebrate settings. The double mutant we identified uncovers a genetic bottleneck that allowed us to genetically identify new, redundant axon-guidance genes, several of which appear to be previously unknown.

Taken together, our studies suggest a pivotal role for glia in initiation of CNS assembly, and open the door to uncovering new axon guidance genes. CEPsh glia are reminiscent of vertebrate radial glia, whose molecular biology is not well understood. Moreover, mammalian homologs of some glial genes we identified have axon guidance roles in vertebrates, and are expressed in glia. Our studies, therefore, may reveal conserved glial mechanisms promoting CNS assembly.

PLCb1 escorts Ago2 to stress granules to change the miR population in response to Osmotic Stress.

A. Singla¹, S. Scarlata¹;
¹Chemistry and Biochemistry, Worcester Polytechnic Institute, Worcester, MA

Phospholipase C-β1 (PLCb1) is activated by G protein signals initiated by different hormones and neurotransmitters on the plasma membrane to mediate increases in intracellular calcium (Ca2+). We have previously found that PLCb1 localizes to the cytoplasm where it interacts with components that can impact RNA-induced silencing. Using methods including fluorescence imaging, mass spectroscopy, and coimmunoprecipitation, we show that PLCb1 directly binds to one of the key components of the RNA-induced silencing complex, Argonaute 2 (Ago2). However, this association only occurs during specific cell states, and most importantly during cell stress. Specifically, we find that during stress, PLCb1 recruits Ago2 into stress granules (SGs) to help protect mRNA from degradation. This protection is inferred by the inverse correlation of PLCb1 levels with protein synthesis and in miR populations associated with cell survival. Our studies show and important and novel feedback between the external environment and mRNA stability through PLCb1.

The ataxia disease gene VPS13D plays an essential role in mitochondrial morphology and transport in Drosophila neurons.
R. Insolera1, E. Seong2, L.M. Rivera-Perez3, D. Lozano4, M. Burmeister2,3,4,5, C.A. Collins1;
1MCDB, University of Michigan, Ann Arbor, MI, 2 Molecular and Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI, 3 Department of Human Genetics, University of Michigan, Ann Arbor, MI, 4 Department of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI, 5Department of Psychiatry, University of Michigan, Ann Arbor, MI

The long term maintenance and survival of neurons is highly dependent on the proper functioning of mitochondria. This is evident by the disproportional representation of mitochondrial genes associated with neurodegenerative disorders. Originally discovered in yeast, vacuolar sorting protein 13 (vps13) has multiple variants in metazoans, three in Drosophila melanogaster (A, B, and D) and four in mammals (A through D). Human mutations in VPS13A, B, and C have all been linked to various forms of neurodegenerative diseases. Recent genetic studies in humans have associated mutations in VPS13D with ataxia. In order to understand the cell biology underlying the defects associated with dysfunction of the vsp13d gene in the nervous system, we are using Drosophila melanogaster as a model system. Loss-of-function mutations in vps13d lead to severe defects in mitochondrial morphology in multiple tissues, and early larval lethality. Targeted knockdown of vps13d in the nervous system circumvents this early lethality to allow further analysis, and reveals similar cell-autonomous mitochondrial defects in neurons. In larval motoneurons lacking vps13d, we observed defects in trafficking of mitochondria to axons and synaptic terminals. Loss of vps13d induces the formation of oversized, atypical mitochondria, some of which contain mitochondrial inner membrane proteins but lack markers targeted to the matrix. Most interestingly, targeted knockdown of vps13d in neurons leads to the accumulation of comparably atypical mitochondria in neighboring supportive glial cells. We are currently characterizing the nature of the cell-autonomous mitochondrial defects in neurons, and the origin of the non-cell autonomous effect on mitochondria in glia. An exciting possibility that we are testing is whether there is transfer of atypical mitochondria from neurons to glia. Altogether, these results suggest that vps13d plays an essential role in mitochondrial biology, and is required in neurons for the proper distribution of mitochondria to distal regions. In addition, vps13d disruption in neurons reveals a previously uncharacterized neuron-glia interaction which may be relevant for its roles in neurodegenerative disease.

Fear conditioning affects adenosine2A receptor and glutamate transporter 1 expression during memory consolidation.
H.E. Merens1, L. De Falcis2, D. Cusmano3, S. Chatterjee4, T. Abel4, J.C. Tudor2;
1Chemistry, University of Pennsylvania, Philadelphia, PA, 2Biology, Saint Joseph's University, Philadelphia, PA, 3Biology, University of Pennsylvania, Philadelphia, PA, 4Molecular Physiology and Biophysics, Carver College of Medicine University of Iowa, Iowa City, IA

Memory consolidation is a critical stage of memory formation, and is associated with waves of gene expression occurring in the hippocampus four hours after memory acquisition. Yet, an understanding of the genes expressed during memory consolidation remains incomplete. One candidate gene is
ADORA2A, which encodes for the neuronal adenosine2A receptor. This receptor is responsive to the molecule adenosine, an inhibitory neurotransmitter that acts as a central nervous system depressant. It has been shown that deactivation of this receptor results in decreased memory impairment, while activation results in increased memory impairment. Furthermore, there is evidence for an antagonistic relationship between the adenosine2A receptor and glutamate transporter 1 (GLT-1). Astrocytic GLT-1 is responsible for the uptake of glutamate, an excitatory neurotransmitter. It remains unclear if the adenosine2A receptor and GLT-1 are regulated, and if they maintain an inverse relationship, during memory consolidation. Therefore, this study aimed to elucidate changes in mRNA and protein expression of the genes encoding the adenosine2A receptor and GLT-1 during memory consolidation. Mice underwent fear conditioning using a two second foot shock. Four hours later, during memory consolidation, hippocampal tissue was collected and compared with unshocked controls to examine changes in mRNA and protein expression using qPCR analysis and western blotting analysis respectively. Adenosine2A Receptor mRNA expression was significantly decreased (p=0.0467), while GLT-1 mRNA expression was significantly increased (p=0.0255), in the hippocampus four hours after fear conditioning compared to unshocked controls. The significant changes in GLT-1 mRNA expression suggest an astrocytic role in memory consolidation. Notably, these changes were inversely related to the decrease in adenosine2A receptor gene expression levels, supporting the notion that the two may maintain an antagonistic relationship. Interestingly, total protein levels of adenosine2A receptor and GLT-1 was not significantly affected at this time point. These findings highlight that there may be complex temporal interactions between transcriptional and translational events for memory consolidation, which cannot be simplified to single time points.

Neurofilament transport may be regulated by the proximity of neurofilaments to their microtubule tracks.
T.L. Nguyen1, P. Jung1, A. Brown2;
1Department of Physics and Astronomy and Quantitative Biology Institute, Ohio University, Athens, OH,
2Department of Neuroscience, Ohio State University, Columbus, OH

Neurofilaments are abundant space-filling cytoskeletal polymers that accumulate in myelinated axons during development to drive the expansion of axon caliber, which is a key determinant of axonal conduction velocity. Neurofilaments are also cargoes of axonal transport that are assembled predominantly in the cell body and move out along axons on microtubule tracks powered by microtubule motor proteins. This dual role of neurofilaments as space-filling structures and cargoes of axonal transport implies a complex relationship between axon caliber, neurofilament influx from the cell body, and neurofilament transport kinetics in the axon. Axonal injury present a good model system to study this complex relationship because of the availability of published morphometric and kinetic data. After injury, retrogradely transported injury signals trigger a transient reduction in neurofilament gene expression in the cell body and a corresponding transient reduction in neurofilament influx into the axon, resulting in a wave of axon thinning that propagates distally at a rate consistent with neurofilament transport. Coincident with these changes, radioisotopic pulse labeling studies have revealed a transient increase the average neurofilament transport velocity. Since axonal neurofilaments normally outnumber microtubules greatly in large myelinated axons, a simple potential explanation for this acceleration of neurofilament transport is that the decrease in neurofilament number due to the decrease in neurofilament influx into the axon results in an increase in the accessibility of neurofilaments to their microtubule tracks, and consequently a greater frequency of movement. To test
this idea, we developed a new computational model for neurofilament transport in which access of
neurofilaments to their microtubule tracks, and their organization in the radial dimension of the axon,
influences their motility. Using this new model, we can explain the time-course of post-injury decrease
in axon caliber and increase in neurofilament transport velocity by a simple reduction of neurofilament
flux, and the subsequent time-course of axonal recovery by a corresponding recovery of neurofilament
flux. These findings demonstrate that proximity of neurofilaments to microtubules may be a key
determinant of their motility. One important prediction of this model is that average neurofilament
transport velocity and axon caliber are sensitive to small changes in neurofilament and microtubule
density and organization. We believe that this simple principle has important implications for the
mechanisms by which neurofilaments accumulate in axons during development, and may also
contribute to the runaway accumulations of neurofilaments observed in neurodegenerative diseases.

Nmnat mitigates sensory dysfunction in a Drosophila model of paclitaxel-induced peripheral
neuropathy.
J.M. Brazill1, R.G. Zhai1, B. Cruz1;
1Molecular and Cellular Pharmacology, University of Miami Miller School of Medicine, Miami, FL

Chemotherapy-induced peripheral neuropathy (CIPN) is the major dose-limiting side effect of many
commonly used antimitotic agents, including paclitaxel, for which there is currently no neuroprotective
treatment. Here we established a paradigm for modeling paclitaxel-induced sensory dysfunction in
Drosophila larvae that recapitulates aspects of chemotherapy-induced sensory dysfunction, specifically
hypersensitivity to thermal nociceptive stimuli. Importantly, we showed that nociceptive sensitivity
following paclitaxel treatment is associated with an increase in peripheral dendrite branch density of
larval class IV dendritic arborization (C4da) nociceptors, uncovering a novel mechanism of paclitaxel-
induced sensory dysfunction. Additionally, we were able to show that boosting expression of Nmnat,
extensively studied for its ability to potently delay axon degeneration, cell-autonomously mitigates
paclitaxel-induced nociceptive sensitization. We demonstrated that endogenous Nmnat is crucial for the
maintenance of Drosophila larval C4da sensory neurons and thermal nociceptive behavior. Our work
establishes a robust and tractable model for studying neuronal mechanisms of CIPN and challenges the
conventional sensory axon degeneration hypothesis. Furthermore, our findings advance our
understanding of Nmnat-mediated neuronal protection and maintenance and highlight Nmnat’s
potential role as a modulator of sensory dysfunction in CIPN.

A preliminary association study in Turkish population: Do IL-17 and UCP2 Gene variants
Contribute to The Ethiology of Microtia?
K. Ozdilli1, M. Bekerecioglu2, S. Pehlivan3, B. Buyukgural4;
1Medipol University Hospital, Istanbul, Turkey, 2Plastic and Reconstructive Surgery, Sutcu Imam
University, Kahramanmaras, Turkey, 3Medical Biology, Istanbul University, Istanbul, Turkey, 4Plastic and
Reconstructive Surgery, Private Clinic, Istanbul, Turkey

Microtia is a congenital deformity affecting the outer ear, characterized by a small, abnormally shaped
auricle. External ear canal is commonly narrowed, blocked or absent and middle ear is underdeveloped
because the outer ear and the middle ear have common embryologic origin. The prevalence of microtia
varies between 0.83 and 17.4 per 10,000 births. Recently, findings suggest that uncoupling proteins (UCPs) may play a protective role against reactive oxygen species in neuron and a thermal signaling role for neuron modulating in vestibular nerve. Interleukin-17 (IL-17) can accelerate the release of many pro-inflammatory cytokines. Although many genetic and enviromental factors are investigated the ethiopathogenesis of microtia is still unclear. The aim of this study was to investigate the links between functional promotor variants of IL-17 (-7488 A/G) and UCP2 (-866 A/G) genes and microtia. Fifteen microtia patients and 30 healthy controls were included in the study. We studied the functional promotor variants of IL-17 (rs763780) and UCP2 (659366) gene, using PCR-RFLP method. The frequencies of the alleles and genotypes in patients and controls were compared by the \( \chi^2 \) test No significant difference was found in the distribution of genotypes and alleles frequencies between patients and healthy controls for both IL-17F (rs 763780) and UCP2 (659366) genes (\( P > 0.05 \)). To our knowledge, this is the first study to assess relationship between the IL-17/UCP2 variants and Microtia in a Turkish cohort. This results do not support any major role of IL-17/UCP2 variants in the etiopathogenesis of microtia in Turkish patients. These results need to be replicated in larger series and examined in microtia.

Alterations in Protein Expression Levels Following Exposure to Mild Traumatic Brain Injury Simulation in 2.5D Culture System.

K. Gilpin\(^1\), T.J. O'Shaughnessy\(^2\);

\(^1\)Materials Science Technology Division, Naval Research Laboratory, Washington DC, DC

Mild traumatic brain injury (mTBI) is a growing diagnosis among returning warfighters and is characterized by a wide array of symptoms lacking a detectable lesion, thus making it challenging to establish a correlation between mTBI and blast exposure. Phenotypic criteria of mTBI includes axonal injury and may include death of neurons and glial cells, but underlying subcellular changes have yet to be discovered. The Naval Research Laboratory (NRL) has developed a two and a half dimensional (2.5D) collagen hydrogel-based culture system with which to study mTBI with the goal of determining and quantifying changes in protein expression after exposure of primary murine cortical neurons to shock tube generated overpressures (simulated blasts). This system has increased physiological relevance as compared with conventional 2D culture systems. Proteins were extracted from the 2.5D cell cultures either with or without exposure to 210 kPa overpressure. Since the cellular responses to stress typically occur relatively quickly after insult, the cell cultures were permitted to recover for 1 hour or 48 hours before protein extraction occurred through a series of incubation/centrifugation steps using collagenase, the enzyme responsible for collagen proteolysis. Expression of caspase-3 increased in lysates exposed to overpressures as compared with control lysates when measured at the 1 hour post-insult time point, but slightly decreased/returned to baseline in exposed lysates when assessed 48 hours after exposure. Expression of Tom-20 showed no substantial changes at either time point. Preliminary evidence shows changes in expression of the intermediate filament neurofilament-medium and the extracellular matrix protein chondroitin sulfate. We will continue our studies on these proteins and report the findings. Additionally, we will assess and report expression levels of cleaved caspase-3 to begin probing the mechanism of death after exposure to overpressures.

Expression of WIPI2B counteracts age-related decline in autophagosome biogenesis in neurons.  
A.K. Stavoe\(^1\), E.L. Holzbaur\(^1\);  
\(^1\)Physiology, University of Pennsylvania, Philadelphia, PA

Autophagy defects are implicated in multiple late-onset neurodegenerative diseases. Since aging is the most common risk factor in neurodegeneration, we examined autophagy in aged neurons. Autophagosome biogenesis is known to occur preferentially at the distal tips of axons, and autophagosomes mature as they transit to the soma. We compared autophagosome biogenesis in neurons from young adult and aged mice, identifying a significant decrease in the biogenesis of autophagosomes during aging. While nucleation and initiation rates did not change during aging, we observed the frequent production of stalled Atg13-positive, LC3-negative isolation membranes in neurons from aged mice. These stalled structures exhibited aberrant membrane morphology and failed to resolve into LC3-positive autophagosomes. Further, the majority of stalled autophagosomal structures were Atg9-positive, while autophagic vesicles that successfully recruited LC3 did not retain Atg9. To identify the underlying molecular defect, we queried expression levels of autophagy proteins and identified a specific reduction in the PI3P-binding protein WIPI2 in aged mouse brain. WIPI2 depletion in young neurons was sufficient to stall autophagosome biogenesis, phenocopying aged neurons. Importantly, reconstituting WIPI2 expression effectively restored autophagosome biogenesis in aged neurons. We additionally determined that the PI3P and Atg16L1 binding domains of WIPI2 were required for WIPI2-induced restoration of autophagosome biogenesis. Together, these data suggest a novel therapeutic target in age-associated neurodegeneration.

Autophagy at the synapse: from biogenesis to breakdown.  
S.E. Hill\(^1\,\,2,3\), S. Yang\(^1\,\,2,3\), D.A. Colón-Ramos\(^1\,\,2,3\);  
\(^1\)Cell Biology, Yale University, New Haven, CT, \(^2\)Neuroscience, Yale University, New Haven, CT, \(^3\)Program in Cellular Neuroscience, Neurodegeneration and Repair, Yale University, New Haven, CT

Autophagy removes bulk cytoplasm or organelles from cells by forming double-membrane autophagosomes that fuse to lysosomes for degradation. Regulation of autophagosome formation and trafficking is especially important in neurons, which have long polarized processes distant from the cell body. We and others have observed that autophagosomes form at presynaptic sites and then undergo retrograde transport towards the cell body. However, the regulation of autophagosome formation, trafficking and degradation is only partially understood. To investigate these processes, we examined the ortholog of Atg8/GABARAP, autophagosome marker GFP::LGG-1, in the *C. elegans* interneuron AII. AII is part of the thermotaxis circuit. Using temperature stimuli to control synaptic firing in AII, we observed a correlation between synaptic activity and autophagosome formation. We also observed that autophagosomes undergo Dynactin/DNC-1-dependent retrograde trafficking from the synapse. Via reverse genetic screens, we determined that UNC-16/JIP3, a motor adaptor protein, is required for the retrograde transport of autophagosomes. We performed a forward genetic enhancer screen in *unc-16/jip3* mutant animals and uncovered a novel lesion in autophagy gene *atg-4.2*, one of the two homologues in *C. elegans* for the cysteine protease ATG-4. We determined that *atg-4.2*, but not *atg-4.1* is important for clearance of autophagosomes, and that loss of *atg-4.2* in the *unc-16/jip3* mutants causes an enhancement of autophagosomes in the neurite. These studies suggest that autophagy at the
synapse begins with synaptic activity, followed by retrograde trafficking and ATG-4-dependendent autophagosome breakdown in the cellular soma.

Clarification of the roles of γ-secretases associated with autophagy.
H. Heo1, J. Chang1;
1Department of Biomedical Sciences, Ajou University School of Medicine, Suwon, Korea, South

Accumulation of various types of abnormal/unwanted intercellular substances has been thought to be responsible for the development of neurodegenerative diseases including Alzheimer's disease (AD). Autophagy is responsible for the degradation of these materials using lysosomes. Thus, efforts have been made to identify the underlying cellular pathogenesis of AD by determination of the relationships between AD-related genetic alterations and autophagy. The series of these studies begin with the study on an important familial AD gene, PSEN1, which encodes a subunit of γ-secretase regulating the processing of beta-amyloid (Aβ) from amyloid precursor protein (APP). In 2010, a research group has shown that PSEN1 is required for the maintenance of the acidic lysosome environment by regulating the lysosomal targeting of a V-ATPase subunit, V0a1, in a manner independent of γ-secretase activity. This finding, however, was challenged by studies conducted by two independent research groups. These groups argued that either absence of PSEN does not alter autophagic substrate turnover, or the defects in turnover would be due to abnormal lysosomal calcium homeostasis rather than the impaired function of proton pump. However, these groups mainly used PSEN1/PSEN2 double knockout (KO) cells as an assay system which also could affect the activity of γ-secretase. Therefore, to clarify this conflict issue, we decided to analyze and compare the autophagic activities in the cells with impaired γ-secretase activity and/or expression of PSEs. First, we generated cell lines lacking γ-secretases by CRISPR/CAS9-mediated knockout of PEN2, a subunit of γ-secretase. Intriguingly, we found that the autophagic flux of these cell lines is more active than in normal cells. We will further elucidate the molecular mechanism underlying autophagic regulation of γ-secretase and PSEs at the molecular level.

ER-mitochondria tethering by PDZD8 regulates Ca^{2+} dynamics in mammalian neurons.
Y. Hirabayashi1, S. Kwon1, H. Paek1, W.M. Pernice2, M.A. Paul1, J. Lee1, P. Erfani1, A. Raczkowski3, D.S. Petrey4, L.A. Pon5, F. Polleux1;
1Department of Neuroscience, Columbia University, New York, NY, 2Department of Pathology and Cell Biology, Columbia University, New York, NY, 3Simons Electron Microscopy Center, New York Structural Biology Center, New York, NY, 4Department of Systems Biology, Columbia University, New York, NY

A network of contact sites between the membranes of different organelles are emerging as critical platforms for various forms of intracellular signaling. The interface between ER and mitochondria is of particular interest as a signaling hub because it is thought to play critical physiological functions ranging from Ca^{2+} exchange, to lipid biogenesis and regulation of mitochondria fission. In addition, changes in the number of these contacts have been observed in neurodegenerative mouse models and/or in the brains of patients presenting with Alzheimer’s disease (AD), Parkinson’s disease (PD), and Amyotrophic lateral sclerosis (ALS). However, despite the fact that multiple proteins are enriched at ER-mitochondria contacts sites, the molecular mechanisms underlying ER-mitochondria tethering are still largely unknown in metazoans. Here, we will report the identification of PDZD8 as an ER protein present at ER-
mitochondria contacts (Hirabayashi et al. Science 2017 in press). The SMP domain of PDZD8 is functionally orthologous to the SMP domain found in yeast Mmm1, a member of the four proteins composing the ERMES complex identified in yeast by Peter Walter’s group as essential for ER-mitochondria contact formation in yeast (Kornmann et al. Science 2009). Using 3D FIB-SEM reconstructions, we demonstrate that PDZD8 is required for the formation of ER-mitochondria contacts in mammalian cells. Using a series of functional rescue experiments, we found that PDZD8-dependent ER-mitochondria contacts are required for proper Ca\(^{2+}\) exchange between ER and mitochondria in mammalian cells. In neurons, PDZD8 is required for Ca\(^{2+}\) uptake by mitochondria following synaptically-induced Ca\(^{2+}\)-release from ER and thereby regulated cytoplasmic Ca\(^{2+}\) dynamics. Thus, PDZD8 represents a critical ER-mitochondria tethering protein in metazoans. We suggest that ER-mitochondria coupling is involved in the regulation of dendritic Ca\(^{2+}\) dynamics in mammalian neurons.

**A retrograde autophagic filter that removes mitochondria in distal nodes of Ranvier.**

N.A. Marahori\(^1\), S. Hannan\(^1\), B. Plomer\(^1\), T. Kleele\(^1,2\), M. Schifferer\(^3,4\), M. Lakadamyali\(^5,6\), M.S. Brill\(^1\), T. Misgeld\(^1,3,4\);

\(^1\)Institute of Neuronal Cell Biology, Technical University Munich, Munich, Germany, \(^2\)Laboratory of Experimental Biophysics, École polytechnique fédérale de Lausanne, Lausanne, Switzerland, \(^3\)German Center for Neurodegenerative Diseases (DZNE) Munich, Munich, Germany, \(^4\)Munich Cluster for Systems Neurology (SyNergy), Munich, Germany, \(^5\)perelman School of Medicine, Department of Physiology, University of Pennsylvania, Philadelphia, PA, \(^6\)Institute for Advanced Study (TUM-IAS), Technical University Munich, Munich, Germany

Neurons have a complex morphology, with processes that can extend beyond a meter in length in larger species. In order to supply distal compartments and synapses, neurons transport mitochondria from the soma in the anterograde direction. Interestingly, significantly less mitochondria return to the soma, where most lysosomal degradation is thought to occur. We investigated whether dysfunctional mitochondria undergo autophagy at distal axonal sites, using the neuromuscular junction (NMJ) as a model. In order to follow the fate of retrogradely moving mitochondria, we employed Thy1-mitoDendra transgenic mice and performed live-imaging following photo-conversion of synapses or intercostal axons. In synapses, we observed about half of mitochondria exiting NMJs are captured before heminodes, i.e. the last node of Ranvier separating axon and synaptic terminal. In contrast, photo-converted mitochondria in the intercostal stem axon were not captured at nodes of Ranvier and were significantly longer than those leaving NMJs. Taken together, we propose a new model, where distal nodes of Ranvier act as checkpoints for retrogradely traveling mitochondria to capture dysfunctional ones, which presumably undergo local mitophagy. We hypothesize that synapses and distal axon branches act as independent ‘mitostatic’ compartments within neurons.

As further evidence pointing towards distal autophagy we found significantly increased densities of lysosomes at distal, but not proximal, nodes of Ranvier. In addition, a cholinergic neuron specific knock-out of the autophagy-related 7 gene (Chat-Cre x Atg7 floxed) led to mitochondrial accumulation and cytoplasmic swelling of synaptic terminals and distal, but not proximal, internodes. Retrograde transport rates decreased in Atg7 knock-out mice, whereas the fraction of captured mitochondria increased, possibly due to accumulation of dysfunctional mitochondria in synaptic terminals. To corroborate the above findings we plan to analyze how captured mitochondria differ in function and morphology using

Monday-309
transgenic mice expressing functional biosensors in neuronal mitochondria, viral vectors to express mitophagy indicators, as well as volumetric ultrastructural analysis. Taken together, our results suggest the existence of a hitherto unknown autophagic filter at distal nodes of Ranvier.

Preliminary characterization of mitochondrial damage-associated molecular patterns using a three-dimensional microfluidic ex vivo model of the blood-brain barrier/neurovascular unit. A.M. Medina-Lopez, B.S.1,2, I.I. Torres-Vazquez1,2, H. Shinogle-Decker, B.S.1,2, T. Neeland2, N. Martinez-Rivera, Ph.D.2, E. Rosa-Molinar, Ph.D.1,2;

1Department of Pharmacology and Toxicology and Neuroscience Graduate Program, University of Kansas, Lawrence, KS; 2Microscopy and Analytical Imaging Resource Core Laboratory, University of Kansas, Lawrence, KS

Interest in mitochondria comes from their role as “potent immunological activators” such as bacteria from which they theoretically evolved. For example, during and following a traumatic brain event, damage to and cell death of brain cells and tissues releases mitochondrial damage-associated molecular patterns (mtDAMPs) into the extracellular space, activating innate immunity and potentially causing a breach in the blood-brain barrier/neurovascular unit (BBB/NVU). To study the role of mtDAMPs in stimulating immunity and potentially breaching the BBB/NVU, we first investigated mitochondrial populations within an intact three-dimensional (3-D) microfluidic ex vivo model of BBB/NVU. We stained mitochondria with cell-permeant MitoTracker™ Red CMXRos (M-7512; Ex 579 nm/Em 599 nm; Thermo Fisher Scientific, Waltham, MA), immunolabeled mitochondrial gap junctions with connexin 43 (Cx43; C6219 [Lot # 045M4882V], Sigma-Aldrich, St. Louis, MO), and visualized them using wide-field epifluorescence microscopy, spinning disk confocal laser microscopy and transmission electron microscopy. In the intact ex vivo model, we noted low numbers of rod-like and circular shaped mitochondria with well-developed cristae were clustered around the nucleus of microvascular endothelial cells and large numbers of rod-like and circular mitochondria with well-developed cristae were randomly distributed throughout the cytoplasm of perivascular astrocytes. Cx43 immunolabeling was unambiguously shown within the mitochondrial membranes of microvascular endothelial cells and perivascular astrocytes. After determining the morphology and numbers of mitochondria, and mitochondrial gap junctions in an intact state, we exposed an intact ex vivo model to mitochondrial DNA to induce a BBB/NVU breach. We are now seeking to identify the location of the breach and to elucidate the role of Cx43 in mtDAMP's release and signaling by using the same microscopies listed above and a fluorescent water-soluble tracer dye (Tracer-653; TR-1001; MTTI, Inc., West Chester, PA) that enables imaging of vascularity, mitochondrial gap junctions, and vascular leakage of the BBB/NVU.

Research partially supported by grants to ER-M from NIH (GM-115042; GM-078441; MH-106245) and NSF (HRD-1137725). AM-L is supported through a fellowship by NIH (GM-008359).

Identification of the NAB2 Nuclear Localization Signal.
T. Grant1, S. D’Angelo-Early1, J.M. LaVallee1, S. Kletsov1, K.W. Adams1;
1Biological Sciences, Bridgewater State University, Bridgewater, MA

NGFI-A binding protein 2 (NAB2) is a transcriptional coregulator that modulates gene expression through protein-protein interactions with early growth response proteins 1-3 (Egr1-3), which are immediate early genes involved in various cell behaviors. Roles for NAB2 and Egr2 are best characterized in the peripheral nervous system, where they are essential for peripheral nerve myelination. Roles for Egr1 and 3 are better documented in the central nervous system, where they contribute to learning and memory through regulation of genes that mediate synaptic plasticity and long-term potentiation. NAB2 acts largely as a transcriptional repressor, at least in part by recruiting the nucleosome remodeling and deacetylase (NuRD) complex upon binding Egr1-3. However, much remains unknown about the molecular mechanisms that regulate NAB2. This study expands our knowledge of NAB2 by identifying its nuclear localization signal (NLS). More specifically, we generated an expression construct encoding a NAB2-GFP fusion protein, which localized to the nucleus following transfection. Analysis of the NAB2 sequence identified two putative NLS’s, one site spanning amino acids 263-277 that match the bipartite NLS consensus sequence (RXK10KRR) and a second site spanning 363-366 (KKXK). K/R-to-A mutation of the potential bipartite NLS did not disrupt NAB2-GFP nuclear localization; however, K-to-A mutation of the site spanning 363-366 resulted in predominantly cytoplasmic localization, indicating it represents the functional NAB2 NLS. Current experiments are using alternative approaches to further test if amino acids 363-366 function as the bona fide NAB2 NLS. In the first approach, we are generating a series of NAB2-GFP truncation mutants with the prediction that truncations retaining amino acids 363-366 will localize to the nucleus, whereas truncations lacking amino acids 363-366 will localize to the cytoplasm. In the second approach, we are generating fusion constructs in which only amino acids 360-370 of NAB2 are linked to GFP to determine if that is sufficient to drive nuclear localization.

Alpha synuclein (aSyn) is involved in synaptic vesicle trafficking and synaptic transmission, but is also strongly linked to Parkinson's disease (PD) and other neurodegenerative disorders. In diseases where aSyn aggregates, or synucleinopathies, it accumulates in and spreads to different brain areas and peripheral organs. Although increased aSyn levels likely underlie familial PD with SNCA mutations thus implicating the protein in disease initiation, most synucleinopathies arise sporadically indicating that the expression of normal levels of wild type aSyn is sufficient for the development of disease. In spite of our increasing knowledge in the field, the physiological function of aSyn and its precise role in disease remain enigmatic urging the development of new tools for further investigations. Here, we report the development and characterization of a new mouse model expressing a GFP-aSyn fusion protein under the control of the endogenous Snca promoter. We describe the expression pattern of the fusion protein in the brain and peripheral organs and characterized its subcellular localization and trafficking in the brain. Primary neurons expressing GFP-aSyn were also successfully derived from this line. In addition, intracerebral injection of aSyn pre-formed fibrils induced formation of GFP-positive inclusions with a
similar distribution pattern to that observed in wild type mice. We anticipate that this new mouse model will facilitate in vitro and in vivo studies that incorporate live imaging and detection of endogenous alpha synuclein, therefore providing new insights into aSyn function in health and disease.

Subcellular fractionation of suspension CHO cells producing a monoclonal antibody by a differential and isopicnic centrifugation based protocol.

S.P. Rodriguez¹, M.R. Lira², N.V. Cruz³, M.T. Roldán¹, O.T. Ramírez²;
¹Departamento de Biología Molecular y Biotecnología, Instituto de Investigaciones Biomédicas, Universidad Nacional Autónoma de México, Mexico City, Mexico, ²Departamento de Medicina Molecular y Bioprocesos, Instituto de Biotecnología, Universidad Nacional Autónoma de México, Cuernavaca, Morelos, Mexico

A variety of fractionation protocols have been reported before for tissue samples like rat and mouse liver, among others. Since each cell line has a specific cellular organization, each should be evaluated separately. Some protocols have been previously reported for CHO cells, but they consist only of a few steps of purification, without deep demonstration of separation. Hence, we have been interested in developing a subcellular fractionation protocol for Chinese hamster ovary (CHO) cell lines. These cells are highly used for the production of therapeutic recombinant proteins, as is the case of monoclonal antibodies, making them important for the pharmaceutical industry. Thus, the cellular biology study of these cells is demanded. The main goal of the present work is to establish a reproducible and efficient protocol to obtain enriched fractions of the major subcellular organelles of suspension CHO cells. We implemented a combination of differential and isopicnic centrifugation steps. Multiple variables were evaluated like homogenization method, buffers, centrifugation conditions and density gradient mediums. CHO cells producing a monoclonal antibody were cultured in T flasks in agitation and subjected to mechanical disruption. Incubation in a hypotonic medium followed by strokes in a Dounce homogenizer resulted in the best rupture. Nuclear, mitochondrial, and microsomal pellets and cytosol were obtained as a result of differential centrifugation of homogenate. Each fraction was characterized by enrichment of specific protein markers by means of Western blot, ELISA and enzymatic activity, and protein content and distribution in SDS-PAGE. Nuclear pellet and cytosol represented each one around 40% of total proteins. Each pellet obtained was further separated in a discontinuous sucrose gradient. Three main protein peaks were detected in the sucrose gradient of each pellet. Nucleus, Golgi apparatus, endoplasmic reticulum, peroxisomes, lysosomes and mitochondria were identified among all protein peaks. Endoplasmic reticulum and cellular membranes constituted the major contaminants identified in most fractions. Only around 20% of initial total proteins correspond to cellular debris and proteins between peaks. On the other hand, the secreted antibody was fully active by recognition of its specific antigen expressed in E. coli. The present protocol provides a method to obtain enriched fractions of the major intracellular components of suspension CHO cells to conduct future physiological, enzymatic, molecular and proteomic assays. Homeostatic remodeling of mammalian membranes in response to dietary lipid perturbations is essential for cellular fitness.
I. Levental\textsuperscript{1}, K.R. Levental\textsuperscript{1}.
\textsuperscript{1}Integrative Biology and Pharmacology, University of Texas Health Science Center at Houston, Houston, TX

A major fraction of cellular bioactivity occurs at membranes, with the lipidic matrix constituting a functional, dynamic interface that actively regulates protein activity and cell physiology. Proper membrane functionality requires maintenance of a narrow range of physical properties under challenge from external inputs. The most prominent example of such maintenance is homeostatic adaptation of membrane properties to variations in ambient temperature, a fundamental and ubiquitous design feature of ectothermic organisms termed homeoviscous adaptation. However, rapid and responsive membrane adaptation has not been observed in homeotherms. We report that challenging mammalian membrane homeostasis by dietary lipid inputs leads to robust lipidomic remodeling to maintain membrane physical properties. Specifically, supplementation of a variety of cultured cell lines and primary cells with polyunsaturated fatty acids (PUFAs) leads to rapid and extensive incorporation of the exogenous fats into membrane lipids, inducing a reduction in membrane packing. These effects are rapidly compensated for by upregulation of fully saturated lipids and cholesterol, via activation of the mammalian sterol regulatory machinery, specifically SREBP2. These lipidomic changes result in a compensatory recovery and normalization of membrane fluidity. Inhibition of membrane remodeling results in decreased cellular fitness when membrane homeostasis is challenged by dietary lipids. These results reveal that mammalian cells possess a cell-autonomous mechanism for homeostatic membrane remodeling to maintain functional membrane phenotypes, analogous to homeoviscous adaptation in poikilotherms. These observations suggest that the ubiquitous process of homeoviscous adaptation in simple organisms has been adapted in mammals to respond to membrane perturbations from dietary sources.

\textsuperscript{1}SciLifeLab, Royal Institute of Technology (KTH), Stockholm, Sweden, \textsuperscript{2}European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Subcellular distribution is one of the main aspects in the characterization of proteins, since the localization to an organelle or structure is strongly connected with the protein’s function. The Cell Atlas, which is an integrated part of the Human Protein Atlas, determined the spatial distribution of the human proteome by indirect immunofluorescence (IF) microscopy using almost 14,000 antibodies. This image-based approach revealed the subcellular localization of 12,003 proteins and mapped them to 32 organelles or subcellular structures.

An intriguing observation was the level of multilocalization among proteins, which led us to define a proteome of multilocalizing proteins (MLPs). More than half of the analyzed proteins (6172) were detected at multiple locations, with around 27% (1653) at three or more locations. The portions of MLPs differ between subproteomes of organelles; e.g. mitochondria mainly contain proteins with a single
location, while cytosol and nucleus contain mainly MLPs. This reflects the nature of organelles, with more autonomous mitochondria and the dynamic exchange between cytosol and nucleus. The reasons behind multilocalization remain unknown for the vast majority of the detected MLPs. MLPs could fulfill the same function at different sites; additional locations are employed as storage site or for controlling the activity; or proteins are moonlighting and perform multiple functions at different sites.

We selected the dual localization of proteins to the nucleus and the Golgi apparatus for further studying MLPs, because these non-neighboring organelles have distinct functions and the number of proteins (173) that are shared by both organelles is overrepresented from what is expected. We are currently performing a siRNA screen to validate the specificity of the antibodies and thereby the detected dual localization. The list of hits contains proteins that are related to specific functions in the nucleus and Golgi apparatus. This indicates that the organelles are closer connected and interact with each other by yet unidentified pathways.

In summary, MLPs are common within the human proteome contributing to cellular complexity, and could help to identify links between distant organelles.

Retrograde Localization of the Contractile Vacuole during Chemotaxis and Cellular Streaming in Dictyostelium discoideum.
S. Fadil¹, K. Smith¹, M. Beshay¹, N. Bawazir¹, M. Myre², C. Janetopoulos³;
¹Biological Sciences, University of the Sciences, Philadelphia, PA, ²Biological Sciences, University of Massachusetts, Lowell, Lowell, MA

Distinct changes often occur in morphology during the formation of cellular polarity. In the case of directed migration, cells form a distinct front and rear, as they migrate towards or away from migratory cues. In many cell types, the microtubule organizing center and nucleus take up discrete localizations relative to one another in migrating cells. During the directed migration that takes place in cellular aggregation, the early process in fruiting body development, Dictyostelium discoideum cells reorganize many cellular components, including their actin and microtubule cytoskeletons. We have discovered that the contractile vacuole network also polarizes towards the back of the cell during migration.

Observations with light microscopy of retrograde contractile vacuole movement were confirmed by imaging cells expressing the fluorescently tagged contractile vacuole marker dajmin. Interestingly, contractile vacuoles only appear in areas where levels of PI(4,5)P2 appear elevated, and formation of protrusions is inhibited in areas where contractile vacuoles are present. Mutants lacking the huntingtin protein (htt-) were found to lack a detectable contractile vacuole or network. htt- cells have previously been shown to have an inability to regulate their osmotic pressure, and the loss of this dynamic organelle is likely critical to this phenotype. htt- cells made very weak cAMP waves and didn’t stream. Our results demonstrate that posterior redistribution of the contractile vacuole in migrating cells plays an important role in recruiting cells into streams and likely contributes to cAMP secretion/relay. We further demonstrate that htt- cells are incapable of regulating their osmolarity and are non-viable under extreme hypoosmotic conditions because of the absence of the contractile vacuole network.
The Amyloid-β Precursor Protein, a protein relevant to the pathology of Alzheimer’s disease, is a permanent resident of the tubular endoplasmic reticulum.

V. Muresan¹, Z. Ladescu Muresan¹;
¹Pharmacology, Physiology and Neuroscience, Rutgers University - New Jersey Medical School, Newark, NJ

The function of the Amyloid-β Precursor Protein (APP), considered at the core of the pathogenesis of Alzheimer’s disease (AD), is poorly understood. Since the intracellular localization of APP could provide insight into its function, we reinvestigated its distribution in a variety of cell types. APP, a type I transmembrane protein, undergoes extensive proteolytic cleavage into smaller polypeptides, which have been implicated in the AD-specific neuronal pathology. In neurons, the cleavage of APP generates N- and C-terminal fragments (NTFs and CTFs), and fragments from the internal region. After cleavage, the NTFs, derived from the ectodomain of APP, are released as soluble, glycosylated polypeptides in the lumen of intracellular membrane-bounded compartments, while the CTFs remain attached to the membrane via their short transmembrane domain. Here we show that, in the brainstem derived neuronal cells, CAD, endogenous APP is cleaved to a large extent in a juxtanuclear compartment of the tubular endoplasmic reticulum (ER). While the CTFs concentrate at the ER exit sites and are subsequently transported into the neuronal processes by TGN-derived vesicles, the NTFs released in the ER lumen never exit the ER, and are being carried to the growth cones within specialized ER tubules where machineries for protein and lipid synthesis are undetectable. The NTFs colocalize with Reticulon 4 (Rtn4), a structural protein of the tubular ER, throughout the neuron, and the NTFs and Rtn4 behave identically under experimental conditions that disrupt the structural integrity of the compartments where they reside. By contrast, the treatment of cells with Brefeldin A, an agent that blocks the anterograde vesicle transport along the traditional secretory route, does not affect the accumulation of NTFs and Rtn4 at the growth cone. Thus, the compartments that contain the NTFs and Rtn4 are identical, and most likely represent a specialized subcompartment of the tubular ER. The presence of NTFs in this ER compartment that extends in the neuronal processes, and the accumulation of NTFs at the growth cone, cannot be simply explained by the diffusion of NTFs from the soma, within the ER lumen. Rather, the NTFs are transported into the processes simultaneously with the extending ER tubules. In addition to CAD cells, we detect similar ER-like distribution of the NTFs in cortical, hippocampal, and DRG neurons, in HEK293 cells, and in all tested endothelial and epithelial cells (HUVEC, BAEC, MDCK). Together, these results suggest that the NTFs are ubiquitous residents of the tubular ER, with functions that remain to be determined. Supported by NIH AG039668 (Z.L.M.), NSF IOS-1347090 (V.M., Z.L.M.), Connecticut Science Fund, and New Jersey Health Foundation (Z.L.M., V.M.).

The interferon inducible human protein “myxovirus resistance protein A” (MxA) is a dynamin-family large GTPase with a broad-spectrum antiviral effect. Human MxA is a cytoplasmic protein which binds to and tubulates lipid membranes. Since 2002, MxA has been often stated to associate with “a
subcompartment of the smooth endoplasmic reticulum” (ER) in uninfected cells, but without evaluation of this co-localization using structural proteins of the ER as markers. In a previous study this inference was evaluated using reticulon-4 (RTN4) and atlastin-3 (ATL3) as structural markers of the standard ER and immunostaining methods. MxA-HA transiently expressed in HEK293T, Cos7 or Huh7/ Huh7.5 cells and in IFN-stimulated Huh7 and endothelial cells was observed in the cytoplasm in a variety of phenotypic forms ranging from small and large endosomes (the MxA endosomes) to larger compact tubuloreticular structures (the MxA reticulum). The previous study showed that by immunofluorescence and immuno-electron microscopy methods, the MxA-positive variably-sized endosomal and larger tubuloreticular structures were largely distinct from RTN4- and ATL3-based standard ER. In the present study, this inference was further tested using an alternative approach based on imaging GFP-tagged MxA in live Huh7 cells expressed using a puromycin-selectable vector. GFP-MxA transiently expressed in Huh7 cells showed association with puncta at the plasma membrane, and with variably-sized endosomes which exhibited spontaneous motility, and which oriented themselves along an intermediate filament meshwork unique to Huh7 cells to generate a reticular pattern. Moreover, in many cells GFP-MxA associated with (a) meshworks of fine tubules with motile segments, and (b) larger reticular structures. Additional imaging data suggested that MxA endosomes likely underwent homotypic fusion to generate elongated tubules that stretched alongside the intermediate filament meshwork to produce a reticulum. Huh7 cells selected for stable GFP-MxA expression using puromycin showed prominent MxA in both endosome and reticular structures. In two-color fluorescence assays these GFP-Mxa structures were distinct from the mCh-RTN4, mCh-KDEL or mCh-CLIMP63-labelled standard ER. The discovery of an alternative membrane reticulum in human cells based on the MxA dynamin-family large GTPase distinct from but lying alongside the standard RTN4-based ER represents a novel advance in mammalian cell biology. Moreover, the data point to the biogenesis of this cytoplasmic MxA reticulum to be from an endosomal compartment and not as a derivative of the ER.

Five exostosin (EXT) genes encoding for glycosyltransferases have been identified in mammals, EXT1, EXT2, EXTL1, EXTL2 and EXTL3. The synthesis of heparan sulfate backbone is mediated by them. Loss of function of EXT1, EXT2 and EXTL3 causes developmental defects in different organisms including mouse, fruit fly, zebrafish and nematode. EXT1 and EXT2 proteins are believed to form a golgi-located heterooligomeric complex that is involved in heparan sulfate chain elongation. The putative tumor suppressor function role of EXT1/2 is supported by evidence of inactivating genomic alterations frequently found in patients with an autosomal dominant genetic disorder known as hereditary multiple osteochondromas (HMO). However, the molecular mechanisms governing the developmental roles of EXT genes are not well understood. Using gene silencing strategies in a HeLa cell line we focused in investigating the role of EXT1 role in endomembrane trafficking. We showed that silencing EXT1 can induce ER stress, enhance anterograde vesicles trafficking, change the energy charge and alter the cell growth. We suggest that EXT1 regulates Endoplasmic Reticulum (ER) structure and dynamics through Rab10, an ER specific Rab
GTPase. EXT1 is thus a novel, important player in the secretory pathway controlling normal cell physiology, metabolism and resistance to oncogenic transformation.

The role of Myelinophore organelles in myelin sheath formation.  
S.A. O'Sullivan¹, M.S. Domowicz¹, S. Szuchet³;  
¹Neurology, University of Chicago, Chicago, IL

Multiple sclerosis (MS) is a neurodegenerative, demyelinating disease with an unknown etiology. The hallmarks of MS pathology involve destruction of oligodendrocytes, the myelinating cells of the central nervous system and neuronal damage. Investigating the molecular mechanisms of myelin production is a critical step for understanding both physiological and pathological myelin sheath formation. Myelinophore organelles (MFOs) are intracellular organelles, found in oligodendrocytes, containing myelin membrane (MyM) tubules. Using transmission electron microscopy and tomography, we have demonstrated the presence of these organelles in ovine oligodendrocyte cultures as well as embryonic avian optic nerves between the ages of embryonic day (E)12 to E21. Immunogold labelling of high pressure frozen avian optic nerve sections, embedded in HM20 resin reveal these MFOs to be positively labelled with galactocerebroside, proteolipid protein and myelin basic protein antibodies indicating the presence of MyMs within. These studies also indicate that MyM tubules are contained within MFOs in the oligodendrocyte soma and transported via oligodendrocyte processes to the site of myelin sheath assembly. As the initial disease trigger in MS may be due to dysfunctional oligodendrocytes, where MyM tubule production or myelin sheath formation has been compromised, defining how these critical cellular processes in oligodendrocytes contribute to MyM production and myelin sheath formation could ultimately lead to the identification of new therapeutic targets for neurodegenerative diseases such as MS.

The centriole assembly factor, CPAP, is important for nascent basal body assembly and organization within a multi-ciliary array.  
M.D. Ruehle¹, C.G. Pearson¹;  
¹Cell and Developmental Biology, University of Colorado School of Medicine, Aurora, CO

Centrioles and basal bodies are microtubule-organizing organelles. Basal bodies nucleate motile cilia and anchor them to resist mechanical forces from ciliary beating. The assembly of new basal bodies occurs adjacent to mature, mother basal bodies, but the dynamics of protein incorporation to build these nascent basal bodies remains poorly understood. Five proteins have been identified as essential for new basal body assembly, including the microtubule binding protein CPAP. Using the ciliate model organism, *Tetrahymena thermophila*, we show that CPAP is enriched at newly assembling basal bodies and that CPAP levels decrease as basal bodies mature. This suggests that there are two protein populations of CPAP at basal bodies: one that is dynamic and transiently associated with daughter basal bodies, and a second that is stably associated with mature basal bodies. These two populations could reflect, respectively, a CPAP population that promotes the elongation of nascent basal bodies, consistent with previous studies, and a CPAP population that stabilizes mature basal bodies to resist cilia-generated forces. In addition, *Tetrahymena* CPAP localizes to basal body-associated structures that are responsible for anchoring basal bodies at the cell cortex. These data suggest that CPAP performs functions beyond
new basal body assembly. Consistent with this hypothesis, genomic knockout of CPAP inhibits new basal body assembly, promotes basal body disassembly, and causes disorganization of the cellular cortical architecture. Together, these data suggest that CPAP plays several distinct roles in assembling, maintaining and organizing basal bodies in multi-ciliated cells.

Identification of Key Rab and Kif Proteins Required for Tether-Dependent Golgi Organization in Epistatic High-Content Screens.
S. Liu1, W.X. Majeed1, M. Betts2, V. Starkviene1, B. Storrie1;
1Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, 2BioQuant, University of Heidelberg, Heidelberg, Germany

In mammalian cells, Golgi apparatus organization is dependent on vesicle trafficking. By light microscopy, knockdown of the retrograde, tether protein complexes, ZW10/RINT1 and COG, leads to fragmentation of Golgi ribbon. In epistatic experiments, this can be suppressed by co-depletion of either Rab6 or a small subset of Rab6 motor effectors (BicD, Myosin II and Kif20A) and by overexpression of the truncated BicD C-fragment. Here, we performed epistatic, visual-based suppression screens directed against 20 different Golgi-associated Rab proteins and all 44 human Kifs in order to establish the key Rab and motor proteins involved and through hit validation experiments to test the hypothesis that aborted Golgi proximal vesicle is central to cisternal disruption. We found that co-depletion of a small number of Rab proteins and Kifs epistatically suppressed both ZW10- and COG3-dependent Golgi fragmentation while ZW10-dependent Golgi fragmentation was suppressed selectively by a separate Rab/Kif set. To our surprise, no Rabs or Kifs selectively suppressed COG3-dependent Golgi fragmentation. Under basal conditions, depletion of suppressive Rab proteins or Kifs generally had little-to-no effect on Golgi cisternal organization. By electron microscopy, individual Rab or Kif hits produced a 3-10-fold accumulation of Golgi proximal vesicles suggesting a tight linkage between inhibited vesicle transport and cisternal organization. In our epistatic suppression assay, Golgi cisternal organization was restored and accompanied by a decrease in the number of Golgi proximal vesicles. Rab6 (Rab6α/Rab6α) co-depletion had a particularly strong effect. We propose that our results are most simply interpreted by a model in the absence of rapid tether-dependent capture, Golgi-derived vesicles can “wander” in a Kif-dependent manner. Under these conditions, the Golgi fragments. Funded in part by grants from the NIH (R01 GM092960 and U54 GM105814)

Model of nucleolar assembly in a developing embryo.
L. Mohapatra1, S.C. Weber2, J. Kondev2;
1Department of Physics, Brandeis University, Waltham, MA, 2Department of Biology, McGill University, Montreal, QC

Cells consist of a number of RNA and protein rich bodies that play important roles in gene regulation. Remarkably, these structures maintain a dynamic yet coherent structure even in the absence of membranes. But the mechanisms by which these organelles form and stably persist are not well understood. Examples include germ granules, stress granules and nucleoli. Here we consider the nucleolus, which is composed of proteins and RNA molecules involved in ribosome biogenesis. Recent experiments in C. elegans embryos have implicated the limiting-pool mechanism as one that is

Monday-318
responsible for controlling the size of the nucleolus. In the limiting pool mechanism, the organelle grows until the pool of its building blocks is depleted to the point where the rates of assembly and disassembly of the organelle are balanced. Here we re-examine recent experimental results on nucleolar assembly to better understand the role of transcription of ribosomal RNA in the assembly process. We show that a simple model that couples transcription with diffusion-limited aggregation of the nucleolar proteins can explain the observed dynamics in a quantitative way. In particular, it reproduces the observed power law scaling of the nucleolus size with time of assembly. Our model makes quantitative predictions that suggest new experiments on nucleolus assembly in developing embryos.

LEM2 recruits CHMP7 for ESCRT-mediated nuclear envelope closure in fission yeast and human cells.
A. Von Appen¹, M. Gu², D. LaJoie³, W.I. Sundquist¹, K.S. Ullman³, A. Frost¹;
¹Department of Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA,
²Department of Biochemistry, University of Utah, Salt Lake City, UT, ³Department of Oncological Sciences, Huntsman Cancer Institute, Salt Lake City, UT

Endosomal sorting complexes required for transport III (ESCRT-III) proteins have been implicated in sealing the nuclear envelope in mammals, spindle pole body dynamics in fission yeast, and surveillance of defective nuclear pore complexes in budding yeast. Here, we report that Lem2p (LEM2), a member of the LEM (Lap2-Emerin-Man1) family of inner nuclear membrane proteins, and the ESCRT-II/ESCRT-III hybrid protein Cmp7p (CHMP7), work together to recruit additional ESCRT-III proteins to holes in the nuclear membrane. In Schizosaccharomyces pombe, deletion of the ATPase vps4 leads to severe defects in nuclear morphology and integrity. These phenotypes are suppressed by loss-of-function mutations that arise spontaneously in lem2 or cmp7, implying that these proteins may function upstream in the same pathway. Building on these genetic interactions, we explored the role of LEM2 during nuclear envelope reformation in human cells. We found that CHMP7 and LEM2 enrich at the same region of the chromatin disk periphery during this window of cell division and that CHMP7 can bind directly to the C-terminal domain of LEM2 in vitro. We further found that, during nuclear envelope formation, recruitment of the ESCRT factors CHMP7, CHMP2A, and IST1/CHMP8 all depend on LEM2 in human cells. We conclude that Lem2p/LEM2 is a conserved nuclear site-specific adaptor that recruits Cmp7p/CHMP7 and downstream ESCRT factors to the nuclear envelope.

The role of DNA content in regulating cell shapes and sizes during zebrafish development.
T. Menon¹, S. Nair¹;
¹Department of Biological Sciences, Tata Institute of Fundamental Research, Mumbai, India

Sizes of cells or intracellular organelles are fundamental properties of biological systems, which are actively regulated in a context specific manner. The phenomenon by which sizes of cells and intracellular organelles are regulated is referred to as biological scaling. During embryonic development, the largest cell is the newly fertilized zygote, which undergoes reductive divisions. However, reductive divisions during early development must be balanced by biological scaling mechanisms to achieve optimum sizes of cells and intracellular organelles during embryogenesis. This is crucial because embryonic development is a dynamic process, which includes germ layer specification, massive co-ordinated
reorganization of germ layers during gastrulation and fate commitments to tissue and organ progenitors. Our research attempts to elucidate the role of DNA content in dictating the sizes and shapes of cells and intracellular organelles during early development in zebrafish embryos. In animals, deviations from diploidy are incompatible with embryonic viability. In zebrafish, deviations from diploidy at fertilization do not elicit early embryonic lethality, but such embryos do not survive beyond 4-6 days post fertilization (dpf). The actual cause of lethality remains unknown and as in other species is generically attributed to dosage compensation errors. Dosage compensation errors can manifest only after the zygotic genome becomes transcriptionally active. Our analysis of the early cell biology in haploid and tetraploid zebrafish embryos reveal that prior to zygotic genome activation (ZGA), specific aspects of the mitotic spindle machinery are altered from the first few cytokinesis cycles onwards. These changes later manifest as altered cell shapes and sizes in haploids and tetraploids prior to initiation of germ layer specification and gastrulation. Analysis of cell behaviors reveals that haploids and tetraploids have defects in gastrulation due to changes in cell shapes and sizes, which culminate in patterning defects. Such early defects in the fundamental nature of the cell biology due to alteration in DNA content is surprising since death of non-diploid zebrafish embryos occur only by 4-6 dpf. Our work reveals that early cell biological defects in addition to dosage compensation errors (perhaps due to faulty ZGA) may exacerbate a faulty developmental program that culminates in eventual lethality of non-diploid embryos. Fundamentally, our work also sheds light on the ability of DNA content to dictate sizes of cells and intracellular organelles in a dynamically evolving system such as a developing vertebrate embryo.

**Inhibition of MEK1/2 and MLK3 impairs plasma membrane repair responses to bacterial pore-forming toxins.**

S. Ray, P.A. Keyel;

1Biological Sciences, Texas Tech University, Lubbock, TX

Diseases like necrotizing fasciitis and gas gangrene are caused by bacterial pathogens like *Streptococcus pyogenes* and *Clostridium perfringens*. These pathogens secrete pore-forming toxins (PFTs) like *Streptolysin O* (SLO) and *Perfringolysin O* (PFO), which form large transmembrane pores on host mammalian cells. Nucleated mammalian cells eliminate these pores using a cohort of poorly-defined membrane repair responses. One response is generation of ceramide, which can signal through downstream mitogen activated protein kinase (MAPK) pathways, including Mixed-Lineage Protein Kinase 3 (MLK3). We tested whether MLK3 and potential downstream kinases Mitogen-Activated Protein Kinase Kinase 1/2 (MEK1/2) and Extracellular Signal-Regulated Kinase 1/2 (ERK1/2) protect cells from PFTs. We treated mammalian cell lines (HeLa, HEK293) or primary cells (murine bone marrow derived macrophages) with either MEK1/2 inhibitor U0126, MLK3 inhibitor URMCO99 or both and challenged cells with SLO or PFO. We found that MEK1/2 or MLK3 inhibition made cells about two fold more sensitive to killing by toxins. We confirmed the role of MEK1/2 in repair using siRNA knockdown. Interestingly, ERK1/2 siRNA did not alter cell sensitivity to toxin challenge. These results suggest a MEK1/2 dependent but ERK1/2 independent mechanism of membrane repair against PFTs. These findings provide a potential link between lipid modification and protein-mediated membrane repair mechanisms. A deeper understanding of membrane repair responses could provide new insight into how SLO and PFO act as virulence factors during diseases like necrotizing fasciitis and gas gangrene.

ESCRT membrane scission revealed by optical tweezers.
J. Schöneberg,1,2,3 S. Yan1,2,4, A.H. Bahrami3, M. Righini5, I. Lee1,2, M.R. Pavlin2,6, L. Carlson1,2, D.H. Goldman1,2,4, G. Hummer3,7, C. Bustamante1,2,4,5,6,8,9, J.H. Hurley1,2,5,8;1Molecular and Cell Biology, UC Berkeley, Berkeley, CA, 2California Institute for Quantitative Biosciences, UC Berkeley, Berkeley, CA, 3Theoretical Biophysics, Max Planck Institute of Biophysics, Frankfurt a. M., Germany, 4Howard Hughes Medical Institute, UC Berkeley, Berkeley, CA, 5Department of Chemistry, UC Berkeley, Berkeley, CA, 6Biophysics Graduate Group, UC Berkeley, Berkeley, CA, 7Institute of Biophysics, Goethe University, Frankfurt/M, Germany, 8Molecular Biophysics and Integrated Bioimaging Division, Lawrence Berkeley National Laboratory, Berkeley, CA, 9Department of Physics, UC Berkeley, Berkeley, CA

ESCRT proteins catalyze the function of membrane budding and scission from the inside of the cytosol to the outside. This process is fundamental in cell biology, comprising multivesicular endosome biogenesis, cytokinesis, viral budding (e.g. HIV, Ebola, Dengue) and other pathways. The mechanism underlying ESCRT-III-mediated membrane budding and scission remains elusive. We have encapsulated within giant unilamellar vesicles (GUVs) a minimal ESCRT module consisting of ESCRT-III subunits and the AAA+ ATPase Vps4. Using optical tweezers, membrane nanotubes reflecting the correct topology of scission can be pulled from these GUVs. Upon photo-uncaging of ATP, surprisingly large forces in the tens of piconewtons were recorded and tube scission could be observed. ESCRT subunit composition and concentration alter force generation and scission behavior. In combining confocal fluorescence microscopy and optical tweezers, the scission events can be observed in both force and fluorescence and studied in detail. For the first time, the biophysics of ESCRT membrane budding and scission are revealed.

The Mechanism of the Membrane Binding of the F-BAR Domain Protein GAS7.
M. Ab Fatah1, S. Suetsugu1;
1Molecular Medicine and Cell Biology Laboratory, Nara Institute of Science and Technology, Nara, Japan

Protein-lipid interactions play important roles in cell signaling, lipid metabolism, membrane trafficking and so on. Bin-Amphiphysin-Rvs (BAR) domains are highly conserved and play major roles in membrane curvature formation. Extended Fes-CIP4 homology (EFC)/FCH-BAR (F-BAR) domain is one of the subfamilies in the BAR domain. The BAR domains are thought to bind to membrane as homodimers, which then assemble into ordered oligomer on the membrane. Growth-Arrest-Specific-Protein-7 (GAS7) consists of the SH3 domain, the WW domain, and the F-BAR domain. It is the only protein in the F-BAR family, with its F-BAR located at the C-terminal. GAS7 is highly expressed in brain, which includes cerebral cortex, hippocampus and cerebellum and also in spleen, lung and heart. GAS7 is shown to be involved in neurite outgrowth, neuronal differentiation and is also involved in cytoskeleton. There are splicing isoforms of GAS7, which are GAS7c (SH3-WW-F-BAR), GAS7b (WW-F-BAR) and GAS7a (only F-BAR domain). In this study, we examined GAS7 and its isoforms, for their ability to bind to the liposomes made of bovine Folch fraction. The binding of the protein to the liposome was examined by liposome cosedimentation assay and the shape of liposome were observed by electron microscope. We have found that all these three isoforms have binding ability under the same conditions. We also introduced mutations to determine the mechanism for their membrane binding ability. We found that characteristic amino-acid residues of GAS7 compared to the other F-BAR domains plays an important role for membrane binding as oligomer.

AMPK Regulates Peroxisomal Cargo Proteins Import via PEX5 Phosphorylation.
J. Jing\textsuperscript{1}, D. Tripathi\textsuperscript{1}, R. Dere\textsuperscript{1}, C. Walker\textsuperscript{1,2};
\textsuperscript{1}CPEH, Baylor college of Medicine, Houston, TX, \textsuperscript{2}CTCR, Texas AM University, houston, TX

Peroxisomes are highly metabolic, autonomously replicating organelles. While their function as metabolic organelles is well known, their place in the world of cell signaling is only just beginning to emerge. AMP-activated protein kinase (AMPK) is a major regulator of cellular energy homeostasis, but has yet to be linked to peroxisome biology. In exploring targets for AMPK phosphorylation, we identified the peroxisome import receptor PEX5, which delivers peroxisome proteins to this organelle to regulate peroxisome function and homeostasis, as a target for this kinase. An optimal AMPK substrate motif used to analyze all PEX proteins in Peroxisome DB 2.0 identified a potential AMPK phosphorylation motif in PEX5 at serine 279 (S279). Using an AMPK-substrate-specific antibody, in vitro kinase assays, and a phospho-specific antibody generated by our group (anti-S279 on PEX5), we identified S279 as a bona fide site for PEX5 phosphorylation by AMPK. Furthermore, we found that AMPK phosphorylation of PEX5 regulated translocation of cargo proteins with a peroxisome targeting sequence (PTS1) recognized by PEX5 to the peroxisome. These data provide a model where under conditions of nutrient/energy stress, activation of AMPK increases the import of proteins essential for peroxisome functions such as beta-oxidation. Thus, we have uncovered a previously unappreciated linkage between the AMPK signaling pathway and the peroxisome, which opens new horizons for understanding peroxisomal homeostasis and its role in cellular metabolism.

The peroxisomal AAA-ATPase Pex1/Pex6 unfolds substrates by processive threading.
B.M. Gardner\textsuperscript{1}, D.T. Castanzo\textsuperscript{1}, S. Chowdhury\textsuperscript{2}, G. Stjepanovic\textsuperscript{1,3}, M.S. Stefely\textsuperscript{1}, J.H. Hurley\textsuperscript{1,3,4}, G.C. Lander\textsuperscript{2}, A. Martin\textsuperscript{1,4,5};
\textsuperscript{1}Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA, \textsuperscript{2}Department of Integrative Structural and Computational Biology, The Scripps Research Institute, La Jolla, CA, \textsuperscript{3}Molecular Biophysics and Integrated Bioimaging Division, Lawrence Berkeley National Laboratory, Berkeley, CA, \textsuperscript{4}California Institute for Quantitative Biosciences, University of California, Berkeley, Berkeley, CA, \textsuperscript{5}University of California, Berkeley, Howard Hughes Medical Institute, Berkeley, CA

The AAA-ATPases Pex1 and Pex6 are essential for peroxisome stability and peroxisomal matrix-protein import in eukaryotes. While mutations in Pex1 and Pex6 cause the majority of peroxisome biogenesis disorders in humans, their exact function is unclear. Together, Pex1 and Pex6 form a heterohexameric motor that is recruited to the peroxisomal membrane by the tail-anchored protein Pex15. At the peroxisome, Pex1/Pex6 is thought to extract the matrix protein receptor Pex5 for repeated rounds of import. Here we determined that in vitro Pex1/Pex6 from S. cerevisiae is a protein translocase that unfolds Pex15 in a pore-loop and ATP-hydrolysis dependent manner. Our structural studies of Pex15 in isolation and in complex with Pex1/Pex6 illustrate that Pex15 binds the N-terminal domains of Pex6 and presents its C-terminal disordered region for engagement by the pore loops of the AAA motor, which then processively threads Pex15 through the central pore. In vitro, Pex5, the expected substrate of Pex1/Pex6, was not engaged by the motor. Instead, we found that Pex15 binds directly to the cargo receptor Pex5 and thereby links Pex1/Pex6 to other components of the peroxisomal import machinery.
Our results thus support a role of Pex1/Pex6 in mechanical unfolding of peroxin proteins and their extraction from the peroxisomal membrane during matrix-protein import, but raise questions as to the true Pex1/Pex6 substrate in vivo.

Diurnal regulation of peroxisome function in RPE cells.
L.L. Daniele1, J. Caughey2, A. Dhingra1, D. Alexander3, N.J. Philp4, K. Boesze-Battaglia1;
1Biochemistry, SDM, University of Pennsylvania, Philadelphia, PA, 2School of Dental Medicine, University of Pennsylvania, Philadelphia, PA, 3Program in Cell and Molecular Biology, Biomedical Graduate Studies, University of Pennsylvania, Philadelphia, PA, 4Pathology, Anatomy, and Cell Biology, Thomas Jefferson University
Department of Pathology, A, Philadelphia, PA

The retinal pigment epithelium (RPE) of the eye is a single layer of supportive epithelium overlying the neural retina. Each day the phagocytic RPE ingests the shed lipid-rich tips of the photoreceptor outer segments (OS) as new material is added basally. Metabolism of OS lipids is an essential function of the RPE, and these lipids are abundant in very long chain fatty acids (VLCFA) that require oxidation within peroxisomes. The committed step in peroxisomal β-oxidation of VLCFA, catalyzed by Acyl CoA Oxidase 1 (ACOX1), produces H2O2 that is reduced by antioxidant enzymes (e.g. catalase). Despite their important role in lipid metabolism, regulation of the biogenesis, activity, and turnover of peroxisomes in RPE is not well characterized. The purpose of this study is twofold; we investigated whether peroxisome function and turnover depends on time of day. We also tested the hypothesis that RPE peroxisomes are degraded by selective autophagy by examining peroxisome number and function in RPE of mice lacking ATG5 or LC3B.

Catalase activity was measured in RPE lysates of Atg5ΔRPE, LC3BΔ and WT (C57Bl6/J) mice at various times relative to light onset using a fluorescence-based assay and normalized either to total protein or to total catalase (specific activity) as assessed by dot blot. The expression of peroxisome-specific membrane proteins Pex14 and PMP70 was assessed by immunohistochemistry (IHC) and Western blot analysis (WB) in RPE from WT, LC3BΔ and Atg5ΔRPE mice. Pex14 mediates the import of peroxisomal enzymes, and PMP70 is an ATP binding cassette transporter for long chain fatty acyl CoA intermediates. Dysregulated autophagy was determined by comparing expression of p62, LC3I, and LC3II in Atg5ΔRPE by WB.

In WT RPE, catalase activity varied diurnally, with the highest at 8 AM and lowest at 3 PM. This was opposed by a 50% increase in catalase concentration in RPE in the afternoon vs. morning. Catalase specific activity had a similar diurnal pattern with maximal activity in the morning. Overall catalase activity did not vary diurnally in LC3BΔ mice. However, catalase specific activity was double in the morning vs afternoon. Pex14 expression did not vary with time of day. Pex14 immunoreactivity was increased by 60% and 70% in ATG5ΔRPE and LC3BΔ mice vs. controls. PMP70 expression was similarly elevated. Additionally, p62 immunoreactivity was increased ~6 fold in Western blots of Atg5ΔRPE vs. controls.

Our data suggest that RPE peroxisomes rely on selective autophagy for degradation that does not vary with time of day. In contrast, activity of the peroxisomal antioxidant catalase varies diurnally through a predominantly post-translational mechanism.

How to build a granule: distinct roles for globular and intrinsically-disordered domains in P granule assembly.

H. Schmidt¹, J. Smith¹, A. Putnam¹, G. Seydoux¹;

¹HHMI, Department of Molecular Biology Genetics, Johns Hopkins Medical School, Baltimore, MD

RNA granules are assemblies of RNA and proteins that form without membranes in the cytoplasm or nucleoplasm of cells. In vitro experiments have suggested that RNA granules assemble by a liquid-liquid phase separation (LLPS) driven by low-affinity interactions between intrinsically-disordered regions (IDRs) in RNA-binding proteins. LLPS is a spontaneous process that allows molecules to distribute passively between a high-concentration phase (granule) and a low-concentration phase (cytoplasm). To examine RNA granule assembly *in vivo*, we are studying the P granules of *C. elegans*. In zygotes, P granules assembly requires the granule scaffold MEG-3 (1). MEG-3 is related to the GCNA family of intrinsically-disordered proteins that contain long IDRs at their N-termini and shorter globular domains at their C-termini (2). Surprisingly, we found that the MEG-3 globular domain is primarily responsible for granule assembly in vivo. Genome editing experiments at the meg-3 locus revealed that the MEG-3 C-terminus is necessary and sufficient to form assemblies that recruit other P granule proteins. The IDR, in contrast, is not sufficient to assemble granules, but is required to concentrate MEG-3 in the posterior cytoplasm. The IDR binds RNA and responds to changes in RNA availability *in vivo*. *In vitro*, full-length MEG-3 forms gel-like condensates that concentrate RNA and P granule proteins. Consistent with a gel-like scaffold, P granules are stable under diluted conditions *ex vivo*. Together, these results suggest that LLPS driven by IDRs is not sufficient to support granule assembly *in vivo*. Our current working model is that P granules assemble around a gel-like polymer that uses MEG-3’s disordered and globular protein domains to recruit RNAs and proteins, respectively.

Nano-scale size holes in ER sheets provide an alternative to tubules for highly-curved membranes.

L.K. Schroeder¹, A.E. Barentine¹,², S. Schweighofer¹,³, D. Baddeley¹,⁴, J. Bewersdorf¹,², S. Bahmanyar⁶;

¹Cell Biology, Yale University, New Haven, CT, ²Biomedical Engineering, Yale University, New Haven, CT, ³Biochemistry, University of Vienna, Vienna, Austria, ⁴Nanobiology Institute, Yale University, New Haven, CT, ⁵Auckland Bioengineering Institute, Auckland University, Auckland, New Zealand, ⁶Molecular Cellular and Developmental Biology, Yale University, New Haven, CT

The endoplasmic reticulum (ER) is a continuous membrane network partitioned into the nuclear envelope and peripheral ER domains. Unlike the large sheets of the nuclear envelope, the peripheral ER is composed of interconnected sheets and tubules. Recent work using super-resolution microscopy revealed that highly dynamic, densely packed ER tubules exist in the peripheral ER, highlighting the importance of revisiting classical views of ER structure with high spatial resolution in living cells. Here, we use live-cell Stimulated Emission Depletion (STED) microscopy to show that highly dynamic, subdiffraction-sized holes are prominent features of flat ER sheets. These fenestrated sheets coexist...
with uniform sheet regions and are clearly distinct from tubular ER regions. The curvature-stabilizing reticulon protein Rtn4 localizes to a subset of these holes. Overexpressing Clmp63 in the ER lumen to stabilize sheets constricts the diameter of holes and decreases their mobility. Analytical modeling demonstrates that holes in ER sheets are a feasible storage location for curvature-stabilizing proteins, suggesting that they serve as reservoirs to support rapid ER tubule extension and retraction. This mechanism does not rely on protein or lipid synthesis and thus provides a new explanation for how the ER locally alters its morphology on fast time scales.

The ribosome preservation factor Stm1 regulates ribosome abundance under starvation.
P. Kimmig1, K. Kostova2,3, J.S. Weissman2,3, M. Peter1;
1Institute of Biochemistry, ETH Zurich, Zurich, Switzerland, 2Howard Hughes Medical Institute, University of California, San Francisco, San Francisco, CA, 3Department of Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA

Proliferation requires that growing cells adjust their protein biosynthetic capacity in response to nutrient availability. This response involves coordinated changes both in the rate of translational initiation as well as in the abundance of the protein synthesis machinery itself, especially ribosomes. Once cells exhaust their nutrients, they enter a resting state known as quiescence. Under such unfavorable conditions cells catabolize macromolecules and organelles including their ribosomes, reducing to the minimal amount required. Yet, some ribosomes need to be preserved during quiescence for the anticipated recovery from nutrient deprivation. Recent evidence suggests that the ribosome-associated protein Stm1 could act as a ribosome preservation factor, clamping 40S and 60S subunit together. Based on the binding of Stm1 on the ribosome, Stm1 may stabilize non-translating 80S ribosomes, thereby preventing ribosome degradation under nutrient deprivation. Functionally, loss of Stm1 leads to decrease in ribosome number under starvation. However, in contrast to this direct preservation model of Stm1, we propose a transcriptionally-regulated response depending on Stm1 that maintains a critical number of ribosomes under starvation. We are currently investigating the molecular mechanism for how Stm1 regulates ribosome abundance.

Inter-ethnic variations of mitochondrial DNA polymerase (POLG1) in two large American populations and their functional analysis.
P. Bajpai1, B. Singh1, K.M. Owens1, V. Srinivasasainagendra2, H.K. Tiwari2, K.K. Singh1,3,4;
1Department of Genetics, University of Alabama at Birmingham, Birmingham, AL, 2Department of Biostatistics, University of Alabama at Birmingham, Birmingham, AL, 3Departments of Pathology, Environmental Health, Center for Free Radical Biology, Center for Aging and UAB Comprehensive Cancer Center, University of Alabama at Birmingham, Birmingham, AL, 4Birmingham Veterans Affairs Medical Center, Birmingham, AL

Purpose: Large fraction of genetic diversity in ethnic population is contributed by germline variants which helps explain the differences in genetic predisposition and susceptibility from population to another. Our previous study revealed that mitochondrial DNA (mtDNA) content is low in African
American (AA) when compared to Caucasian American (CA). Since catalytic subunit of DNA polymerase gamma (POLG1) performs critical function in mtDNA replication and repair, perturbations in POLG1 function can impair integrity of mtDNA causing reduction of mtDNA. We were thus interested to analyze if the differences in allelic frequencies of mutated POLG1 between the two American populations affect cellular state and mtDNA content.

Methods: We conducted comprehensive race based bioinformatics analysis of POLG1 gene in 33,000 European-Americans and 5,000 African-Americans and discovered several unique germline variants specifically present in one population but absent in another and common variants with relative different mutation frequency in two American populations with different ancestry. Human POLG1 at and around 1143, 251 and 587 amino acid position is evolutionary conserved; we therefore envisioned that these variations might be associated with altered mitochondrial functions. We generated these germline variants by site directed mutagenesis and cloned human wild-type (WT) POLG1, E1143G, PT2511, P587L and double mutant T2511/P587L in p426ADH yeast constitutive expression vector and transformed these constructs in BY4741 yeast strain individually and allowed them grew in YPD media for clone formation. Another set of constructs were generated in inducible mammalian expression vector, pTRE-Tight-BI-AcGFP1 using above-mentioned germline variants along with WT-POLG1.

Results: Yeast petite formation assay with POLG1 mutations (T2511, P587L and E1143G) increased petite clone formation indicative of mitochondrial respiratory chain defects.

Conclusion: We demonstrate that POLG1 genetic variants contribute to disruption of mitochondrial function. Other functional assays i.e stability of OXPHOS supercomplexes, mitochondrial complex activity, cellular respiration including analysis of mtDNA content with constructs employing mammalian expression vector pTRE-Tight-BI-AcGFP1 are under investigation.

Mitochondrial calcium dynamics promote the buildup of reducing equivalents that fuel oxidative phosphorylation and ATP production for cellular metabolism. Mitochondria sequester cytosolic calcium into the matrix through the Mitochondrial Calcium Uniporter (MCU). Although MCU plays an integral role in regulating mitochondrial bioenergetics, its function in in-vivo energy homeostasis remains elusive. We found that the tissue-specific deletion of the Mcu gene in mouse liver exhibited loss of mitochondrial calcium uptake, depletes matrix calcium, reduced glucose and fatty acid coupled mitochondrial oxygen consumption and leads to the accumulation of lipids. Loss of MCU results in hepatic lipidome remodeling with increased diglyceride and triglyceride lipid species in the mouse model. MCU-knockout Danio rerio generated by targeted disruption of Mcu gene using CRISPR/Cas9 approach, recapitulate the lipid accumulation phenotype. Mouse hepatic lipid accumulation is associated with decreased phosphorylation of AMPK. This indicates that besides beta-oxidation of fatty acids, AMPK phosphorylation regulated lipid synthesis is also controlled by MCU. Deletion of MCU in liver promoted extramitochondrial calcium-dependent protein phosphatase-4 (PP4) activity that dephosphorylates AMPK. Treating the hepatic MCU-knockout mice with Metformin restored AMPK-dependent lipid clearance in the liver by an MCU-independent mechanism. MCU appears to be key in a
regulatory circuit involving mitochondrial calcium-dependent activation of AMPK to control hepatic lipid metabolism.

Deciphering the function of CLYBL, a missing human gene and a mitochondrial orphan metabolic enzyme.
H. Shen1, V. Mootha1;
1Department of Molecular Biology, Massachusetts General Hospital/Howard Hughes Medical Institute, Boston, MA

CLYBL is a "missing" human gene that is absent in approximately 2.7% of human chromosomes and whose homozygous loss is associated with reduced circulating vitamin B12 levels. CLYBL encodes an orphan mitochondrial matrix enzyme whose enzymatic activity, pathway assignment, and link to B12 are unknown. Here, we demonstrate that CLYBL loss leads to a cell autonomous defect in the mitochondrial B12 metabolism. By combining enzymology, structural biology and activity-based metabolite profiling we discover that CLYBL operates as a citramalyl-CoA lyase. Cells lacking CLYBL accumulate citramalyl-CoA, an intermediate in metabolism of the C5-dicarboxylates, including itaconate, a recently identified human antimicrobial metabolite and immunomodulator. We find that itaconyl-CoA is a substrate analogue, cofactor-inactivating inhibitor of the mitochondrial B12-dependent methylmalonyl-CoA mutase (MUT). Our work de-orphants the activity of CLYBL, explains why its loss leads to B12 deficiency, and reveals a novel mechanism of B12 poisoning by the CoA ester of itaconate, an immunomodulatory metabolite.

Sulfotransferase 1C2 (SULT1C2) post-translationally increases mitochondria respiration.
1Biology, Indiana University-Purdue University Indianapolis, Indianapolis, IN, 2Medicine, Indiana University School of Medicine, Indianapolis, IN, 3Cellular and Integrative Physiology, Indiana University School of Medicine, Indianapolis, IN

Sulfotransferases are enzymes responsible for xenobiotic detoxification. Mechanistically, these enzymes add a sulfate group to xenobiotics which increases their water solubility and urinary excretion. We identified SULT1C2 in a proteomic screen of mitochondria isolated from ischemic preconditioned kidneys. Using hydrodynamic gene delivery, we show that SULT1C2 protects against subsequent ischemia one week after gene delivery. To determine SULT1C2’s mechanism of action, we assayed mitochondria function with and without human recombinant SULT1C2 and its substrate, 3’ Phosphoadenosine-5’-phosphosulfate (PAPS). Mitochondria respiration was assayed using an Oroboros Oxygraph O2K. We found that that PAPS and SULT1C2 incubated with mitochondria increase mitochondria state 3 respiration (add O2 consumption data), following succinate and rotenone addition, 3-fold compared to mitochondria (P<0.05). The increase in SULT1C2/PAPS dependent respiration was inhibitable with antimycin A but not rotenone. Mitochondria incubated with SULT1C2/PAPS have increased cholesterol sulfate as determined by thin layer chromatography assays and incubating isolated mitochondrial with cholesterol sulfate increases state 3 respiration. In conclusion SULT1C2 and PAPS increase the efficiency of state 3 respiration by modifying cholesterol in mitochondria membranes and
potentially increasing oxidative phosphorylation. This is a novel new function for an enzyme that heretofore was considered to be solely involved in detoxifying xenobiotics.

Mitochondria are specialized cellular compartments that function in energy production and calcium homeostasis. Using Intravital Subcellular Microscopy (ISMic) we previously found that mitochondrial metabolic activity in the salivary glands of live rodents exhibits rapid and periodic oscillations under basal physiological conditions. The mitochondrial oscillations are also synchronized within the salivary epithelium through the activity of gap junctions. While mitochondrial oscillations may exert tissues specific biological functions, their physiological roles and how they are orchestrated particularly at the whole organismal level is still not exactly clear. Moreover, increasing reports have suggested dysfunctional mitochondrial oscillations are associated with many metabolic diseases including obesity, cardiovascular disease, developmental defects and cancers, suggesting a need to better understand the metabolic oscillations in vivo. Here, by using selected transgenic mouse models we have extended our previous work and characterized mitochondrial metabolic oscillations in several tissues under both physiological and pathological conditions, thus providing for the first time: 1) a detailed quantitative analysis of their characteristics and spatio-temporal coordination, and 2) a correlation with other signaling pathways (e.g. ROS, Ca\(^{2+}\)).

Mitochondrial morphology, which is associated with changes in metabolism, cell cycle, cell development and cell death, is tightly regulated by the balance between fission and fusion. In this study, we found that S6 kinase 1 (S6K1) contributes to mitochondrial dynamics, homeostasis and function. Mouse embryo fibroblasts lacking S6K1 (S6K1-KO) MEFs exhibited more fragmented mitochondria and a higher level of Dynamin related protein 1 (Drp1) and active Drp1 (pS616) in both whole cell extracts and mitochondrial fraction. In addition, there was no evidence for autophagy and mitophagy induction in S6K1 depleted cells. Glycolysis and mitochondrial respiratory activity was higher in S6K1-KO MEFs, whereas OxPhos ATP production was not altered. However, inhibition of Drp1 by Mdivi1 (Drp1 inhibitor) resulted in higher OxPhos ATP production and lower mitochondrial membrane potential. Taken together the depletion of S6K1 increased Drp1-mediated fission, leading to the enhancement of glycolysis. The fission form of mitochondria resulted in lower yield for OxPhos ATP production as well as in higher
mitochondrial membrane potential. Thus, these results have suggested a potential role of S6K1 in energy metabolism by modulating mitochondrial respiratory capacity and mitochondrial morphology.

Deep mutational scanning reveals characteristics important for mitochondrial targeting of a tail-anchored protein.

A. Keskin¹, E. Akdogan¹, C.D. Dunn¹²;  
¹Department of Molecular Biology and Genetics, Koç University, Istanbul, Turkey; ²Institute of Biotechnology/HiLIFE, University of Helsinki, Helsinki, Finland

Proteins localized to mitochondria by a carboxyl-terminal tail anchor (TA) play key roles in apoptosis, mitochondrial dynamics, and mitochondrial protein import. In order to reveal structural characteristics of TAs that may be important for mitochondrial targeting, we focused our attention upon the TA of the *Saccharomyces cerevisiae* Fis1 protein. We generated a library of Fis1p TA variants fused to the transcription factor Gal4p, and by selecting for mutations within the TA that permit Gal4p to translocate to the nucleus and activate transcription, we were able to enrich for TA variants within our mutant pool which led to decreased membrane insertion. Next-generation sequencing allowed quantification of each TA variant in our mutant library before and after selection, and high-throughput results were confirmed by microscopy-based and functional analysis of individual, reconstructed Fis1p TA mutants. Consistent with the prediction that the Fis1p TA is alpha-helical, prolines within the TA generally prevented membrane insertion. Moreover, our data affirm previous results indicating that the charged carboxyl-terminus of Fis1p is important for specific localization and insertion at the mitochondrial outer membrane. In further experiments, we found that lengthening or shortening the Fis1p TA by up to three amino acids did not alter its behavior or localization, arguing against a model in which TA length directs insertion into specific organelles. Most prominently, while charged residues within the hydrophobic core of the Fis1p TA were also able to perturb membrane insertion, we found that positively charged residues were much more acceptable at several positions within the Fis1p TA than negatively charged residues. These results provide strong, *in vivo* evidence that lysine and arginine can “snorkel,” or partition the nonpolar portion of their side chains into the hydrophobic region of the lipid bilayer while placing the terminal charge near the polar interface of the membrane.

Mitochondria are crucial players in cell metabolism, which requires tight regulation of ion exchange between the cytosol and mitochondrial matrix. This exchange is mediated by a class of multi-membrane spanning proteins localised to the mitochondrial inner membrane, known as the mitochondrial carrier proteins. Mitochondrial carrier proteins are inserted into the inner membrane by a protein import complex known the Translocase of the Inner Membrane 22 (TIM22 complex). Despite the tight conservation of protein import subunits from yeast to humans, the human TIM22 complex has a distinct subunit composition to its yeast counterparts. In this study, we discovered the presence of a novel subunit, Acylglycerol kinase (AGK), which was previously described to be a mitochondrial lipid kinase. Mutations in AGK cause Sengers syndrome, a mitochondrial disorder characterised by lactic acidosis, hypertrophic cardiomyopathy, skeletal myopathy and congenital cataracts. We generated a CRISPR knock-out of AGK and established that the protein has a kinase-independent function at the TIM22 complex, where it mediates the assembly of TIM22 complex and the import of mitochondrial carrier proteins. We observed similar protein import defects and destabilisation of the TIM22 complex in mitochondria isolated from Sengers syndrome patient cells. Consistent with this phenotype, loss of AGK also affects cellular metabolism via perturbation of TCA cycle flux. This data uncovers the important and unexpected relationship between the TIM22 complex, mitochondrial protein import and Sengers syndrome.

Functional analysis of mitochondria subpopulations by novel nanoscale flow cytometry platform.
J.A. MacDonald¹, A.M. Bothun¹, A.R. Ivanov², J.L. Tilly¹, D.C. Woods¹;
¹Biology Department, Northeastern University, Boston, MA, ²The Barnett Institute of Chemical and Biological Analysis, Northeastern University, Boston, MA

Mitochondria play an essential role in the function of numerous cellular processes, principally bioenergetics. To support these diverse activities, mitochondria adapt in size and morphology to serve cell-specific and tissue-specific functions, resulting in a high-degree of mitochondrial heterogeneity. New tools are needed to understand mitochondria at the scale of individual organelles, as well as the role of mitochondria subpopulation dynamics within cells. Herein we sought to precisely evaluate the functional differences in mitochondria subpopulations, using a novel nanoscale flow cytometry platform.

All analyses were conducted using a custom-built BD FACSaria III, calibrated using nanoparticle calibration beads (0.22- 2.0µm). With our platform, we directly isolated mitochondria populations from whole cell lysates prepared from dissected mouse tissues, using the mitochondria specific fluorescent dye, Mitotracker GreenFM (MTG). We subjected our sorted samples to several validation techniques to confirm the identity, purity, and functionality of the isolated events. Sorted MTG⁺ events were enriched in mitochondria DNA (mtDNA) over nuclear DNA via PCR (n=3), and sorted samples processed for scanning-electron microscopy displayed conserved mitochondrial morphology. Isolated mitochondria were labeled with stable isotope TMT tags, and subjected to nLC-MS/MS analysis. Pathway enrichment analysis confirmed mitochondrial identity, and quantitative and differential expression analysis revealed differentially expressed proteins between tissues (p<0.01 cutoff). Ultimately we sought to determine whether sorted mitochondria retained functional competence. Mitochondria sorted from cultured cells as well as primary cells isolated from mouse liver tissue were capable of generating quantifiable levels of ATP when provided an ADP substrate (Cells: 15.12 nM ATP; Liver: 19.27 nM, n=3). Pretreatment of the isolated mitochondria with the membrane potential uncoupler FCCP completely inhibited this ability.
(P<0.01, n=3). Furthermore, subpopulations of mitochondria were successfully sorted based on the incorporation of the membrane potential probe, JC-1. Actively respiring mitochondria more readily incorporate JC-1, resulting in a shift in fluorescence emission from 525 nm to 590 nm. Co-labeling cells with MTG and JC-1 allowed the collection of MTG⁺JC-1₅₂⁵ and MTG⁺JC-1₅₉₀ populations, hypothesized to be low respiring and high respiring, respectively, based on membrane potential. This hypothesis was supported by a confirmatory ATP generation assay (MTG⁺JC-1₅₂⁵: 9.39 nM; MTG⁺JC-1₅₉₀: 36.92, n=3), with only the MTG⁺JC-1₅₉₀ population exhibiting ATP production following pretreatment with FCCP (7.56 nM, n=3), highlighting the dynamic heterogeneity of mitochondria subpopulations.

Mitochondrial subpopulations exhibit differential dynamic responses to support increased energy demand during exocytosis.

N. Porat-Shliom¹, L.N. Malec¹, O. Harding¹, R. Weigert¹;
¹Laboratory of Cellular and Molecular Biology, National Institute of Health, NCI, Bethesda, MD

Mitochondria are highly dynamic organelles that undergo fission, fusion, and translocation in support of cellular metabolic needs. Although the mechanisms regulating these processes have been extensively studied in cultured cells, little is known about mitochondrial dynamics and their overall distribution in cells within tissues. We applied Intravital Microscopy (IVM) to study the spatio-temporal regulation of mitochondrial dynamics in the salivary glands of anesthetized mice. We found that 60-70% of mitochondria are positioned within 2 microns of the basolateral plasma membrane while 30-40% are scattered in the cytosol. A similar distribution pattern is conserved in other exocrine glands including the pancreas, lacrimal and parotid glands. Interestingly, by using a transgenic mouse expressing a mitochondrial-targeted photoswitchable probe (i.e. Dendra2) we found that under basal conditions: 1) basolateral mitochondria are static, whereas central mitochondria exhibit a microtubule-dependent motility; 2) both populations exhibit a low rate of fusion and fission; and 3) both populations do not mix over the course of 4 hours of observation. Since the differential distribution, dynamic properties, and segregation of these two subpopulations suggest distinct functions, we investigated their behavior under conditions of increased energy demand namely, during stimulated protein or water secretion, which are regulated by the b-adrenergic and the muscarinic receptors, respectively. We found that central mitochondria motility significantly increases during protein exocytosis, but not water secretion. In contrast to non-stimulated conditions, this increase in motility correlated with fusion and elongation of central mitochondria that consequently lead to mixing with the basolateral mitochondria. In support of the increased fusion, b-adrenergic stimulation triggered Protein Kinase A (PKA)-dependent phosphorylation of the fission protein Drp1 on the residue S637, resulting in inhibition of its fission activity. Finally, under these conditions the central mitochondria increased the frequency of interactions with lipid droplets. Current experiments explore the possibility of free fatty acids transfer, as a mean to provide substrates for ATP production. Taken together, our results define for the first time two distinct mitochondria populations in the secretory epithelia that undergo acute dynamic remodeling in response to increase in tissue energy demand.

Nutrient-regulated destruction of mitochondrial metabolite carriers by the MDC pathway.
1Department of Biochemistry, University of Utah, Salt Lake City, UT

Mitochondrial dysfunction is a hallmark of aging, and underlies the development of many age-associated and metabolic disorders. Cells maintain mitochondrial health through a number of quality control systems that can detect dysfunctional mitochondria and repair or eliminate problematic organelles. We have now discovered a new mitochondrial quality control system conserved from yeast to humans, the Mitochondrial-Derived Compartment (MDC) pathway, which eliminates proteins from dysfunctional mitochondria by autophagy. Unlike many common mitochondrial autophagy pathways, this system selectively sorts and removes a subset of membrane proteins from the mitochondrial inner and outer membranes, while leaving the remainder of the organelle intact. Selective removal of preexisting proteins is achieved by membrane remodeling and sorting of proteins into a newly discovered mitochondrial-derived compartment, or MDC, followed by release through mitochondrial fission and elimination by autophagy. We have screened the mitochondrial proteome to catalog the substrates of this pathway, and found that the primary target of this system is a large class of inner membrane nutrient transporters called the SLC25A nutrient carrier protein family, which promote all nutrient exchange across the mitochondrial inner membrane. Based on this unique substrate selectivity, combined with our results that MDC formation is triggered by high levels of cytoplasmic amino acids, we propose that the MDC pathway acts as a mechanism to control levels of mitochondrial nutrient transporters to protect mitochondrial from metabolic stress. We are now working to understanding how cells form MDCs and selectively sort proteins into them, and how nutrient signals are relayed to the MDC activation machinery.

From Dictyostelium to Human Airway Epithelium: Adenine Nucleotide Translocase as a Protector Against Cigarette Smoke.
J. Nguyen, C. Kliment, S.M. Claypool, P. Iglesias, R. Sidhaye, D.N. Robinson;
1Cell Biology, Johns Hopkins University, Baltimore, MD, 2Pharmacology and Molecular Sciences, Johns Hopkins University, Baltimore, MD, 3Medicine, Division of Pulmonary and Critical Care, Johns Hopkins University, Baltimore, MD, 4Physiology, Johns Hopkins University, Baltimore, MD, 5Electrical and Computer Engineering, Johns Hopkins University, Baltimore, MD, Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Chronic obstructive pulmonary disease (COPD), the 3rd leading cause of death in the U.S., is primarily caused by cigarette smoke. Despite ongoing research, treatments for COPD have been stagnant due to the difficulty of conducting studies in the complex tissue of the human lung. Hence, we utilized a simpler model organism, the social amoeba Dictyostelium discoideum, as a tool to identify new genetic targets that associate with causal pathways. Adenine nucleotide translocase (ANT) was discovered to be protective in Dictyostelium and human bronchial epithelial cells (HBE) exposed to cigarette smoke extract (CSE). By examining ANT’s protective functions, we can elucidate its potential as a therapeutic target for COPD.

ANT resides at the inner mitochondrial membrane and functions as an ATP4/ADP3 exchanger. Given the role of ANT in mitochondria, we examined the effects of ANT1 and ANT2 expression on mitochondrial...
metabolism in the context of cigarette smoke using the Seahorse XF96e FluxAnalyzer. ANT2 overexpression increases oxidative phosphorylation and ATP flux in HBEs. Interestingly, ANT overexpression also abrogates the decrease in these parameters caused by CSE exposure. Utilizing MitoSOX staining and high-throughput imaging to assess mitochondrial reactive oxygen species (ROS) production, we see a reduction in ROS production with ANT overexpression when HBEs are acutely exposed to CSE. Surprisingly, while examining ANT localization in human lung tissue, we identified that the canonical mitochondrial protein also resides at the plasma membrane of ciliated airway epithelium. We find novel functions of ANT, particularly ANT2, on ciliary function in primary normal human bronchial epithelial cells (NHBEs). Confocal images of the airway surface liquid (ASL) stained with Texas Red dextran reveal that ANT2 overexpression increases ASL height compared to control, confirmed using various ANT inhibitors which abrogate this effect on ASL. ANT2 overexpression also maintains a normal ciliary beat frequency (CBF) in NHBEs when exposed to cigarette smoke, a noxious stimuli that decreases CBF in control cells. From our results, we conclude that ANT has protective functions against cigarette smoke in the mitochondria and unexpectedly, in the cilia of the airway. ANT improves cell viability, cell metabolism, and ciliary function. Further studies will evaluate the mechanisms behind ANT’s functions in the airway including whether ANT is responsible for ATP transport into the ASL. This will provide insight on a key regulatory step in airway surface hydration, which is essential for many airway diseases including COPD and cystic fibrosis.

Tracking global changes in acetylated mitochondria by immunofluorescence provides new insight into HDAC class I and class III crosstalk.
A. Law1, H. Horita1, K. Middleton1;
1RD Department, Cytoskeleton Inc., Denver, CO

Lysine acetylation is a critical post-translational modification that has been shown to play a fundamental role in epigenetic histone regulation. Recent acetylome studies indicate that acetyl-lysine regulation expands well beyond histones, and can target thousands of proteins and many different cellular processes. Many of these acetylome studies often link changes in global acetylation to disease progression. Of interest, changes in the acetylated mitochondrial protein profiles are linked to neurologic, oncogenic, cardiac, and diabetic pathologies. A recent study by Horton et al. specifically identified hyperacetylation of mitochondrial proteins in patients with heart failure. As hyperacetylation of mitochondrial proteins appear to be a critical marker of metabolic disease, having tools to quickly access the acetylated mitochondrial state may be beneficial for diagnosis or treatment. A new, pan-acetyl-lysine antibody was developed that can identify acetylated mitochondrial proteins by immunofluorescence. Importantly, this antibody was tested in combination with mitotracker, and co-localized with the mitochondria marker; conversely, the acetyl-lysine antibody did not co-localize with the LAMP 1 lysosomal marker. This acetyl-lysine antibody identified acetylated mitochondrial proteins in fibroblast, epithelial, and fibroblast-like cell lines highlighting its range of utility. Metabolic-regulating drugs, as well as class I and class III HDAC inhibitors were used to examine the antibodies ability to detect changes in the acetylated mitochondria profile. Global acetylated mitochondrial protein changes in response to these various drug treatments were detected with the acetyl-lysine antibody. Suprisingly, class I HDAC inhibitor, TSA, promoted significant down regulation of global acetylated mitochondria signal, which was reversed with class III HDAC inhibitor treatment. This result supports previous
publications showing opposing regulation between class I and class III HDACs; however, this is the first report implicating global acetylation of mitochondrial proteins as a target of this crosstalk. In summary, these data highlight the ability of this novel antibody to detect and track acetylation in the mitochondria, and may be a critical tool to gain a better mechanistic understanding of the role of HDACs in disease, and ultimately, may be an important diagnostic tool for dysfunctional mitochondrial related diseases.

Posttranslational Arginylation Enzyme Ate1 Controls Mitochondrial Functions and Cellular Warburg Effects.
C. Jiang¹, D.M. Patel¹, A. Kumar¹, B.T. Moorthy¹, M. Birnbaum¹, B. Alfonso², J. Huang², A. Barrientos³, A. Lampidis⁵, F. Fontanesi⁴, F. Zhang¹,²
¹Molecular Cellular Pharmacology, University of Miami, Miami, FL; ²Human Genetics, University of Miami, Miami, FL; ³Department of Neurology, University of Miami, Miami, FL; ⁴Biochemistry Molecular Biology, University of Miami, Miami, FL; ⁵Cell Biology, University of Miami, Miami, FL; ⁶Sylvester Comprehensive Cancer Center, University of Miami, Miami, FL

The Warburg effect is the preference of glycolysis over mitochondrial respiration in the presence of oxygen. This phenotype is commonly seen in cancer cells but its cause still remains less clear. Here we report that the down-regulation of an evolutionarily conserved enzyme, arginyltransferase 1 (Ate1), is sufficient to cause the Warburg effect at the cellular level.

As a central component of the N-end rule, Ate1 is the sole enzyme in mammalian cells mediating posttranslational addition of an extra arginine in a process called arginylation. In this study, by measuring the rates of glucose intake and lactate production, and by measuring glycolytic profiles with the Seahorse metabolic analyzer, we found that a knockout (KO) or a down-regulation of Ate1 is sufficient to up-regulate glycolysis. Consistently, by using glycolysis inhibitors 2-DG and 2-FDG, we found that the portion of glycolysis derived ATP was increased by the KO or down-regulation of Ate1, and such a phenotype can be rescued when recombinant Ate1 is expressed in the Ate1-KO cells. Therefore, our data indicates that a down-regulation of Ate1 increases glycolysis. In contrast, the KO of Ate1 appears to impair the function and morphology of mitochondria. By using Western blot on whole cells and isolated mitochondria separated on denaturing or native PAGE, we found that the Ate1-KO, while not affecting the quantity of mitochondria in the cell, changed its quality with defects in the formation of respiration chain complexes and super complexes. Particularly, Ate1-KO appears to compromise the formation and the function of succinate dehydrogenase (complex II) by impairing the import and modification of several subunits. Importantly, we found that the level of hypoxia-inducible factor 1a (HIF1a) is increased in Ate1-KO cells and the knockdown of HIF1a was able to suppress the glycolytic phenotype in these cells.

We also found that the increase of HIF1a in Ate1-KO cells are mediated by two pathways, the arginylation-dependent degradation of this protein by the N-end rule, and the increase of succinate level as expected by the compromise of succinate dehydrogenase. Finally, by confocal microscopy and by biochemical assays, we found that a portion of Ate1 is located inside mitochondria, and this may be explained by the evolutionary origin of Ate1 as a gene transferred from the mitochondrial ancestors. Our study shows for the first time that Ate1 is tightly connected to mitochondrial function, established HIF1a as a previously unknown substrate of the N-end rule, and discovered a novel pathway in mediating the cancer Warburg effect by an evolutionarily posttranslational modification enzyme.

Mitochondrial protein transport in Trypanosoma brucei: The divergent machinery for conserved function.
M. Chaudhuri¹, U. SINGHA¹, J.T. Smith¹, L. Quinones¹, C. Darden¹;
¹Microbiology and Immunology, Meharry Medical College, Nashville, TN

A vast majority of mitochondrial proteins are nucleus-encoded and are imported into mitochondria via translocases of the mitochondrial outer and inner membrane, TOM and TIMs, respectively. These multi-protein complexes have been studied mostly in eukaryotic supergroups, opisthoknots (i.e. fungi and animals) and in archaeplastida (i.e. plants). There are two major types of mitochondrial targeting signals (MTS) located either at the N-terminal or internal of the substrate proteins, which are recognized by different subsets of Tom and Tim proteins during translocation. In spite of similarities in basic characteristics of the MTSs and evidences of multiple cross-species protein translocation into mitochondria, the TOM and TIM complexes in trypanosomatid parasites that belong to the eukaryotic supergroup excavatae, are uniquely divergent. Trypanosoma brucei, a unicellular parasitic protozoan and the infectious agent for African trypanosomiasis, possesses a non-canonical TOM complex, known as ATOM consisting of Atom40 and several other trypanosome-specific Tom proteins. In spite of two TIM complexes in fungi and animals, trypanosomatids most likely possess a single TIM capable of importing different substrate proteins. One of the major components of the TbTIM complex is TbTim17, the single member of the Tim17/Tim23/Tim22 family proteins found in other eukaryotes. We found that TbTim17 is associated with at least two other novel trypanosome-specific proteins, TbTim62 and TbTim54, and three small TbTims, TbTim9, TbTim10, and TbTim8/13, and also as a relatively conserved protein TbTim50. Using both in vitro and in vivo import assays we determined the substrate specificities of these TbTims. Our results show that TbTim17 is involved in the import of both the N-terminal and internal MTS-containing proteins. TbTim62 and TbTim50 are needed primarily for translocation of the N-terminal MTS-containing proteins, whereas TbTim54 and small TbTims are required for import of internal signal-containing proteins. TbTim62, TbTim50 and TbTim17 are membrane integral components, while small TbTims and TbTim54 are peripherally associated with TbTim17 and located in the intermembrane space. TbTim62 and small TbTims are essential for the stability and assembly of the TbTim17 complex. Together, the data suggest that TbTim62, TbTim17, and small TbTims are the core components of the TbTIM complex whereas TbTim54 and TbTim50 are accessory components required to be associated with the complex for translocation of different substrate proteins. Investigation of the role of ubiquitination in mitochondrial dynamics and mitophagy.
S. Shields¹;
¹Biology, Gustavus Adolphus College, Saint Peter, MN

It is well known that defects in the proper targeting and regulation of ubiquitination of mitochondria can have disastrous consequences for a cell and an organism as a whole. A classic example being the deregulation of the ubiquitin ligase Parkin, which of is associated with the in neurodegenerative disease Parkinson’s. We sought to characterize the role deubiquitinating enzymes (DUBs) play in the morphology, dynamics, and degradation of mitochondria in Saccharomyces cerevisiae. First, localization of the DUBs was determined during conditions of exponential growth condition, oxidative stress, and

Monday-335
nitrogen starvation. DUBs that were found to have localization to the mitochondria, were then screened for their role in mitochondrial homeostasis. Yeast strains deficient in the known DUBs were screened by microscopy and immunoblot for defects in mitochondrial network morphology, membrane potential, dynamics, and mitophagy. Interestingly, a previously uncharacterized DUB was found to have exclusive localization to the mitochondria, be a negative regulator of mitochondrial network morphology and dynamics but not affect membrane potential.

Improvement of Cell Metabolism through Direct Mitochondrial Transfer.
M. Kim¹, J. Hwang¹, C. Yun¹, C. Park¹, Y. Choi¹;
¹Biotechnology, CHA university, Seongnam, Korea, South

Mitochondria are essential cellular organelles involved in the maintenance of cell growth and function, and have been investigated as therapeutic targets in various diseases. Recent studies have demonstrated that direct mitochondrial transfer can restore cellular functions of cells with inherited or acquired mitochondrial dysfunction. However, previous mitochondrial transfer methods are inefficient and time-consuming. Here, we developed a simple and easy mitochondrial transfer method based on centrifugation that is cell type independent and that does not require further cultivation. After functional characterization of isolated mitochondria they were transferred into target cells using centrifugation. The high mitochondrial transfer efficiency was unaffected by the amounts of mitochondria being transferred. We first established that exogenous mitochondria could be transferred into target cells via centrifugation without causing intracellular damage, which led to increase in ATP content and improved metabolic activity. Then, we investigated whether transferring intact mitochondria into mitochondrial DNA-deleted Rho0 cells and dexamethasone-induced atrophic muscle cells could restore their metabolic functions. The transfer of intact mitochondria normalized impaired mitochondrial functions such as ATP production, membrane potential, mitochondrial ROS, and oxygen consumption rate. We also demonstrated that intact mitochondria delivered to atrophied muscle cells blocked the AMPK/FoxO3/Atrogenes pathway leading to muscle atrophy. In conclusion, it is expected that simple and rapid mitochondrial transfer can be used as a useful method for further mitochondria-related investigations into the rescue of atrophy and the restoration of muscular function.

Loss-of-function mutations in the SIGMAR1 gene cause distal hereditary motor neuropathy by impairing ER-mitochondria tethering and Ca2+ signaling.
S. Zanin¹, E. Gregianin³, A. Petrucci⁴, G. Vazza¹, R. Rizzuto¹, G. Pallafacchina¹,²;
¹Department of Biomedical Sciences, University of Padova, Padova, Italy, ²CNR Neuroscience Institute, University of Padova, Padova, Italy, ³Department of Biology, University of Padova, Padova, Italy, ⁴Neuromuscular and Rare Neurological Diseases Centre, San Camillo-Forlanini Hospital of Rome, Rome, Italy

Distal Hereditary Motor Neuropathies (dHMN) are clinically and genetically heterogeneous neurological conditions characterized by degeneration of the lower motor neurons. To date, 19 dHMN genes have been identified but 80% of dHMN cases remain without genetic description. By a combination of autozygosity mapping, identity-by-descent segment detection and whole-exome sequencing approaches we identified two novel homozygous mutations in the SIGMAR1 gene (p.E138Q and p.E150K) in two
distinct Italian families affected by an autosomal recessive form of HMN. Sigma non-opioid intracellular receptor 1 (sigma-1R) is a 28 kDa chaperone protein of the endoplasmic reticulum (ER) that localizes at the mitochondria-associated ER membrane (MAM). It is involved in several aspects of cellular homeostasis in the nervous system, including regulation of ion channels, neurite growth and Ca2+ signalling. Functional analyses in several neuronal cell models strongly support the pathogenicity of the sigma-1R mutations and provide insights into the underlying pathomechanisms involving the regulation of ER-mitochondria tethering, Ca2+ homeostasis and autophagy. Indeed, we demonstrated that, in vitro, both sigma-1R mutations behave as “loss-of-function” mutations reducing cell viability, leading to the formation of abnormal protein aggregates preventing the correct targeting of sigma-1R protein to the MAM and thus impinging on the intracellular Ca2+ handling and triggering autophagy. In line with this, primary skin fibroblasts derived from patients with homozygous E150K sigma-1R mutation showed marked alterations of MAM number and distribution, and an increased level of basal autophagy compared to controls. Our data definitively point out the role of sigma-1R in motor neuron survival and homeostasis by correlating, for the first time in the Caucasian population, mutations in SIGMAR1 gene to distal motor disease highlighting the importance of this protein in MAM establishment and maintenance and in Ca2+ signaling modulation as a critical aspect of motor neuron degeneration in dHMN pathology.

Kinetic model of free radical generation in complex II of mitochondria.
P. Lee1, J. Bazil2
1Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI, 2Physiology, Michigan State University, East Lansing, MI

For the sites of free radical generation from mitochondria, mainly complex I and III have been studied in electron transport chains of mitochondrial respiration. However recently the roles of complex II are revealed in disease models such as ischemia-reperfusion, inflammatory response, and neurodegeneration. We hypothesize that complex II, involving both in electron transport chain and tricarboxylic acid (TCA) cycle plays an important role in the physiological development of cardiac differentiation. To characterize the conditions for the reactive oxygen species (ROS) generation, for the first step, we developed a kinetic model of ROS generation with multiple states of electron occupancy. The complex protein of complex II is constituted with flavin adenine dinucleotide (FAD) and three iron-sulfur clusters. The forward and backward transition rates are thermodynamically constrained with specific midpotentials from E0 to E6 states. The hydrogen peroxide is supposed to be generated with competitive binding by reduction of ubiquinone (Q) to ubiquinol (QH2) in Qp site, oxidation of oxygen to H2O2 or oxidation of succinate to fumarate in FAD site catalyzed by succinate dehydrogenase and fumarate reductase. The superoxide is assumed to be generated while electrons are shuttled through the iron-sulfur clusters as well as via the intermediate chemicals of FAD semiquinone and semiquinone. In the steady state of transition, we obtained the distribution of electron occupancy and fluxes of free radical generation in terms of ratio of succinate and fumarate concentrations, Q-pool, and oxygenation. The computational model predicts that the ROS generation is highly elevated in low succinate to fumarate ratio and low oxygen levels. The model will be validated with experiments and integrated with the reactions in complex I and III.

The new functions of the Nek family in mitochondria context.

Biochemistry and Tissue Biology, Unicamp, Campinas, Brazil, Institute of Biomedical Sciences, USP, São Paulo, Brazil, Faculty of Pharmaceutical Sciences, Unicamp, Campinas, Brazil

NIMA-related kinases (NEKS) are involved in cell cycle control, DDR and more recently mitochondrial functions. In humans, eleven members were identified, named Nek1 to Nek11. Despite the conserved kinase domains, the selectivity and diversity of partners is due to heterogeneity of the regulatory domain. We investigate the interacting partners of Nek1 (Hanchuk et al, 2017), Nek3, Nek5 and Nek10 by immunoprecipitation followed by Mass Spectrometry. Most of the identified partners are mitochondrial proteins involved in biological process such as apoptosis, metabolism and DNA repair. Using cell fractionation followed by Western blot, we identified for the first time Nek5 and Nek10 in mitochondria. We showed that stable cells expressing Nek5 regulate cell death by decreasing the level of Reactive Oxygen Species. Additionally, Real-Time PCR in Hela and Hela Nek10-silenced cells evaluated the total and mtDNA content. Nek10 depletion causes the mtDNA increase, suggesting that Nek10 is controlling mtDNA replication. Using OROBOROS Oxygraph-2k the mitochondrial respiration rates were analyzed in Nek5 and Nek10 knockdown cells. Nek5 silenced cells presented 1.7 fold increased basal rates of respiration, especially at the electrons transfer steps from TMPD to cytochrome c and at the complex II (Hanchuk et al, 2015). On the other hand, in Nek10 depleted cells it was observed a decrease in oxygen consumption in response to rotenone, a complex I inhibitor. Taken together these results showed that Nek5 and Nek10 have important roles in cell respiration, which could be regulated by its interactors. The roles Neks during the cell cycle are clear, but now, those findings raise a new role of the family associated to mitochondrial cell death and respiration. In this context, the function of each member and its partners need to be re-evaluated.

Mitochondrial electron transport chain Complex I and II in the modulation of Ca\(^{2+}\) homeostasis in breast cancer cells.
F. Jaña, P. Cruz, G. Bustos, F. Urra, C.E. Basualto-Alarcon, M. Ríos, M. Madesh, J.C. Cardenas

University of Aysén, Coyhaique, Chile, Geroscience Center for Brain Health and Metabolism, Santiago, Chile, Program of Anatomy and Developmental Biology, Institute of Biomedical Sciences, University of Chile, Santiago, Chile, Department of Medical Genetics and Molecular Biochemistry, Center for Translational Medicine, Temple University, Philadelphia, PA

Mammalian cells use calcium ions (Ca\(^{2+}\)) as signaling agents to regulate metabolism and other cellular functions. The flow of calcium into mitochondria, the chief producers of energy-rich ATP molecules in cells, allows them to get enough reductive equivalents and building blocks for surviving and proliferation. Krebs cycle, into the mitochondrial matrix, relies on Ca\(^{2+}\) supply for the proper functioning of at least three dehydrogenases which are essential for the generation of reduced equivalent NADH, which is used by the electron transport chain (ETC). ETC consists of four protein complexes embedded in the internal mitochondrial membrane, and they transport electrons from NADH through Complex I (CI)
to Complex IV, bombing protons from the matrix out to the inter-membrane space, generating a proton gradient used by ATP synthase to generate ATP. The main entrance of electrons to the ETC is CI. This complex has at least 40 subunits, and its assembly is a intricate process which involves several assembly factors and intermediaries. On the other hand, a secondary electron entrance is succinate dehydrogenase (SDH), also called Complex II (CII). SDH oxidizes succinate to fumarate and reduces ubiquinone. Together, complex I and II deliver most of the electrons used by ETC.

Until now, the role of CI and CII in the regulation of mitochondrial Ca$^{2+}$ homeostasis has not been studied. To assess this, we used lentiviral particles to generate stable MCF7 cells expressing a shRNA against the assembly factor of CI, NDUFAF3 and CII subunit, SDHA. Knockdown (KD) levels of 75% for NDUFAF3 and 80% for SDHA generate a severe reduction of respiratory parameters. The reduction in respiration induces a bioenergetic crisis that is accompanied by AMPK phosphorylation. Although the ETC was defective in these cells, the mitochondrial membrane potential was unchanged in both NDUFAF3 and SDHA KD cells, probably by the reverse function of the ATP synthase. Considering that the dominant driving force for Ca$^{2+}$ accumulation is the membrane potential no changes were expected. Surprisingly, we found that extramitochondrial Ca$^{2+}$ uptake by mitochondria was decreased in both NDUFAF3 and SDHA KD cells, as well as the Ca$^{2+}$ efflux.

Also, we observed an increased resistance to cell death induced by mitochondrial stressors in KD cells, suggesting that cells with CI or CII downregulated have less calcium available to be released, and this has implications in cell death. Surprisingly, we did not observe an effect on cell proliferation, although a diminution in cell migration in CII KD cells was observed. In summary, we show that NDUFAF3 and SDHA are essential for mitochondrial respiration and mitochondrial Ca$^{2+}$ uptake and efflux, and CII downregulation has an impact on migration of cancer cells.

Examining the role of ubiquitination in mitochondrial morphology, membrane potential, and mitophagy in Saccharomyces cerevisiae.

M.R. Mir$^{1}$, S. Shields$^{1}$

$^{1}$Biology, Gustavus Adolphus College, Saint Peter, MN

Ubiquitination plays a vital role in mitochondrial homeostasis through regulating and targeting proteins for degradation. Defects in the ubiquitination mechanism are known to cause destructive consequences for the cell and organism, as seen with certain neurodegenerative diseases such as Parkinson’s disease. Deubiquitinating enzymes (DUBs) reverse the effects of ubiquitination and are integral in regulation. We investigated the role of DUBs in mitochondrial structure, membrane potential, dynamics, and mitophagy in baker’s yeast (Saccharomyces cerevisiae). Our primary subject for analysis is UBP11p, a previously uncharacterized DUB that we localized to the mitochondria. *ubp11Δ* and wildtype cells were imaged via epifluorescence microscopy with a mitochondrial-localized GFP (mtGFP, Westermann and Neupert 2000) in order quantify morphological changes. Morphological network data was obtained using Mitograph (Viana et al., 2015), an ImageJ Z-stack processing software, for structural analysis. Preliminary data suggests the *ubp11Δ* cells have larger mitochondrial networks with greater surface and skeletal volume. Mitochondrial membrane potential was examined with MitoLoc (Vowinckel et al., 2015), an indicator of mitochondrial functional deficiency, and then compared in wildtype and *ubp11Δ* cells with data suggesting no qualitative defects. However, the UBP11p does appear to have a role in mitophagy, as determined by the quenching of the pH sensitive GFP fused with a pH stable RFP, Rosella-m, a biosensor of mitophagy function (Rosado et al., 2008). Together, these data suggest a role for the
uncharacterized DUB UBP11p in the regulation of mitochondria.

Bioinformatic and functional analysis of uncharacterized open reading frames YPL247C and YGR021W in *Saccharomyces cerevisiae*.
Z. Brown, M.R. Mir, S. Shields;
1Biology, Gustavus Adolphus College, Saint Peter, MN

Approximately 10% of open reading frames (ORF) in the Saccharomyces cerevisiae genome are considered uncharacterized for the gene ontology (GO) terms molecular functions, biological processes, and cellular components. Combined, “¼ of the ORFs are considered to have an unknown function in at least one of these GO terms. Specifically, we sought to characterize ORFs associated with mitochondrial function. The ORFs YPL247C and YGR021W are uncharacterized genes (ORFans) in Saccharomyces cerevisiae with known DNA sequences but unknown functions for all three GO terms. Through the bioinformatics-based workflow established by the Yeast ORFan Gene Project (Bowling et al., 2015), we analyzed existing data using conserved domain database (CDD) analysis, multiple sequence alignment, protein family sequencing, and cellular localization. Previous data indicated that both ORFs localize to the mitochondria with increased localization of YPL247C under autophagy inducing conditions (rapamycin). Additionally, it was found that YPL247C is homologous to the mammalian DDB1- and CUL4-associated factor 7 (DCAF7), which contains multiple WD40 repeats that facilitate protein-protein interactions and enable the assembly of multiprotein complexes. Combined with phenotypic data indicating that overexpression of YPL247C causes cell cycle arrest, we hypothesised a role of YPL247C in regulating mitochondrial fission during cell division. The localization of YPL247C to the mitochondria was confirmed by microscopy of GFP-tagged alleles of this ORFan. Phenotypic assays in ypl247Δ cells are currently being performed to define the function of YPL247C. Furthermore, YGR021W was found to have homology to TACO1, which is a translational activator of cytochrome c oxidase I and has many known interactions with the mitochondrial translation machinery. We hypothesized that YGR021W is involved in mitochondrial translation. Again, the localization of YGR021W to the mitochondria was confirmed with GFP-tagged alleles, and phenotypic assays are ongoing to determine the role of YGR021W in the mitochondrial function.

Board Number: B554
Bioinformatic and functional characterization of the ORFs YPR117W and YHL018W in *Saccharomyces cerevisiae*.
D. Edholm, N. Carlson, S. Shields;
1Biology, Gustavus Adolphus College, Saint Peter, MN

Yeast is an ideal model organism for modern cell biology research due to its relatively low price, homology with other eukaryotes including humans, and the relative ease of genetic manipulation. Most of the genome of Saccharomyces cerevisiae (Baker’s or Brewer’s yeast) has been studied and characterized for function. Still, around 10% of open reading frames in the genome (ORFs) are categorized as unknown for the gene ontology terms (GO terms) cellular component, molecular function and biological process. Using the bioinformatic workflow of the Yeast Gene ORFan project, the uncharacterized genes YPR117W (BSH1) and YHL018W (MCO14) were studied. First, genetic interactions, multiple sequence alignment, cellular localization data, gene deletion phenotypes and
homology protein homology were studied. BSH1 was found to contain several conserved domains: a Golgi-body localization protein domain at the C-terminus, three domains from the Fmp27 family involved in RNA pol II promoter, one N-terminal domain highly conserved in fungi but of unknown function. In addition, BSH1 was predicted to localize to the mitochondria and interacts with several proteins with the GO term of organelle organization and cytoskeleton organization. We then hypothesized that BSH1 would localize to the Golgi and have a role in transcriptional regulation and/or cytoskeleton dynamics. Current efforts are underway to determine the cellular localization of BSH1 using GFP-tagged proteins as well as phenotypic assays to determine the biological function. In contrast, MCO14 was found to exclusively to localize to mitochondria and have a predicted function as a regulator of NF1a and be a dehydratase of pterin-4a-carbinolamine. We hypothesized that MCO14 to regulate gene transcription in the mitochondria. Currently, phenotypic assays examining mitochondrial dynamics, morphology, and membrane potential are underway.

MICU1 Restricts Spatial Crosstalk Between InsP₃R and MCU Channels by Regulating Threshold and Gain of MICU1-Mediated Inhibition and Activation of MCU. R. Payne¹, H. Hoff¹, A. Roskowski¹, J.K. Foskett¹,²; ¹Physiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, ²Cell and Developmental Biology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Ca²⁺ entry into mitochondria is mediated by the Ca²⁺ uniporter channel complex containing MCU, the Ca²⁺-selective pore, and associated regulatory proteins. The roles of MICU proteins are controversial. MICU1 was proposed to be necessary for MCU activity whereas subsequent studies suggested it inhibits the channel in the low-cytoplasmic Ca²⁺ ([Ca²⁺]ₜ) regime, a mechanism referred to as “gatekeeping”, that imposed a [Ca²⁺]ₜ threshold for channel activation at ~1-3 micromolar. Here we quantitated MCU activity over a wide range of quantitatively-controlled and recorded [Ca²⁺]ₜ. MICU1 alone can mediate gatekeeping as well as highly-cooperative activation of MCU activity, whereas the fundamental role of MICU2 is to regulate the threshold and gain of MICU1-mediated inhibition and activation of MCU. Our results provide a unifying model for the roles of the MICU1/2 hetero-dimer in MCU-channel regulation and suggest an evolutionary role for MICU2 in spatially-restricting Ca²⁺ crosstalk between single InsP₃R and MCU channels.

Phosphatidylinositol synthesis is controlled at the level of substrate availability. N. Sengupta¹, D.J. Tóth¹, J. Pemberton¹, Y. Kim¹, T. Balla¹; ¹NICHD, NIH, Bethesda, MD

Phosphatidylinositol (PI) is an important lipid having roles as key membrane component as well as precursor of phosphoinositides, the tiny lipids that control essential cellular functions in both plants and animals. Phosphatidylinositol synthase (PIS) enzyme catalyzes the biosynthesis of PI from CTP-activated diacylglycerol produced from phosphatidic acid (PA). PI synthesis is accelerated during stimulation by agonists that activate phospholipase C (PLC), but beyond that little is known about the mode of regulation of the PIS enzyme. Here we investigated the substrate-product relationship of PI synthesis.
both in intact cells and membrane preparations from cells expressing the PIS enzyme. In crude membranes we found that PIS can work both in forward and reverse modes depending on the relative amounts of products and precursors. Overexpression of PIS had no major impact on the level or synthetic rate of PI in intact cell and CRISPR/Cas9-mediated gene targeting indicated that while the enzyme is essential, haploid cells showed no major abnormalities. These results suggested that PI synthesis is not controlled at the level of the amount of PIS enzyme. Using intact cells and short-term labeling with [3H]-inositol to evaluate PI synthetic rate we found that PI synthesis is highly dependent on the availability of PA, especially when PI turnover is increased by stimulation of PLC enzymes. We also found that a significant amount of PA is derived from de novo synthesis from glycerol-3-phosphate, in addition to recycling the PLC hydrolytic product, diacylglycerol. Accordingly, inhibition of de novo PA synthesis inhibited PI synthesis both under basal and angiotensin stimulated condition. Taken together our results indicated that PI levels are controlled by the availability of PA produced by either the de novo biosynthetic pathway or by diacylglycerol kinase. More importantly, these studies also pointed to the importance of PI removal as part of the control of PI synthesis, a process presumably mediated by PI lipid transport pathways.

Acute control of plasma membrane PtdIns(4,5)P2.
R.C. Wills¹, J.P. Zewe¹, B. Goulden¹, G. Hammond¹;
¹Department of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

The inner leaflet of the plasma membrane (PM) is a bustling hub for cellular proteins that facilitate membrane traffic, signal transduction, cytoskeletal assembly and ion flux at the cell surface. Many of these proteins, including ones executing each of the previous functions, engage the PM lipid phosphatidylinositol(4,5)-bisphosphate [PtdIns(4,5)P₂]; binding to this lipid recruits and/or a activates these proteins. Therefore, harmonious PM function is contingent on tightly regulated control of PtdIns(4,5)P₂ levels - and interrogation of these functions is greatly informed by the ability to acutely manipulate PtdIns(4,5)P₂ levels. Whereas approaches to acutely deplete PtdIns(4,5)P₂ have been available for over a decade, tools that permit acute increases in the lipid have been lacking. We found that expression of constitutive or acutely PM-recruited PI4P 5-kinases (PIPSK) lead to basally elevated PtdIns(4,5)P₂ levels as well as depletion of the substrate for this enzyme, PtdIns4P. These alterations were present in the case of the recruitable PIP5K even prior to PM recruitment. We therefore developed a new acutely recruitable PIP5K, based on a mutant kinase domain unable to homodimerize with endogenous PIPSKs. This enzyme does not effect basal lipid levels, but does produce acute (~minutes) elevations in PM PtdIns(4,5)P₂ and concomitant depletion of PM PtdIns4P. We are using this tool to evaluate how dynamic PM functions such as clathrin mediated endocytosis, PLC activation, PI3K-signaling and cortical actin assembly are influenced by acute changes in these lipids. There results provide insights into how homeostasis of one crucial lipid impacts multiple aspects of cellular function.
Uncovering a novel and Ca\textsuperscript{2+} dependent mechanism that regulates phosphatidylinositol 4-phosphate production at the plasma membrane.

I. Ulengin-Talkish\textsuperscript{1}, R.K. Bond\textsuperscript{1}, A. Gingras\textsuperscript{2}, N. St-Denis\textsuperscript{2}, M.S. Cyert\textsuperscript{1};

\textsuperscript{1}Biology, Stanford University, Stanford, CA, \textsuperscript{2}Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Canada

Phosphoinositides (PtdIns) are low-abundance membrane phospholipids with major roles in diverse cellular processes including membrane trafficking and signal transduction. Distribution of specific PtdIns to distinct cellular membranes establishes the membrane identity for each organelle and plays regulatory roles in their activities. At the plasma membrane (PM), phosphatidylinositol 4-phosphate (PI4P), the most abundant PtdIns at the PM, and its downstream metabolite P(4,5)P\textsubscript{2} not only establish an ionic gradient which regulates the activity and targeting of PM-associated proteins, but are also critical signaling lipids that ensure ligand-induced Ca\textsuperscript{2+} signaling from G-protein coupled receptors (GPCR). The synthesis of PI4P at the PM requires the recruitment of the PI4-kinase (PI4KIII\textalpha) from the cytosol to the PM. This is mediated by an evolutionary conserved complex comprised of the PM anchor of the complex, EFR3B, and the cytosolic shuttling proteins, TTC7B and FAM126A. In yeast, complex formation and function requires the complex to be dephosphorylated, however such a regulatory mechanism has not been shown in higher eukaryotes. We show that the Ca\textsuperscript{2+}/calmodulin-activated serine/threonine protein phosphatase, calcineurin (CN) associates with the PI4-kinase complex at the PM. Specifically, the PI4-kinase complex interacts preferentially with an isoform of CN, CnA\textbeta, which has distinct physiological and regulatory properties from other, better characterized CN isozymes. We characterize CnA\textbeta1 to be membrane-associated, in part through palmitoylation of its C-terminus and that it co-localizes with the PI4P. Furthermore, we identify a CN-binding motif in FAM126A, the auxiliary component of the PI4-kinase complex that evolved in higher eukaryotes, that is necessary and sufficient for CnA\textbeta1 binding both in vivo and in vitro. We find that a FAM126A CN-binding mutant is hyper-phosphorylated and forms a complex with PI4-kinase and TT7CB in the cytosol. However, this complex has significantly reduced PM association, suggesting that CnA\textbeta1 promotes the stable association of the PI4-kinase complex at the PM. Overall our findings propose a mechanism wherein the regulation of PI4P synthesis at the PM is mediated via CnA\textbeta1-dependent dephosphorylation of the PI4-kinase complex. We hypothesize that this Ca\textsuperscript{2+} dependent mechanism would replenish PI4P levels consumed during ligand activated PLC-coupled GPCRs to promote sustained Ca\textsuperscript{2+} signaling under high stimulatory conditions.

Novel biosensors for an enigmatic phosphoinositide.

B. Goulden\textsuperscript{1}, J.P. Zewe\textsuperscript{1}, R.C. Wills\textsuperscript{1}, J.E. Pacheco\textsuperscript{1}, G.R. Hammond\textsuperscript{1};

\textsuperscript{1}Department of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Phosphatidylinositol-3,4-bisphosphate (PtdIns(3,4)P\textsubscript{2}) functions at the nexus of plasma membrane (PM) signaling and trafficking. Specifically PtdIns(3,4)P\textsubscript{2} is produced from PtdIns4P during endocytosis or from PtdInsP\textsubscript{3} during signaling. Elucidating the relative roles of these pathways requires the capacity to image this lipid’s production with real-time live-cell microscopy. However, the biosensors currently employed either recognize both PtdIns(3,4)P\textsubscript{2} and PtdInsP\textsubscript{3}, or have insufficient affinity to image these low abundance lipids. We therefore set out to identify PtdIns(3,4)P\textsubscript{2} and PtdInsP\textsubscript{3} probes that have high sensitivity and fidelity. Pleckstrin homology (PH) domains from Akt, Btk, ARNO, and GRP1 have been
shown to recognize and bind PtdInsP3, while the C-terminal PH domain from TAPP1 has been reported to interact with PtdIns(3,4)P2. To increase their efficacy as probes, we cloned a fluorescent protein in tandem with these PH domains as monomers, dimers, or trimers. Using TIRF and confocal microscopy, we demonstrate that our trimer TAPP1-PH and dimer ARNO-PH-2G constructs are specific and sufficient for detecting PtdIns(3,4)P2 and PtdInsP3, respectively. In addition, we developed several chemical- and opto-genetic tools to specifically manipulate P(3,4)P2 in living cells. A rapamycin inducible system was used by conjugating FKBP to P(3)K C2a and INPP4B (PtdIns(3,4)P2-specific 4-phosphatase), and a photoactivatable PtdIns3 P 4-kinase derived from Legionella pneumophila (LepB) was also used to manipulate PtdIns(3,4)P2. Collectively, the tools produced in this study provide powerful new means of understanding the spatiotemporal control of PtdIns(3,4)P2 and PtdInsP3 in signaling and membrane traffic.

Diffusion of lipids and GPI-anchored proteins in actin-free plasma membrane vesicles measured by STED-FCS.
E. Sezgin1, C. Eggeling1;  
1Weatherall Institute of Molecular Medicine, University of Oxford, Oxford, United Kingdom

Diffusion and interaction dynamics of molecules at the plasma membrane play an important role in cellular signalling, and they are suggested to be strongly associated with the actin cytoskeleton. Here, we utilize super-resolution STED microscopy combined with fluorescence correlation spectroscopy (STED-FCS) to access and compare the diffusion characteristics of fluorescent lipid analogues and GPI-anchored proteins (GPI-APs) in the live cell plasma membrane and in actin cytoskeleton-free cell-derived giant plasma membrane vesicles (GPMVs). Hindered diffusion of phospholipids and sphingolipids is abolished in the GPMVs while transient nanodomain incorporation of ganglioside lipid GM1 is apparent both in the live cell membrane and in GPMVs. For GPI-APs, we detect two molecular pools in living cells; one pool showing high mobility with transient incorporation into nanodomains, and the other pool forming immobile clusters, both of which disappear in GPMVs. Our data underline the crucial role of the actin cortex in maintaining hindered diffusion modes of many but not all of the membrane molecules, and highlight a powerful experimental approach to decipher specific influences on molecular plasma membrane dynamics.

Membrane scission activity of Endophilin A2 depending on phospholipid composition.
K. Kida1, M. Kitamata1, K. Hanawa-Suetsugu1, S. Suetsugu1;  
1Molecular Medicine and Cell Biology Laboratory, Nara Institute of Science and Technology, Nara, Japan

The shape of the plasma membrane changes during various cellular processes. The dynamic changes of membrane shapes associate with the fission and fusion of membrane vesicles. Endophilin A2 with the Bin-Amphiphysin-Rvs167 (BAR) domain which determines the formation of the lipid membrane curvature were found to have the membrane scission activity. Endophilin A2 is involved in receptor endocytosis, regulating the amount of growth factor receptor localized at the cell membrane. Here we
focused on a reported mutation of endophilin A2 at the tip of the putative structure. We examined the interaction between the lipid membrane and the endophilin A2 mutant by liposome co-sedimentation method using ultracentrifugation, with fluorescence lipid as sedimentation marker. When the size of liposomes was changed to smaller one, the sedimentation efficiency was reduced and fluorescence was detected in the supernatant after ultracentrifugation. Liposomes were prepared from three kinds of natural organ sources. However, both wild type and the mutant had different scission activities dependently on the source of lipids, and the mutant had stronger membrane scission activity than the wild type when the liposome was made of kidney derived lipids. Then, we examined the lipid compositions by thin layer chromatography, and found that lipid composition differs among three lipid different sources. Phospholipids are classified by the hydrophilic head groups, but they have two hydrophobic fatty acids that have great variety. Based on the lipid composition of kidney, reconstituted membrane was prepared by synthetic phospholipids of defined fatty acid composition. We found that endophilin A2 had scission activity only when the liposomes were made of phospholipids that have certain types of unsaturated fatty acids in kidney phospholipid composition, but not with the other compositions. In addition, the mutant had stronger membrane scission activity than wild type. Therefore, membrane scission activity of endophilin A2 is dependent on the fatty acid composition as well as types of phospholipids.

Rab1 is essential of lipid droplet biogenesis.
1Pathology, Tel Aviv University, Tel Aviv, Israel, 2Clinical Microbiology and Immunology, Tel Aviv University, Tel Aviv, Israel

Lipid droplets (LD) are regulated dynamic intracellular lipid storage organelles. Abnormal lipid storage regulation is associated with various pathologies. LD biogenesis occurs at the endoplasmic reticulum (ER) following accumulation of synthesized lipids. In spite of extensive research, many steps in this process are still unclear. Several proteins have been described to be involved in LD biogenesis. However, depletion of these proteins, while affecting LD size or distribution, did not abolish LD formation. Here we report that Rab1, a small GTPase previously linked to ER-to-Golgi trafficking, is an LD associated protein. Overexpression of its dominant-negative (DN) form abolished all steady state LDs. Inhibition of ER-to-Golgi trafficking using brefeldin A, an ADP ribosylation factor guanine exchange factor (Arf-GEF) inhibitor did not affect LD formation. Loss of function mutations in TBC1D20, a Rab1 GTPase-activating protein (GAP), were found to be associated with Warburg Micro syndrome (WARBM) a severe genetic disorder. Interestingly, fibroblasts from WRBM patents and mouse fibroblasts with similar mutations, show enlarged LDs upon induction of LD formation, further linking Rab1 to LD biogenesis. Transfection of TBC1D20 into these mouse fibroblasts rescued LDs size. Furthermore, Rab1-GFP and Diacylglycerol O-Acyltransferase 2 (DGAT2), an LD associated triglyceride synthesis enzyme accumulated around these large LDs under similar conditions. This accumulation was inhibited by expression DN-Rab1. These results support a model in which Rab1 controls ER budding and connectivity and thus the allocation of biogenesis essential factors and establishes Rab1 as an essential LD biogenesis mediator.

Rapid sterol transfer in vitro by a StAR-kin domain from Lam4p, a Lipid transfer protein Anchored at a Membrane contact site (LAM) in yeast.
L.H. Wong¹³, T. Levine¹;
¹UCL Institute of Ophthalmology, University College London, London, United Kingdom

Sterol traffic inside cells does not require vesicular traffic. Using processes that are completely independent of vesicles passing through the exocytic and endocytic pathways, sterol moves between all membrane bound organelles rapidly and reversibly. Such processes have not been described at the molecular level, but they have been widely ascribed to various lipid transfer proteins that can solubilise sterol, typically by taking it inside a hydrophobic pocket. Such sterol-specific lipid transfer proteins might be able to pick up sterol from donors and deliver it to acceptors with some specificity, and the proteins may even apply some directionality to the lipid traffic. But much remains to be described, including whether the currently known group of sterol-specific lipid transfer proteins has the capacity to meet cellular demand for sterol traffic. Even this parameter is not completely mapped out, but cellular capacity for sterol traffic between the endoplasmic reticulum (where it is made) and the plasma membrane (where it mostly resides) is typically estimated as 4-10 fold higher than needed for cell growth alone.

In 2015 we published the discovery of a large family of Lipid transfer proteins Anchored at Membrane contact sites (called LAMs) common to most eukaryotes. We showed that in budding yeast Lam4p and its parologue Ysp2p have two domains each that solubilise the major species of sterol: cholesterol from mammals, and ergosterol from fungi. Here we have carried out detailed lipid transfer experiments in vitro with the second StAR-kin domain of Lam4p (Lam4S2). Our main finding is that the Lam4S2 in solution, without any accessory domains, transfers sterol at a fast rate compared to most other lipid transfer proteins. By designing symmetric lipid transfer assays, where donor and acceptor are essentially identical, we calculate rate constants for individual steps in more complex transfer reactions. This allows us to dissect each separate step within an entire round of lipid transfer to a greater extent than is usually reported.

During autophagy, functional lysosomes are consumed by their fusion with autophagosomes, leading to formation of autolysosomes. The pool of functional lysosomes is maintained by a process named...
autophagic lysosome reformation (ALR). Lysosomal membrane components are extruded from autolysosomes to form new lysosomes. Most proteins involved in ALR are encoded by genes responsible for neurodegenerative diseases when mutated. This suggest that ALR is important for neuron survival. However, its mechanisms have only been investigated in non-neuronal models so far. Here, we investigated the role of one key player of ALR in neurons, spatacsin that is encoded by SPG11, a gene responsible for a severe form of hereditary spastic paraplegia when mutated. Loss of function of spatacsin impairs ALR leading to autolysosome accumulation and free lysosomes depletion as well as lipids accumulation in lysosomes. We showed that loss of function of spatacsin led to the accumulation of simple gangliosides in autolysosomes in a knockout mouse model, primary cultures of neurons and neurons of cortical organoids derived from induced pluripotent stem cells of SPG11 patients. By preventing gangliosides synthesis in Spg11 knockout cells or by inducing their accumulation in lysosomes in wild-type cells, we demonstrated that elevated concentrations of gangliosides in lysosomes blocked their recycling and promoted the accumulation of autolysosomes. Our results suggest that altered ALR in absence of spatacsin is a consequence of the accumulation of gangliosides rather than a direct role of the protein in lysosome recycling.

Lipid-laden macrophages downregulate Akt phosphorylation and metabolize lipid droplets via autophagy.
R. Sultana1, I. Ratnayake2, M. Schenk1, P. Ahrenkiel2, N. Thiex1;
1Biology Microbiology Department, South Dakota State University, Brookings, SD, 2Department of Nanoscience Nanoengineering, South Dakota School of Mines Technology, Rapid City, SD

Macrophages contribute to plaque formation in atherosclerosis. Macrophages take up modified low-density lipoproteins and store excess cholesterol and triglycerides in lipid droplet organelles. Evidence of lipid-laden macrophages or “foam cells” is apparent on histology sections of diseased arteries, and this lipid-laden appearance can be recreated in cell culture upon exposure of primary macrophages to modified LDLS. Previous work in a variety of cell types suggests that under nutrient stress, neutral lipids in lipid droplets are hydrolyzed by lipolysis, autophagy, or both. However, these processes are not well understood in macrophages. We created lipid-laden macrophages by 24-h exposure to acetylated LDL or oxidized LDL and analyzed dynamics of lipid droplet degradation following removal of LDL from cell culture medium. We found that lipid droplets in these macrophages are cleared within 24 h of LDL removal from the medium. During lipid droplet clearance, there is no evidence of fatty acid delivery to the mitochondria suggesting these lipid droplets are not used as an energy source. Electron microscopy visualization of lipid droplets during formation and degradation showed the presence of double membrane structures surrounding lipid droplets at early stages of degradation. This may indicate the involvement of autophagy in lipid droplet disappearance from macrophages. Inhibition of autophagosome formation by 3-methyl adenine prevented lipid droplet degradation. Immunostaining of phosphorylated Akt showed decreased Akt activation in lipid laden macrophages during lipid droplet degradation. Altogether, these data indicate lipid droplets formed by exposure of macrophages to modified LDLS are degraded by an autophagic process that could be signaled via disruptions in growth factor signaling. Studying the mechanisms of lipid droplet degradation will allow us to understand how lipid droplets could be cleared from foam cells residing in atherosclerotic plaques and identify potential therapeutic targets for treating atherosclerosis.

*Mechanisms of selective death of tumor cells after COPI complex depletion.*  
A. Gasparian¹, M. Aksenova¹, D. Oliver³, E. Levina³, S. Lee³, K. Myttheye³, M. Wyatt³, E. Broude¹, M. Shtutman¹;  
¹Drug Discovery and Biomedical Sciences, University of South Carolina, Columbia, SC, ²Biological Sciences, University of South Carolina, Columbia, SC, ³Chemistry and Biochemistry, University of South Carolina, Columbia, SC

The coatomer protein complex 1 (COPI) is a multisubunit complex that coats intracellular vesicles and is involved in intracellular protein trafficking. Recently we and others found that depletion of COPI complex subunits zeta (COPZ1) and delta (ARCN1) preferentially kills tumor cells relative to normal cells. Here we studied the cellular effects of COPI complex depletion in tumor cells. We showed that this depletion led to the inhibition of mitochondrial oxidative phosphorylation and elevation of ROS production, followed by accumulation of lipid droplets and autophagy associated proteins LC3-II and SQSTM1. At a later stage, the COPI complex depletion caused classical apoptosis of the tumor cells. Inhibition of ROS level in COPI-depleted cells with the mitochondrial-specific quencher mitoquinone (MitoQ) attenuated this apoptosis and drastically decreased both size and number of lipid droplets. Similar results were obtained after treatment of COPI-depleted cells with SP600, an inhibitor of JNK kinase which is known to inhibit mitochondrial ROS production. In COPI depleted cells LC3-II and SQSTM1 colocalized with lipid droplets, suggesting that these droplets may be associated with autophagosomes. However, electron microscopy of COPI depleted cells showed that these droplets are not surrounded by double membranes indicative of autophagic degradation of the lipids. Moreover, no excessive autophagic vacuole formation was seen in COPI-depleted cells. Our findings suggest a sequence of cellular events triggered by COPI-depletion, starting with inhibition of oxidative phosphorylation, followed by ROS activation and accumulation of lipid droplets, which in turn further elevate the level of ROS and triggers apoptosis. This mechanism is highly promising in the development of novel cancer therapy by targeting tumor cells with the diminished level of COPI proteins.

Pascale', Naples, Italy, ⁴Biochemistry Department, Berlin University, Berlin, Germany, ⁵Department of Cellular and Molecular Medicine, University of Copenhagen, Copenhagen, Denmark, ⁶Medical Center, Stony Brook University, Stony Brook, NY

The GOLPH3 oncogene is located on a human chromosome region, which is frequently amplified in solid tumours. GOLPH3 encodes a Golgi complex associated protein involved in membrane trafficking and Golgi structure maintenance. While GOLPH3 role in the stimulation of cell proliferation pathways is widely accepted, how GOLPH3 gain of function mediates oncogenesis is not completely understood. Here we show that GOLPH3 regulates proliferation by promoting sphingolipid glycosylation. Specifically,
we found that GOLPH3 interacts with sphingolipid glycosylating enzymes at the Golgi complex and controls their intra-Golgi recycling during cisternal progression. Through this mechanism GOLPH3 counteracts the physiological leakage sphingolipid enzymes to lysosomes and their consequent degradation thus resulting in increased enzyme levels. Alterations in proteostasis of glycosylating enzymes and in sphingolipid metabolism induced by increased GOLPH3 levels impact on growth signalling pathways, thus promoting uncontrolled proliferation. Importantly, GOLPH3 overexpression/amplification tightly correlates with the sensitivity of tumour cells to pharmacological inhibition of sphingolipid glycosylation suggesting that inhibition of sphingolipid metabolism represents a valuable therapeutic option for patients affected by GOLPH3 dependent tumours.

Molecular mechanisms of Scavenger Receptor SR-BI regulation: linking HDL binding to cholesterol transport.
P.E. Marques¹, S. Nyegaard¹, R.F. Collins¹, W.S. Trimble¹, S. Grinstein¹;
¹Cell Biology, The Hospital for Sick Children, Toronto, ON

Cholesterol is delivered to cells by LDL (low-density lipoprotein) and removed from them by HDL (high-density lipoprotein). Excess cholesterol removed from peripheral tissues by HDL is transported to the liver for conversion into bile acids that are excreted with gastrointestinal contents, a process known as reverse cholesterol transport. HDL also delivers cholesterol to adrenocortical cells for steroid hormone synthesis. Delivery of cholesterol from HDL to these tissues is mediated by the scavenger receptor SR-BI. To better understand the molecular mechanism whereby SR-BI removes cholesterol from HDL before releasing the depleted lipoprotein, we analyzed the subcellular distribution of the receptor, its mobility in the membrane and the dynamics of its internalization. To this end, we developed a receptor-specific short-chain antibody (ScFv). Immunostaining using ScFv covalently labeled with fluorescent probes confirmed that SR-BI is highly expressed on the surface of adrenocortical and liver cells. Monitoring SR-BI in live cells revealed that, strikingly, this receptor was retained at the surface of cells for extended periods, while other receptors and the bulk of the PM were being constantly and rapidly internalized. Failure to internalize did not result from attachment of SR-BI to cytoskeletal structures, since single-particle tracking indicated that the receptors move freely in the plane of the membrane. Accordingly, removal of the PDZ-binding domain proposed to anchor SR-BI to the cytoskeleton did not affect its retention on the membrane. Quantitative analysis of ScFv binding showed that SR-BI exists on the surface of adrenocortical cells as large multimers consisting of an average 10 receptor molecules. These large clusters fail to enter clathrin coated pits, caveolae or GEEC/CLICs, accounting for the inordinate retention of the receptors at the surface. Importantly, SR-BI was able to remove cholesterol from HDL while at the cell surface, without requiring internalization. Cholesterol transported from the lipoprotein to the PM via SR-BI was delivered to the endoplasmic reticulum and eventually to lipid droplets. In this regard, HDL-associated cholesterol is handled very differently from that bound to LDL, which was rapidly internalized and routed through the endocytic pathway. We suggest that the surface retention of SR-BI is attributable to its ability to multimerize and that this feature plays an important role in its function.

Cell-cell fusion is essential for fertilization and sculpting of bones, muscles, epidermis and placenta in different organisms. However, the proteins that mediate membrane fusion between cells have not yet been well-characterized and in some cases are still unknown. HAP2(GCS1) are membrane glycoproteins essential for gamete fusion in plants, Chlamydomonas, Plasmodium, Tetrahymena, and Dictyostelium. To investigate whether HAP2 is not only essential but also sufficient for cell-cell fusion, we expressed the Arabidopsis sperm HAP2 in cultured baby hamster kidney cells that normally do not fuse. We found that HAP2 expression in these heterologous cells results in the formation of multinucleate cells by cell-to-cell fusion. Genetic and cell biological analyses showed that HAP2 has to be present in only one of the fusion partners (usually the male gamete) to fuse. However, we found that when expressed in mammalian cells, Arabidopsis HAP2 is sufficient to fuse them only when expressed in both fusing cells. Thus, HAP2-mediated plasma membrane merger occurs via a bilateral zipper mechanism reminiscent to intracellular fusions mediated by SNAREs, atlastins and mitofusins. Furthermore, expression of HAP2 on the surface of pseudotyped vesicular stomatitis virus results in virus-cell fusion only to cells that also express HAP2. Thus, we propose that, in addition to sperm HAP2, a HAP2-like protein is needed in the egg for gamete fusion. Structural modeling of the HAP2 protein family predicts that it is homologous to class II viral fusion proteins (e.g. Zika, rubella and dengue) and the somatic cell fusogen EFF-1 from C. elegans. Moreover, the recently solved crystal structure of Chlamydomonas’ HAP2 demonstrates structural homology with EFF-1 and class II viral fusion proteins. We name this superfamilly FUSEXINS: Fusexins proteins essential for sexual reproduction and EXplasmic merger of plasma membranes. Fusexins mediate enveloped virus entry into cells, sexual reproduction, and somatic cell fusion. These proteins share the same structure and function but use distinct mechanisms to merge membranes. We hypothesize that modern fusexins have existed since the dawn of eukaryotic cells.

Short Chain Ceramides Disrupt Segregation of Liquid-ordered from Liquid-disordered Components in the Plasma Membrane.
D. Holowka1, B.A. Baird2;
1Department of Chemistry and Chemical Biology, Cornell University, Ithaca, NY

Perturbation of plasma membrane structure by lipid derivatives could provide a general method for assessing functional roles for ordered membrane regions in cell biology. We previously reported that short chain ceramides with either C2 or C6 acyl chains reduce the fluidity of giant plasma membrane vesicles (GPMVs) derived from RBL mast cells; at similar micromolar concentrations, these ceramides
effectively inhibit antigen-stimulated Ca\(^{2+}\) mobilization in these cells (Gidwani et al., J Cell Sci., 2003). We now find that these ceramide analogues inhibit liquid order-liquid disorder phase separation in these GPMVs that normally occurs at low temperatures. Furthermore, they are effective inhibitors of antigen-stimulated tyrosine phosphorylation, as well as thapsigargin-stimulated store-operated Ca\(^{2+}\) entry. The latter points to a role for liquid ordered-like membrane structure in Orai1-mediated Ca\(^{2+}\) entry. In Jurkat T cells, C2-ceramide is also effective at inhibiting Ca\(^{2+}\) mobilization stimulated by either anti-TCR or thapsigargin, consistent with the view that these short chain ceramides effectively interfere with functional responses that depend on ordered membrane structure.

Symmetry breaking and the establishment of spatial patterns of molecules in a dynamic, fluid environment is a hallmark of cellular organization in living systems. Central to many of these cellular signal pathways are phosphorylation reactions, driven by competing lipid kinases and phosphatases. Here, we describe the biochemical reconstitution of a lipid kinase-phosphatase reaction system that drives the interconversion of PI(4)P and PI(4,5)P2 lipids on planar membrane surfaces. This system can be tuned to exhibit bistability and spontaneous pattern formation. Using micropatterned membranes to spatially confine the competitive reaction, we discover that final reaction outcome can be modulated by the geometric size and shape of the membrane environment. The physical mechanism of this process, which we call stochastic geometry sensing, is based on the system’s asymmetrical response to stochastic compositional fluctuations in enzyme copy number and the corresponding local changes lipid density. The fundamental finding is that stochastic geometry sensing provides a relatively simple route for a biologically relevant chemical reaction to form patterns and differentially respond to the geometric constraints of the reaction environment.

Ca\(^{2+}\) releases E-Syt1 autoinhibition to couple ER-plasma membrane tethering with lipid transport.
X. Bian\(^*1,2,3\), Y. Saheki\(^1,2,3,4\), P. De Camilli\(^1,2,3,5\);
\(^1\)Department of Neuroscience and Cell Biology, Yale University School of Medicine, New Haven, CT, \(^2\)Howard Hughes Medical Institute, New Haven, CT, \(^3\)Program in Cellular Neuroscience, Neurodegeneration, and Repair, Yale University School of Medicine, New Haven, CT, \(^4\)Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore, \(^5\)Kavli Institute for Neuroscience, Yale University School of Medicine, New Haven, CT

The extended synaptotagmins (E-Syts) are endoplasmic reticulum (ER) proteins that bind the plasma membrane (PM) via C2 domains and transport lipids between them via SMP domains. E-Syt1 tethers and transports lipids in a Ca\(^{2+}\)-dependent manner, but the role of Ca\(^{2+}\) in this regulation is unclear. Of the

Monday-351
five C2 domains of E-Syt1 only C2A and C2C contain Ca2+-binding sites. Using liposomes-based assays, we show that Ca2+ binding to C2C promotes E-Syt1-mediated membrane tethering by releasing an inhibition that prevents C2E from interacting with the Pl(4,5)P2-rich membrane, as reported in semipermeabilized cells. Importantly, Ca2+ binding to C2A enables lipid transport by releasing a charge-based autoinhibitory interaction between this domain and the SMP domain. Supporting these results, E-Syt1 constructs defective in Ca2+ binding in either C2A or C2C failed to rescue two defects in PM lipid homeostasis observed in E-Syts KO cells, delayed diacylglycerol clearance from the PM and impaired Ca2+-triggered phosphatidylserine scrambling. Thus, a main effect of Ca2+ on E-Syt1 is to reverse an autoinhibited state and to couple membrane tethering with lipid transport.

The β4-subunit of the voltage-gated calcium channel down-regulates Wnt/β-catenin signaling and cell proliferation.

M. Rima1,2,3, M. Daghshi1,4, A. Lopez5, Z. Fajloun3, L. Lefrancois5, M. Dunach6, Y. Mori7, P. Merle5, J.L. Bruses8, M. De Waard1,2,9, M. Ronjat1,2;  
1 L’Institut du thorax, INSERM, CRNS, University of Nantes, Nantes, France, 2 LabEx Ion Channels Science and Therapeutics, Nantes, France, 3 Azm Center for Research in Biotechnology and Applications, Lebanese University, Tripoli, Lebanon, 4 Laboratoire de Génétique Humaine, Université de Tunis El Manar - School of Medicine, Tunis, Tunisia, 5 Hepatology - Croix-Rousse Hospital, Claude Bernard University - Centre of Research in Cancology of Lyon, Lyon, France, 6 Universitat Autonoma de Barcelona, Barcelona, Spain, 7 Department of Synthetic Chemistry and Biological Chemistry, Kyoto University - Graduate School of Engineering, Kyoto, Japan, 8 Natural Sciences, Mercy College, Dobbs Ferry, NY, 9 Smartox Biotechnology, Saint-Martin d’Hères, France

The voltage-gated calcium channel is a heteromeric protein complex comprised of a main pore-forming α1-subunit and the auxiliary subunits β, α2δ and γ. The β-subunits (CACNB) (β1 to β4) are structurally related cytosolic proteins with varying tissue expression patterns that regulate trafficking of the pore-forming α1-subunit to the cell membrane and channel biophysical properties. Mutations in the neuronal β4-subunit (CACNB4) are linked to neuropsychiatric disorders in humans including epilepsy and intellectual disabilities; however, whether the pathogenic mechanism involves channel dysfunction or other cellular processes affected by β4-subunit mutations has not been elucidated. In addition to interacting with the pore-forming α1-subunit, the β4-subunit binds to B56β (a regulatory subunit of the protein phosphatase 2A), translocates to the cell nucleus and regulates gene transcription and cell proliferation, suggesting that the β4-subunit partakes in signaling pathways involved in cell cycle progression. This study investigated whether the β4-subunit regulates the canonical Wnt/β-catenin signaling pathway and affects cell proliferation. We found that co-expression of the β4-subunit with actors of the canonical Wnt/β-catenin pathway in a hepatoma cell line inhibits Wnt responsive gene transcription and decreases the rate of cell division. Treatment with LiCl, which increases β-catenin stability and Wnt signaling by inhibiting glycogen synthase kinase 3 (GSK3), has no effect on β4-subunit-mediated inhibition of Wnt signaling, indicating that the β4-subunit acts downstream GSK3. In contrast, expression β4-subunits mutants unable to translocate to the cell nucleus does not affect Wnt signaling, indicating that nuclear translocation of β4-subunit is necessary to inhibit the Wnt signaling pathway. Co-immunoprecipitation assays show that β4-subunit interacts with the Transcription Factor 4 (TCF4) and overexpression of TCF4 reverses the inhibitory effect of β4-subunit on Wnt signaling. We therefore...
hypothesize that β4-subunit interaction with TCF4 in the cell nucleus interferes with TCF4 binding to β-catenin and inhibits TCF4-mediated gene transcription, suggesting that β4-subunit is a member of the TCF4 repressor family. Regulation of the cell cycle in neuronal precursors is critical for determining the cell number and composition of the cerebral cortex; therefore, these findings suggest that expression and subcellular localization of the β4-subunit regulates neural development and that CACNB4 mutations may affect the physiology of the mature central nervous system by interfering with Wnt signaling in neuronal progenitors.

Divergence in the temporal dynamics of Extracellular-signal regulated kinase (ERK) activity between subcellular compartments.

J.D. Keyes¹, A. Ganesan², J. Zhang¹,²; ¹Pharmacology, University of California San Diego, San Diego, CA, ²Biomedical Engineering, The Johns Hopkins University School of Medicine, Baltimore, MD

The ERK1/2 pathway plays critical roles in eukaryotic biology by transducing extracellular signals into cell-fate decisions. One conundrum is in understanding how disparate signals induce specific responses through a common, ERK-dependent kinase cascade. One major mechanism to control ERK-signaling to induce proper cellular responses is through precise regulation over the temporal dynamics of ERK activity. For example, in the pheochromocytoma PC-12 cell line, ERK exhibits transient activity in response to Epidermal Growth Factor (EGF), ultimately resulting in proliferation. On the other hand, PC-12 cells respond to Nerve growth factor (NGF) with sustained ERK activity and eventual differentiation into neuronal-like cells. An additional mechanism of control over ERK is through spatial regulation of activity; however, it has been difficult to accurately examine differences in activity among specific subcellular locations. To address this issue, we have expanded the toolbox of FRET-based ERK biosensors by creating a series of improved biosensors that are specifically targeted to various subcellular regions. Using these sensors, we have tested the hypothesis that a single extracellular signal can induce different temporal dynamics between subcellular compartments in PC-12 cells. We report that EGF induces transient ERK activity in the cytosol and nucleus, as expected based on previous reports. However, we have discovered that EGF simultaneously induces sustained ERK activity at the plasma membrane of PC-12 cells. Furthermore, we report that PKA and cAMP play an integral role in the differential regulation of ERK at the plasma membrane and the cytosol. Specifically, we observe that increasing basal cAMP induces a more transient activity at the plasma membrane without changing the temporal nature of ERK activity within the cytosol. Inhibiting PKA slows and minimizes the ERK response in the cytosol without affecting ERK activity at the plasma membrane. These spatially disparate results indicate that subpopulations of ERK are differentially regulated in a spatiotemporal manner and that crosstalk with other signaling pathways play an integral role in the regulation of these subpopulations, furthering our fundamental understanding of how this central kinase is regulated in cells.

Transient activation of fission yeast AMPK is required for cell proliferation during osmotic stress.
K.L. Schutt¹, J.B. Moseley¹;
¹Biochemistry and Cell Biology, Dartmouth College, Hanover, NH

The heterotrimeric kinase AMPK acts as an energy sensor to coordinate cell metabolism with environmental status in species from yeast through humans. Low intracellular ATP leads to AMPK activation through phosphorylation of the activation loop within the catalytic subunit. Other environmental stresses also activate AMPK, but it is unclear whether cellular energy status affects AMPK activation under these conditions. Fission yeast AMPK catalytic subunit Ssp2 is phosphorylated at Thr-189 by the upstream kinase Ssp1 in low-glucose conditions, similar to other systems. Here we find that hyperosmotic stress induces strong phosphorylation of Ssp2-T189 by Ssp1. Ssp2-pT189 during osmotic stress is transient and leads to transient regulation of AMPK targets, unlike sustained activation by low glucose. Cells lacking this activation mechanism fail to proliferate after hyperosmotic stress. Activation during osmotic stress requires energy sensing by AMPK heterotrimer, and osmotic stress leads to decreased intracellular ATP levels. We observed mitochondrial fission during osmotic stress, but blocking fission did not affect AMPK activation. Stress-activated kinases Sty1 and Pmk1 did not promote AMPK activation but contributed to subsequent inactivation. Our results show that osmotic stress induces transient energy stress, and AMPK activation allows cells to manage this energy stress for proliferation in new osmotic states.

Signal transduction of human Fc gamma RIIIb for neutrophil extracellular trap (NET) formation.
O. Alemán¹, N. Mora¹, E. Uribe-Querol², C. Rosales¹;
¹Instituto de Investigaciones Biomédicas, Universidad Nacional Autónoma de México, Mexico City, Mexico, ²Facultad de Odontología, Universidad Nacional Autónoma de México, Mexico City, Mexico

Neutrophils are considered the first line of defense during inflammation and infections. Neutrophils migrate from the circulation to sites of infection where they are responsible for antimicrobial functions, including phagocytosis, degranulation, and formation of neutrophil extracellular traps (NETs). Many microorganisms, including bacteria, fungi, and parasites, induce NET formation. Some pharmacological stimuli, such as phorbol 12-myristate 13-acetate (PMA), can also induce NETs. Antigen–antibody complexes are also capable of inducing NET formation. Only, FcgammaR and FcgammaRIIIb have been reported as receptors for NET formation, similarly to PMA stimulation. Direct cross-linking of FcgammaRIIA or integrins did not promote NET formation. FcgammaRIIIb-induced NET formation presented different kinetics from PMA-induced NET formation, suggesting differences in signaling. We explored the signaling pathway activated by FcgammaRIIIb leading to NET formation. FcgammaRIIIb was stimulated by cross-linking it with specific monoclonal antibodies, and NET formation was evaluated in the presence or absence of pharmacological inhibitors. The antibiotic LL Z1640-2, a selective inhibitor of TAK1 prevented FcgammaRIIIb-induced, but not PMA-induced NET formation. Both PMA and FcgammaRIIIb cross-linking induced phosphorylation of ERK. But, LL Z1640-2 only inhibited the FcgammaRIIIb-mediated activation of ERK. Also, only FcgammaRIIIb, similarly to transforming growth factor-beta, induced TAK1 phosphorylation. A MEK (ERK kinase)-specific inhibitor was able to prevent ERK phosphorylation induced by both PMA and FcgammaRIIIb. These data show that FcgammaRIIIb
cross-linking activates TAK1, and that this kinase is required for triggering the MEK/ERK signaling pathway to NETosis.

Testing a model of CK1 autoinhibition.
S.N. Cullati\textsuperscript{1}, Z.C. Elmore\textsuperscript{2}, R.X. Guillen\textsuperscript{2}, J. Chen\textsuperscript{2}, K.L. Gould\textsuperscript{2};
\textsuperscript{1}Cell and Developmental Biology, Vanderbilt University, Nashville, TN

CK1 enzymes signal in a variety of important cellular pathways, including DNA damage repair, mitotic checkpoint signaling, circadian rhythm, Wnt signaling, and neurodegenerative disease progression. Like other multifunctional kinases, CK1 must be regulated in space and time in order to target specific subsets of its substrates in each of the pathways it participates in. However, CK1 is generally regarded as a “rogue” kinase, which is constitutively active, ubiquitous throughout cells and tissues, and unregulated except by autoinhibition.

The current model of autoinhibition holds that CK1 autophosphorylates its flexible carboxy-terminal tail in cis, which causes the C-terminus to interact intermolecularly with the catalytic domain and inhibit kinase activity by acting as a pseudosubstrate. It has been shown that autophosphorylation is a conserved property of CK1 enzymes, that it primarily occurs on the C-terminal tail, and that it results in decreased kinase activity, but we are unaware of evidence demonstrating that the phosphorylated tail actually binds the kinase domain. Therefore, our laboratory is evaluating this proposed mechanism of autoinhibition by identifying autophosphorylation sites on CK1 and biochemically testing the interaction between the C-terminus and the kinase domain. Because CK1 is nonessential in Schizosaccharomyces pombe, we can then investigate the significance of autophosphorylation in vivo.

Using a combination of phosphopeptide mapping and mass spectrometry, we have identified six autophosphorylation sites on the C-terminus of S. pombe Hhp1 and are testing candidate sites on Hhp2 as well as the human homologues CK1d/e. We have produced the C-terminal fragments of Hhp1, Hhp2, CK1d, and CK1e recombinantly and are comparing their abilities to bind the kinase domains when phosphorylated or dephosphorylated. Hhp1 mutants with single autophosphorylation sites mutated to alanine or glutamate have a wildtype phenotype in vivo; now, we are concurrently mutating all of the sites in the C-terminus to determine the functional consequences of autophosphorylation. With this work, we hope to elucidate conserved mechanisms of regulation for the CK1 family of enzymes, which are apical mediators of cell signaling.

ASK1 Activation in Platelets by Oxidized LDL is Independent of CD36.
K. Golla\textsuperscript{1}, R. Sharma\textsuperscript{1}, M. Naik\textsuperscript{1}, U. Naik\textsuperscript{1};
\textsuperscript{1}Cardesa Foundation for Hematologic Research and Center for Vascular Biology Research, Department of Medicine, Thomas Jefferson University, Philadelphia, PA

Oxidized low-density lipoprotein (oxLDL) is a major contributor to platelet hyper-activation in hyperlipidemic conditions. OxLDL induces a prothrombotic phenotype by sensitizing the platelets for activation. Several receptors have been identified for oxLDL on platelets, but majority of the studies were focused on CD36. OxLDL binding to CD36 results in activation of multiple signaling molecules including Src family kinases (SFKs), Vav 1&3, JNK2, ERK5, and reactive oxygen species (ROS). The mechanism(s) by which oxLDL sensitizes platelets for activation is poorly understood. We have recently

Monday-355
identified Apoptosis Signal Regulating Kinase 1 (ASK1), a MAP kinase kinase kinase, in platelets. Here, we show that in human platelets ASK1 is activated by oxLDL as determined by its activation-specific phosphorylation on T845. ASK1 activation was evident with oxLDL concentrations as low as 10μg/ml, with maximal activation observed with 100μg/ml. In contrast, native LDL (nLDL, 10-200μg/ml) failed to stimulate ASK1 activation. The activation of ASK1 was rapid peaking at 1 minute and returning to baseline by 5 minutes. To determine if ROS is responsible for the activation of ASK1, we pretreated platelets with MnTMPyP, a ROS scavenger. MnTMPyP failed to inhibit the activation of ASK1 induced by oxLDL. To determine the mechanism by which oxLDL induces ASK1 activation, we pretreated platelets with 10μM each of pharmacological inhibitors, PP2 for SFKs, Y27632 for Rho kinase, bisindolylmaleimide for PKC, LY294002 for PI3 Kinase, U73122 for PLC, and 25μM of BAPTA-AM to chelate calcium. We found that platelets pretreated with U73122 and BAPTA-AM abolished oxLDL induced ASK1 activation, whereas others had no effect suggesting that ASK1 is activated in a calcium-dependent manner. To investigate the role of CD36 in oxLDL induced ASK1 activation, we used FA6-152, a function-blocking antibody for human CD36, and murine CD36 null platelets. Interestingly, either blocking or lack of CD36 had no effect on oxLDL-induced ASK1/p38 activation suggesting that CD36 is not involved in oxLDL induced ASK1 activation. To determine if ASK1 plays a role in oxLDL-induced sensitization of platelets for activation, we treated platelets with GS-4997, a specific ASK1 inhibitor, before stimulating them with ADP and oxLDL. ADP (10μM) or oxLDL (100μg/ml), showed no aggregation, but combination of oxLDL and ADP showed robust aggregation of vehicle-treated platelets. However, pretreatment of platelets with GS-4997 significantly inhibited oxLDL-induced potentiation of ADP-induced platelet aggregation suggesting that ASK1 plays a role in platelet activation under hyperlipidemic conditions.

ARL11/ARLTS1 is a novel regulator of ERK signaling in macrophages.
S.B. Arya1, H. Kaur1, A. Tuli1;
1Cell Biology and Immunology, CSIR-Institute of Microbial Technology, Chandigarh, India

Although there are more than 20 members of ADP-ribosylation factor (Arf)-like (Arf) family of small GTPases in mammals, function of most Arls remain unknown. Arl11 is a cancer-predisposing gene that has remained functionally uncharacterized to date, except its ectopic expression in cancer cell lines is known to induce apoptosis and inhibit tumor growth. In this study, we report that mammalian Arl11 is expressed in macrophages and its expression is increased upon LPS stimulation. Notably, depletion of Arl11 in both primary macrophages and macrophage cell lines impaired secretion of pro-inflammatory cytokines and phagocytic function of macrophages (including killing of intracellular bacteria). Analysis of LPS-mediated signaling events revealed that ERK1/2 phosphorylation was substantially compromised in Arl11-silenced macrophages. In contrast, increased expression of Arl11 in macrophages led to constitutive ERK1/2 phosphorylation, resulting in macrophage exhaustion and a failure to respond to subsequent LPS stimulation. These findings suggest that Arl11 is both essential and sufficient for MAPK signaling, which in turn regulates pro-inflammatory functions of macrophages. Finally, we found that Arl11 colocalizes and interacts specifically with the phosphorylated form of ERK1/2 associated with cortical actin structures. Taken together, our findings establish Arl11 as one of the target genes upregulated upon pro-inflammatory signaling in macrophages that in turn promotes ERK signaling required for macrophage activation and their immune function.

Cdk2 dependent activation of β-cell metabolism is eclipsed by its inhibitory effect on plasma membrane excitability and insulin secretion.  
S.M. Sdao¹, C. Poudel¹, B.A. Schmidt¹, K.M. Mortensen¹, M.J. Merrins¹;  
¹Department of Biomolecular Chemistry, University of Wisconsin-Madison, Madison, WI

The loss of insulin secretion is a hallmark of diabetes, and it is becoming clear that cell cycle regulators control insulin secretion as well as proliferation. We recently reported that embryonic deletion of cyclin-dependent kinase 2 (Cdk2) in β-cells (Pdx1-Cre:Cdk2−/−) results in impaired glucose tolerance due to defective insulin secretion (Kim et al., J Biol Chem, 2017), revealing a developmental or perinatal requirement of Cdk2. Here, we show that tamoxifen-inducible deletion of Cdk2 in adult β-cells (MIP-CreER:Cdk2−/−) results in improved glucose tolerance and enhanced insulin secretion. Despite these differences, both models of Cdk2 depletion exhibited a strong increase in the glucose dependence of β-cell calcium oscillations. This effect is likely due to the loss of ATP-sensitive K+ (KATP) channels, since kir6.2 transcript was reduced in Cdk2−/−null β-cells, and pharmacological inhibition of Cdk2 correspondingly reduced KATP channel conductance. These results reveal that Cdk2 inhibits insulin secretion by limiting plasma membrane excitability via KATP. In adult β-cells lacking Cdk2, we also observed a 45% reduction in depolarization-induced exocytosis, indicating that Cdk2 is required for the metabolic amplification of insulin secretion. Within the intermediary metabolic pathways, Cdk2-null β-cells exhibited reductions in glucose-dependent lactate accumulation, mitochondrial membrane potential, and mitochondrial NADH utilization. Together, these studies reveal that Cdk2 transcriptionally limits β-cell membrane excitability and the insulin secretory response, and is required to maintain proper metabolic function.

**Board Number: B583**  
PTP activity for IRS-1 regulated by the interaction of C1-Ten with PIP3 via SH2 domain.  
E. Kim¹, D. Kim², H. Jeong², A. Koh², J. Lee², W. Cho³, S. Ryu³;  
¹Division of Integrative Biosciences and Biotechnolog, Pohang University of Science and Technology, Pohang, South Korea, ²Department of Life Sciences, Pohang University of Science and Technology, Pohang, South Korea, ³Departments of Chemistry, University of Illinois at Chicago, Chicago, IL

The termination of tyrosine phosphorylation of insulin receptor substrate-1 (IRS-1) is essential for the regulation of insulin signaling. C1-Ten has previously been implicated in the regulation of IRS-1 as a relevant protein-tyrosine phosphatase (PTP). However, the molecular basis for its regulatory mechanism is not fully understood. Here, we report the characterization of lipid binding property of C1-Ten SH2 domain as a novel character and the role of its SH2 domain in the PTP activity of C1-Ten. C1-Ten SH2 domain has strong preference and high affinity for PtdIns(3,4,5)P3, this allows C1-Ten to function as PTP in cell. Lipid-binding deficient mutant of C1-Ten completely abrogates PTP activity that even though it has activity in vitro. Thus, PTP activity for IRS-1 is regulated by the interaction of C1-Ten with PtdIns(3,4,5)P3 through SH2 domain. These findings have important implications for negative feedback regulation of IRS-1 tyrosine phosphorylation through C1-Ten mediated by PtdIns(3,4,5)P3.

Role of ERK Pathway Inhibition and Retinoic Acid on the Neuronal Differentiation of Mouse ES Cells. Author: Sri Kona, PI: Dr. Eduardo Martinez Ceballos, Southern University and A and M College, Btr LA.
S.D. KONA1; 1Biology, Southern University and A and M College, Baton Rouge, LA

Embryonic stem cells derived from the blastocyst of mouse are pluripotent in nature. These cells can give rise to one of the three germ layers i.e. Ectoderm, Mesoderm or Endoderm. Retinoic acid (RA), a morphogen can induce Hoxa1 through the activation of retinoic acid receptors (RARs). Binding of RA to the RARy receptor may lead to ectodermal (neuronal) differentiation, while binding to RARβ may induce endodermal differentiation and suppression of ectodermal signaling. We have found that the ERK cell signaling pathway plays a major role in ES endodermal differentiation. Inhibition of ERK using the pharmacological inhibitor PD98059 (PD) promotes neurogenesis, which confirms the role of this cell signaling pathway in germ layer specification. In the present study, we have investigated the effect of cell signaling pathways on neuronal vs endodermal differentiation. For this purpose, we treated mouse ES cells with 1μM RA, 10μM PD, 40μM PD and the combination of RA and PD for about 48hrs followed by culturing them in neurobasal medium supplemented with B27. The inhibitor PD and RA increased the generation of neuronal precursors. This was assessed by analyzing the gene expression profiles of various ectodermal, endodermal and mesodermal genes were tested using RT PCR. Upon treatment with 1μM PD, real time PCR analysis showed a drastic increase in expression levels of Nestin and beta tubulin III, which are ectodermal markers. The ectodermal gene expression was also tested at protein level using immunofluorescence. Neurons were generated in the cells treated with PD and RA plus PD. Hence PD treatment could possibly lead to generation of more neurons in 2D cultures. This study might help in tissue engineering and neurodegeneration treatment in long run and also may lead to cost effective regenerative medicine to treat brain diseases.

D. Katoh1, R. Hashizume1, K. Imanaka-Yoshida1, T. Yoshida1; 1Department of Pathology and Matrix Biology, Mie University Graduate School of Medicine, Tsu, Mie, Japan

It has been generally recognized that acidic extracellular pH (pHe) is an important feature of solid tumors that induces tumor invasion and metastasis. We investigate whether acidic pHe induce epithelial mesenchymal transition (EMT) using breast cancer cell line MCF-7. MCF-7 cells normally showed tightly-packed clusters, characteristic of epithelial cells. The cells cultured in acidic medium (pH 6.6) for 2 days showed loss of cell-cell adhesion and delocalization of E-cadherin and β-catenin from cell-cell contact. These changes were also observed in other breast cancer cell line, T-47D. The absolute amounts of E-cadherin and β-catenin were not changed after EMT in total lysates. N-cadherin, vimentin or transcriptional factor that regulate EMT were not upregulated in 2 days, indicating that the change is not complete EMT. Phosphorylation of p38MAP kinase at T180/Y182 was elevated up to approximately three folds after culturing with acidic medium for 3 hours, while Either ERK1/2 or SAPK/JNK did not change in acidic condition. Phosphorylation of SRC at Y416 and FAK at Y925 of SRC substrate site was enhanced after acidic treatments for 30 minutes and 3 hours, respectively. Furthermore,
phosphorylation of cortactin at Y421 and Y466, known as tyrosine residue of SRC substrate, was also enhanced, and the phosphorylated cortactin was co-localized with vinculin at the focal adhesions. SRC kinase inhibitor (PP2) inhibited EMT-like change induced by acidosis, whereas p38MAP kinase inhibitor (SB203580) did not. In conclusion, lowered pHe could induce EMT-like change showing loss of intercellular adhesion. SRC/FAK activation in acidosis might evoke phosphorylation of cortactin and the dislocation from intercellular junctions to the focal adhesions, suggesting promotion of cell motility.

Mechanisms of cross pathway regulation in Saccharomyces cerevisiae.
B. Wang¹, J.P. Shellhammer², A.E. Allen³, S.K. Suzuki¹, H.G. Dohlman¹;
¹Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Crosstalk between signaling pathways is a complex process for which the mechanism is poorly understood. For example, in the model organism Saccharomyces cerevisiae, crosstalk occurs between the high osmolarity glycerol (HOG) and pheromone mating pathways. Although these pathways share several protein components, S. cerevisiae maintains the capacity to initiate distinct responses to the appropriate environmental stimulus. These responses include activation of the terminal MAPKs in the pheromone pathway, Fus3 and Kss1, which are homologous to ERK1/2. The MAPK in the osmotic stress pathway, Hog1, is homologous to p38. Here we describe two mechanisms of cross-pathway inhibition, one by branched chain amino acid second messengers and the second by accumulation of a monophosphorylated and inhibitory form of the MAPK. By conducting a metabolomic screen and genetic studies we found three branched chain amino acids derivatives (HIV, HIC, HMVA) that accumulate in response to salt stimulation. These derivatives dampen the pheromone response in part by phosphorylation of the G protein Gpa1, mediated by the AMPK kinase Elm1. Under the same conditions, we observe accumulation of a monophosphorylated, inhibitory Fus3 species which dampens and delays the mating response. Finally, an important and unexpected consequence of crosstalk is increased cell-to-cell variability. We proposed that output noise in the pheromone response represents a bet hedging strategy that confers a selective advantage to the population in response to stress. We are determining the mechanism by which distinct responders arise by combining transcriptional fluorescent reporters, genetic approaches and mathematical models. Altogether, we are able to propose various mechanisms for cross pathway regulation that offer the potential for more targeted therapies.

The role of MAPK and SCF in the destruction of Med13 in cyclin C mediated cell death.
D.C. Stieg¹, S.D. Willis¹, J. Scuorzo², M. Song³, V. Ganesan¹, R. Strich¹, K.F. Cooper¹;
¹Molecular Biology, Rowan University Graduate School of Biomedical Sciences, Stratford, NJ, ²Medicine, Rowan University School of Osteopathic Medicine, Stratford, NJ

In response to stress, the yeast and mammalian cyclin C translocate from the nucleus to the cytoplasm, where it associates with the GTPase Drp1/Dnm1 to drive mitochondrial fragmentation and apoptosis. Therefore, the decision to release cyclin C represents a key life or death decision. In unstressed cells, the cyclin C-Cdk8 kinase regulates transcription by associating with the Mediator of RNA polymerase II. We previously reported that the Mediator component Med13 anchors cyclin C in the nucleus. Loss of Med13 function leads to constitutive cytoplasmic localization of cyclin C, resulting in fragmented mitochondria, hypersensitivity to stress and mitochondrial dysfunction due to
loss of mtDNA. Recently we showed that this molecular switch operates in a two step process. First, efficient cyclin C nuclear release requires its ROS-induced phosphorylation by the MAP kinase Slt2 in a carboxyl terminal region of cyclin C, which includes a putative Med13 interaction site. The second step involves ROS-induced Med13 destruction by the SCFGrp1 ubiquitin ligase. Med13 associates with Grp1 in two-hybrid assays, and SCF mediated degradation of Med13 requires active cyclin C-Cdk8. However, phosphorylation of Med13 by cyclin C-Cdk8 does not trigger Med13 destruction. This suggests a model in which this kinase primes the Med13 degron for SCFGrp1 and either Slt2, or an as yet unidentified kinase, triggers its destruction. Taken together, these results are consistent with a model in which cyclin C phosphorylation by Slt2 permits its disassociation from Med13, and that Med13 destruction allows full cyclin C release and prevents re-accumulation of the cyclin in the nucleus.

Snf1 dependent destruction of Med13 is required for programmed cell death following oxidative stress in yeast.
S.D. Willis1, D.C. Stieg1, R. Shah1, A.K. Strich1, K.F. Cooper1;
1Molecular Biology, Rowan University, Stratford, NJ

All eukaryotic cells, when faced with unfavorable environmental conditions have to decide whether to mount a survival or cell death response. The conserved cyclin C and its kinase partner Cdk8 play a key role in this decision. Both are members of the Cdk8 kinase module that, along with Med12 and Med13, associate with the core mediator complex of RNA polymerase II. In S. cerevisiae, oxidative stress triggers Med13 destruction, which thereafter releases cyclin C into the cytoplasm. Cytoplasmic cyclin C associates with mitochondria where it induces hyper-fragmentation and programmed cell death. This suggests a model in which oxidative stress mediated destruction of Med13 represents a key molecular switch which commits the cell to programmed cell death. Thus it is important to decipher the precise molecular mechanisms that control Med13 destruction following exposure to oxidative stress. Previous studies have revealed that both cyclin C/Cdk8 and Slt2, the MAPK of the cell wall integrity pathway, are required for the SCFGrp1 mediated destruction of Med13 following oxidative stress. Here we show that the conserved AMP kinase Snf1 is also required for this event. Deletion of Snf1 results in stable Med13 protein levels and predominantly reticular mitochondria morphology following H2O2 treatment. Consistent with this, deletion of Sak1, a Snf1 activating kinase or using the inactive snf1K84R mutant as the only source of Snf1 results in the same phenotypes. Deletion analysis has revealed that the Snf1 degron lies adjacent to the Slt2 degron and contains a potential Snf1 phosphorylation site. Taken together, these results suggest that ubiquitin mediated destruction of Med13 is very tightly controlled, requiring the action of 3 different kinases. As Med13 destruction results in cyclin C nuclear translocation these results support a model in which Med13 degradation plays a key role in controlling a molecular switch that dictates cell fate following exposure to adverse environments.

Type 2 diabetes is linked genetically to cyclin-dependent kinase (Cdk) signaling, however the significance of Cdk1/Cyclin B1 signaling in adult ß-cells remains largely unknown. Here, we show that one of the key mitotic functions of Cdk1/Cyclin B1 – the activation of mitochondrial respiratory Complex I – is active in adult ß-cells and hyperactive in ß-cells from obese (ob/ob) mice. In wild-type islets, an analysis of TCA cycle and electron transport chain (ETC) fluxes with NAD(P)H FLIM and respirometry revealed that 65 ± 13% (P = 0.0106) of Complex I flux and 49 ± 12% (P < 0.05) of State 3 respiration is sensitive to Cdk1 inhibition. Islets from ob/ob mice express more Cyclin B1 and exhibit an even higher sensitivity to Cdk1 blockade, which reduced Complex I flux by 76 ± 11% (P < 0.001) and State 3 respiration by 79 ± 6% (P < 0.001). While Cdk1 signaling and ETC flux were correlated with the activity of glucose-stimulated Ca²⁺ oscillations, insulin secretion increased following Cdk1 inhibition as carbon shifted to the ATP-independent metabolic amplifying pathways. These results reveal that ETC activity is inversely proportional to insulin secretion. Our results further demonstrate that Cdk1 and Complex I are control points for ß-cell metabolism which, in the setting of obesity, rebalance the insulin secretory pathway.

Involvement of specific Akt isoforms in the decidualization mechanisms of the mouse uterus.

P. Adam¹, F. Fabi¹, F. Demontigny¹, L. Tardif¹, S. Parent¹, E. Asselin¹;
¹Medical Biology, Université du Québec à Trois-Rivières, Trois-Rivières, QC

Canadian couples find it increasingly difficult to conceive; unsurprisingly, infertility is a rising problem that currently touches 16% of Canadians trying to conceive. Similar statistics are observed in the USA. Many factors can contribute to this condition, which is thought to mainly arise from dysregulation in the maternal-embryonal communication mechanisms. Successful implantation necessitates an extraordinarily well-coordinated interaction between both the embryonic and maternal cells. In order to achieve this, the endometrium is required to be fully prepared and receptive for implantation; this "window of implantation" is dependent on the process of decidualization. Under the effect of progesterone, estrogen and cyclic AMP, the endometrial stromal cells undergo fundamental phenotypical changes, transitioning from fibroblasts to epithelial, secretory, glycogen-filled cells. Little is known on the signaling pathways involved in the intricate regulation of the decidualization process; the role of multiple crucial pathways, involved in proliferation and apoptosis, remain largely obscure. It has been demonstrated previously that Akt is involved in cell survival and in glycogen synthesis. Three isoforms of Akt have been identified and it is well recognized that they have distinct physiological and pathological roles. We hypothesize that this is also the case during decidualization and the pregnancy onset. The aim of this study is to investigate the regulation of PI3K/Akt pathway during the decidualization process of endometrial stromal cells. Previous in vitro results obtained in our lab using Human

Monday-361
Immortalized Endometrial Stromal Cells suggest that the decrease of specific Akt isoforms and the downregulation of the Akt pathway is necessary for the decidualization process to successfully occur. Therefore, we developed a novel endometrial-targeted mouse model with simple and combine KO of each Akt isoforms. By artificially inducing mouse uterine decidualization, the specific cellular localization, the expression and the activation of each Akt isoforms was investigated during this process in order to evaluate the regulation of PI3-K/Akt pathway. Our results suggest that there is a specific regulation of each Akt isoforms during decidualization that could reveal distinct role during this biological process. Moreover, differences in uterus morphological aspects and average mouse litter number as been observed depending of the KO genotype. Thus, it is clear that the PI3-K/Akt pathway has an important role in fertility. Further studies will allow us to understand the precise signaling mechanisms by which this pathway is regulated and will lead to a better understanding of the cellular and molecular aspects of infertility.

Membrane-localized proteins are essential to transmit signals into the cell. An important issue is the interaction of these proteins with cytosolic proteins. To quantify such often short-lived interactions we have introduced a method based on the combination of micro-structured surfaces and TIRF microscopy.(1,2) We have used the assay to validate the efficacy of medically relevant receptor tyrosine kinase (RTK) modulators.(3) Bait epidermal growth factor (EGF) receptor molecules were forced into microscopic domains, while monitoring co-recruitment of fluorescent intracellular prey Grb2 molecules. Pretreatment with pharmacologically active ingredients used for the treatment of human cancers significantly reduced this interaction. A similar approach was used for the quantitative analysis of the interaction between different insulin receptor substrate (IRS) proteins and the insulin/IGF-I receptor.(4) The micro-patterning technique enabled the measurement of equilibrium associations and interaction dynamics of these molecules with high specificity. We revealed that several domains of IRS critically determine the turnover rate of the receptors. Furthermore, we found significant differences among IRS proteins in the strength and kinetic stability of the interaction with the receptors, which could account for the diverse IRS functions. Finally, we studied the interaction of the GPCR ß2-adrenoceptor (ß2AR) with arrestin-3.(5) By measuring arrestin-3 recruitment and the stability of arrestin-3-receptor complexes in real time using FRAP analysis on micro-patterned surfaces, we could demonstrate that arrestin-3 dissociates quickly and almost completely from the ß2AR. Recently, we have implemented micro-structured and functionalized multi-well plates. This development step sets a milestone in terms of throughput rates of our methodology.

G-protein coupled receptors (GPCRs) are the largest and most diverse group of membrane receptors in eukaryotes, and detects a wide array of physiological cues in the human body. We describe a new molecular device that couples CRISPR-Cas9 programmed genome regulation to natural and synthetic extracellular signals via GPCRs. The design of our synthetic device, named CRISPR ChaCha, displays superior performance over an architecture proposed by the previously reported Tango system. Using a parsimonious mathematical model and gene-reporter assays, we find that CRISPR ChaCha can recruit and activate multiple Cas9 molecules for each GPCR molecule. We also characterize key molecular features that modulate CRISPR ChaCha performance. We adopt the design to diverse GPCRs that sense synthetic and natural ligands including chemokines, mitogens, and fatty acids, and observe efficient conversion of signals to customizable genetic programs in mammalian cells, including regulation of endogenous genes. The new class of CRISPR-coupled GPCRs provides a robust and efficient platform for engineering cells with novel behaviors in response to the diverse GPCR ligand repertoire.

Developing platforms to interrogate membrane protein oligomerization and its functional impact.
A. Khan¹, B. Hawes², A. Weinglass¹;
¹Screening and Compound Profiling, Merck Sharp Dohme Corp., Kenilworth, NJ, ²Project Management, Merck Sharp Dohme Corp., Kenilworth, NJ

Despite the dramatic increase in high resolution integral membrane protein structures and growing evidence with respect to their oligomerization properties over the last decade, the native oligomeric state of GPCRs, ion channel and transporters is uncertain. Moreover the physiological role of oligomerization remains largely elusive. Given the potential impact on pharmacological modulation, resolving this ambiguity provides a potential path to the design of more ‘relevant’ screening assays to identify novel chemical matter. Utilizing GLP-1R and TRPC6 as case studies, here we describe experiments aiming to probe oligomeric state in recombinant and physiologically relevant cells using either genetic or pharmacologic tools. Covalent modification of oligomeric test-pairs with donor or acceptor fluorescent proteins allows an assessment of proximity-based resonance energy transfer. Notably, the approach indicates that when expressed in recombinant cells, GLP-1R as well as TRPC6 forms homo-oligomers. In addition, TRPC6 forms hetero-oligomers with TRPC3, but not TRPC5. Utilizing a complementary approach, fluorescent ligand based TR-FRET, we’ve been working to develop a system enabling the translation of recombinant cell observations to physiologically relevant cells (PRC’s). Preliminary observations provide orthogonal support for the GLP-1R homo-oligomers observed with
fluorescent proteins in recombinant cells, and serve as a starting point to evaluate oligomeric state in PRC’s. By utilizing these approaches in conjunction to CRISPR we aim to develop an ‘oligomerization toolbox’ to provide additional texture into membrane protein biology and modulation strategies.

\(^1\)Biology, Saint Joseph’s University, Philadelphia, PA

The cyclic adenosine monophosphate (cAMP)/Protein Kinase A (PKA) pathway promotes arousal in nematodes, fruit flies and mammals. *Caenorhabditis elegans* displays unique forms of sleep: developmentally timed sleep (DTS) and stress-induced sleep (SIS). The cAMP/PKA pathway is downregulated during both DTS and SIS, however where in the nervous system this is occurring is unknown. *C. elegans* provides a unique avenue for studying the ubiquitous cAMP/PKA pathway with single cell resolution in a living animal. To do this, we have introduced a red light activated adenyl cyclase (AC) called ilac22 and a Förster resonance energy transfer (FRET)-based cAMP biosensor called epac1-camps, into the *C. elegans* system. We have found that activation of IlaC in the DVA interneuron is sufficient to disrupt DTS, SIS and non-physiological quiescence induced by over-expression of neuropeptides. Next, we expressed epac1-camps in the DVA neuron. We predict that during sleep, cAMP will be reduced in the DVA relative to other neurons, and we are currently testing this hypothesis. PKA phosphorylation of the metabolic regulator adenosine monophosphate-activated protein kinase (AMPK) inhibits its activity. To determine if AMPK is functioning downstream of cAMP/PKA we are quantifying AMPK-phosphorylation during SIS.

\(^1\)Biology, The College at Brockport, State University of New York, Brockport, NY

The cellular context within which G protein-coupled receptors reside ultimately dictates their overall function. This is particularly important to consider when studying signaling pathways during tissue development. Our laboratory explores pathways that dictate differentiation of adipocytes as well as those that are significantly impacted by this transformation from pre- to post-adipocyte. Of particular interest is the melanin-concentrating hormone (MCH) signaling pathway, which plays a critical role in the physiology of feeding, sleep-wake cycles, mood, metabolism and energy expenditure in higher mammals through its binding to neuronal and/or peripherally localized G protein-coupled receptors, MCHR1 and MCHR2. MCHR1 is localized to the plasma membrane of pre- and post-adipocytes and physiological responses to MCH seem to vary depending on dose, but in an unusual way such that responses are more pronounced with less hormone; this seems to be the case for influence on lipid droplet formation, cell size and cell senescence. We’ve also discovered that MCHR1 translocates to a transient primary cilium on the surface of differentiating 3T3-L1 pre-adipocytes and we hypothesize that this translocation significantly impacts MCH signaling. Furthermore, we hypothesize that the activity of MCHR1 influences 3T3-L1 cell differentiation. We performed RNA-Seq analysis to compare transcriptomes of preadipocytes under four conditions: +/- MCH and +/- primary cilia. We were able to
confirm that MCH significantly alters gene expression profiles and that ciliated cells have an altered transcriptional response to MCH when compared to non-ciliated cells. Quantitative PCR was subsequently used to verify changes in individual transcripts. We have identified gene expression changes in those responsible for lipolysis, lipid droplet formation, circadian rhythm, and the inflammatory response. Future directions include verifying protein responses and expanding the study to include fully differentiated adipocytes.

To Investigate the Roles of Lysophosphatidic Acid Type 2 Receptor in Cell Senescence.
W. Chen¹, H. Lee¹;
¹Life Science, National Taiwan University, Taipei, Taiwan

Cellular senescence is the state of cell ceases to replicate and has been considered as tumor-suppressive mechanism. Senescent cells reduced rate of cell proliferation, enhanced accumulation of reactive oxygen species (ROS), cell apoptosis and positive signal of senescence activated-β-galactosidase (SA-β-gal) staining. Lysophosphatidic acid (LPA) is a growth factor-like lipid mediator that regulates multiple physiological functions via activation of six LPA GPCR. Moreover, LPA2 was reported to be a protective factor against radiation caused cell damage. However, the roles of LPA and LPA2 in cell senescence still remain unclear. Therefore, we aim to investigate the physiological function of LPA2 in cellular senescence. HEK-293 cell was treated by selective LPA2 agonist compound GR1977143 (GRI) or shRNA to knockdown Lpa2r transcript. Activation of LPA2 in HEK-293 induced accumulation of reactive oxygen species (ROS) and caused high percentage of SA-β-gal+ cells. In addition, activation of LPA2 enhanced expression level of p53 mRNA and led to higher percentage of apoptotic cells in Annexin V/PI flow-cytometry assay. Taken together, our results demonstrated that activation of LPA2 correlates with the accumulation of ROS, enhanced cell apoptosis, and further promotes cell senescence in HEK-293 cells.

Coagulation factor VIIa-mediated protease-activated receptor 2 activation leads to enhanced topoisomerase1 level and contributes to breast cancer progression.
A. ROY¹, P. SEN¹;
¹Department of Biological Chemistry, Indian Association for the Cultivation of Science, kolkata, India

Thrombotic complications have significant impact on the mortality and morbidity of cancer patients, therefore understanding of the molecular interrelation between coagulation factors and tumour development mechanism is vital for thromboprophylaxis. Our finding deals with the intriguing relationship between coagulation activation and cancer development. Role of blood clotting proteins TF-FVIIa in tumour progression have been suggested in various studies. Expression level of tissue factor and its enhanced activity after binding with FVIIa has an augmentative effect on tumour metastasis and cancer associated thrombosis. This binary complex leads to activation of GPCR transmembrane protein protease activated receptor 2 (PAR2), which leads to activation of various cancer signalling pathways. Never before, it has been suggested that coagulatory proteins directly affect the DNA topology. Our finding first time suggests that TF-FVIIa interaction leads to enhanced replicatory and transcriptional progression in cancer cells by relaxing the negatively supercoiled DNA of cancer cells. In-vitro experiments in breast cancer cells showed enhanced transcript and protein level of topoisomerase 1 (TOP1) due to TF-FVIIa interaction by activating the NFκB pathway. Our findings suggest that enhanced
level of cytokines critical for tumour progression are regulated by TF-FVIIa interaction via TOP1 enhanced activity. Coagulation factor VIIa treatment enhances the sensitivity of cancer cells towards camptothecin (TOP1 inhibitor) by several folds. Our observations clearly suggest that the combined effect of FVIIa and camptothecin critically leads to accumulation of potentially lethal DNA lesions in cancer cells leading to its enhanced apoptosis. Our results provide a novel platform to modulate the targeted chemo-therapy against breast cancer cells.

**Molecular Signatures of Opioid Receptors in Response to Ethanol.**

S.J. Tobin¹, O. Golfetto¹, S. Biswas¹, D.L. Wakefield¹, E.E. Cacao¹, V. Vukojevic², L. Terenius², T. Jovanovic-Talisman¹;

¹Molecular Medicine, Beckman Research Institute of the City of Hope Comprehensive Cancer Center, Duarte, CA, ²Clinical Neuroscience, Karolinska Institutet, Stockholm, Sweden

Alcohol (i.e., ethanol) is one of the most widely used and abused psychoactive substances, with a substantial negative effect on health and public safety. Despite considerable scientific and industrial efforts, there are few drugs available for an effective treatment of alcohol dependence. This is partially explained by the fact that ethanol, unlike most psychoactive drugs, does not act on a specific receptor system. Instead, ethanol modulates, directly or indirectly, a variety of important central nervous system functions, including neurotransmission. Interestingly, naltrexone (NTX) – a general pharmacological antagonist of opioid receptor (OR) function – has been reported to reduce relapse in heroin and alcohol abuse. While mechanisms of NTX action on opiate (heroin) abuse are well understood, little is known about the mechanisms underlying its effect on non-opiates (ethanol). To elucidate molecular mechanisms of ethanol action, we are utilizing quantitative super-resolution microscopy techniques. In particular, we are employing pair-correlation analysis of photoactivated localization microscopy data (PC-PALM). Our results indicate that within cells, pharmacologically relevant ethanol concentrations alter the nano-domain distributions of mu- and kappa-opioid receptors (MOR, KOR), actin, and, the lipid raft marker glycosylphosphatidylinositol (GPI). Specifically, ethanol 1) affects short- and long-range organization of ORs in a concentration dependent manner, 2) induces actin polymerization, and 3) increases GPI. We have found that pretreatment of cells with NTX protects against ethanol-induced reorganization of MOR and the lipid raft marker GPI. Unexpectedly, treatment with NTX significantly affects KOR organization, inducing formation of larger and more occupied nano-domains.

**Activation of Airway T2R Bitter Taste Receptors by Pseudomonas aeruginosa Quinolones.**

J.R. Freund¹, B. Chen¹, D.B. McMahon¹, N.D. Adappa¹, J.N. Palmer¹, D.W. Kennedy¹, D.R. Reed¹, P. Jiang², R.J. Lee¹,²,³;

¹Otorhinolaryngology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, ²Monell Chemical Senses Center, Philadelphia, PA, ³Physiology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA

In recent years, taste receptors have become a potential therapeutic target for many diseases because functional bitter taste receptors have been discovered in a vast array of tissues outside of the oral cavity. We previously showed that cells in the airway express a variety of bitter taste receptors (T2Rs). These T2Rs are responsible for innate immune responses in the airway, which are therapeutically
important for ailments such as Chronic Rhinosinusitus and infections. Therefore, it is imperative to understand T2Rs full range of functions in the airway. T2Rs are G protein coupled receptors (GPCRs) that couple to G beta-gamma (Gβγ) (which in turn facilitates IP3 production and calcium release) and Ga-gustducin (a Gai that decreases cAMP). We previously reported that T2Rs found on airway cilia increase ciliary beating and nitric oxide (NO) production when activated by bitter taste receptor agonists. The increased ciliary beating of these cells promotes the movement of mucus and the secreted NO is bactericidal. These actions provide an innate immune response that helps clear the airway of bacteria. One category of bacterial secretions called acyl-homoserine lactone quorum sensing molecules activates T2Rs and elicits an immune response from primary airway cells. However, another type of bacterial quorum sensing molecule, quinolones, had yet to be explored. Non-bacterial quinolones such as quinine and chloroquine are bitter and activate T2Rs. To elucidate whether or not bacterial quinolones are T2R agonists and if they elicit an immune response, calcium and cAMP responses from transfected HEK293T cells and cultured and primary airway cells were analyzed. Various T2Rs were expressed heterologously in HEK293T cells and exposed to bacterial quinolones, 2-heptyl-3-hydroxy-4-quinolone (PQS), 2,4-dihydroxyquinoline (DHQ), and 4-hydroxy-2-heptylquinoline (HHQ). In the transfected HEK293T cells, PQS activated T2R4, 16, 38, and 39 and HHQ activated T214, while DHQ appeared to have no effect. PQS also activated calcium responses in cultured and primary airway cells, and decreased cAMP concentrations in cultured airway cells. In primary airway cells, PQS activated bactericidal NO synthesis and release. Ultimately, we found that T2Rs recognize some bacterial quinolones to activate an innate immune response to these bacterial secreted products.

LAT-associated molecules show distinct kinetic and spatial recruitment during TCR signaling in T cells.
J. Yi¹, L. Balagopalan¹, K. McIntire¹, T. Nguyen¹, L.E. Samelson¹;¹NCI, National Institutes of Health, Bethesda, MD

Engagement of the T cell antigen receptor (TCR) by a peptide-bound major histocompatibility complex molecule (pMHC) results in the rapid formation of microclusters at the site of activation in T cells. Microclusters contain numerous molecules involved in the TCR signaling cascade and are the basic signaling units required for immunological synapse formation and T cell activation. Although TCR microclusters have been studied extensively using confocal microscopy, the stoichiometry and spatial relationships of their signaling components, the kinetics of their recruitment to the microcluster, and the fate of these structures have not been well characterized due to limits in image resolution and acquisition speed. Using TIRF-SIM to examine the kinetics of microcluster formation in Jurkat T cells, and by altering activation conditions, we observed surprising delays between the sequential recruitment of TCR, ZAP70, and LAT-associated signaling proteins. These kinetic delays were affected by activation of co-stimulatory and inhibitory pathways. In addition, TIR-SIM images showed spatially distinct patterns of localization for TCR and LAT-associated signaling molecules. These results reveal novel insights into the spatial and kinetic regulation of TCR microcluster formation and T cell activation.

Basigin (CD147) associates with toll-like receptor 4 (TLR4) via its transmembrane domain.
J.D. Ochrietor¹, J.M. Brown¹;
¹Department of Biology, University of North Florida, Jacksonville, FL

It is known that inflammatory signaling pathways are used by metastatic cancer cells for proliferation and the ability to alter cell interactions. Basigin variant-2, or CD147, is a ubiquitously-expressed member of the immunoglobulin superfamily that is found on tumors and serves as a cell surface marker for the identification of some cancer cells. In addition to being implicated in the Wnt/beta-catenin pathway, CD147 activation also leads to signal transduction pathways using MyD88 and TRIF, despite the lack of consensus amino acid binding sequences for those signaling molecules. Toll-like receptors (TLRs) are a major group of pattern recognition receptors that recognize molecular patterns associated with all classes of pathogenic microorganisms. TLR4 recognizes the lipopolysaccharide component of Gram-negative bacterial cell walls and is the only TLR known to induce signaling through both the MyD88 and TRIF pathways. The purpose of the present study was to determine if CD147 uses TLR4 for signal transduction. It was hypothesized that CD147 interacts with TLR4 using its transmembrane domain, and that the glutamate residue positioned at the center of the otherwise hydrophobic domain plays a role in the interaction. Enzyme-linked immunosorbent binding assays were performed using endogenous TLR4 and recombinant CD147 proteins. The analyses demonstrated that the transmembrane domain of CD147 does interact with TLR4 using the glutamate residue, as well as hydrophobic amino acids within the transmembrane domain. The data suggest that CD147 interacts with TLR4 to influence signaling cascades using MyD88 and TRIF and may be involved in inflammatory signaling cascades used in metastatic cancer cells.

Optogenetic control of TrkA signaling.
J.M. Hope¹, L. Duán¹, S. Guo¹, A. François²,³,⁴,⁵, Q. Ong¹, G. Scherrer²,³,⁴,⁵, B. Cui¹;
¹Department of Chemistry, Stanford University, Stanford, CA, ²Department of Anesthesiology, Perioperative and Pain Medicine, Stanford University, Stanford, CA, ³Department of Molecular and Cellular Physiology, Stanford University, Stanford, CA, ⁴Department of Neurosurgery, Stanford University, Stanford, CA, ⁵Stanford Neurosciences Institute, Stanford University, Stanford, CA

Nerve growth factor/tropomyosin receptor kinase A (NGF/TrkA) signaling plays a key role in neuronal development, function, survival, and growth. TrkA is also implicated in diverse neurodegenerative diseases including Alzheimer’s disease, pain disorders, inflammations and cancers. NGF binds the extracellular domain of TrkA, leading to receptor dimerization and auto-phosphorylation of its intracellular kinase domain. The signaling cascade initiated by NGF/TrkA binding is highly dynamic and complex, and dissection of finer spatial and temporal aspects of TrkA signaling has proven difficult using traditional biochemical methods. We have developed light-inducible strategies that allow for optical control of TrkA activity based on A. thaliana cryptochrome 2 (CRY2) and its binding partner CIB1. We have been able to recapitulate native NGF/TrkA function by optically inducing the plasma membrane recruitment and homo-interaction of the intracellular domain of TrkA. This method successfully initiates PI3K/Akt and Raf/ERK signaling, promotes neurite growth in PC12 cells, and supports the survival of DRG neurons in the absence of NGF. The ability to activate TrkA using light bestows high spatial and temporal resolution for future investigation of dynamic NGF/TrkA signaling.

The Na,K-ATPase β2-subunit modulates epidermal growth factor signaling through NF2/Merlin.
A. Litan1,2, Z. Li1, O. Vagin3, S.A. Langhans1;
1 Nemours/A.I. duPont Hospital for Children, Wilmington, DE, 2 Biological Sciences, University of Delaware, Newark, DE, 3 VA Greater Los Angeles Healthcare System, Los Angeles, CA

The Na,K-ATPase is a ubiquitously expressed integral membrane protein that carries out the extrusion and uptake of Na\(^+\) and K\(^+\) ions across the plasma membrane of most animal cells. The pump consists of a catalytic α-subunit and a regulatory β-subunit, both of which have multiple isoforms. Previous studies from our laboratories and others have established additional roles for Na,K-ATPase as a signaling scaffold and a cell adhesion molecule, independent of its pump activity. While the β1-subunit of Na,K-ATPase is found in most animal cells, the expression of the β2-subunit is mostly restricted to brain and muscle, suggesting tissue-specific functions. To distinguish between isoform specific-functions of the β1- and β2-subunits we chose to use cerebellar granule precursor (CGP) cells, which, unlike most other cell types, express both the β1- and β2-subunit isoforms. In CGP cells, mRNA and protein levels of both the β1- and β2-subunits increased during post-natal maturation. Nevertheless, during this differentiation period, the transcription of the β1- and β2-subunits were regulated by distinct mechanisms, further suggesting that the two isoforms may have separate functions. Knockdown studies of the β1- and β2-subunits in medulloblastoma cells, which originate from CGP cells, and studies in primary mouse CGP cultures revealed a role for the β2-subunit, but not the β1-subunit, in Epidermal Growth Factor (EGF) induced reorganization of the actin cytoskeleton. Our studies further showed that knockdown of the β2-subunit, but not the β1-subunit, resulted in increased Merlin/NF2 levels, accompanied by Merlin-mediated changes in the kinetics of Epidermal Growth Factor Receptor (EGFR) signaling. Thus, our studies for the first time provide a functional link between the Na,K-ATPase β2-subunit and Merlin/NF2, a member of the ERM family of proteins, suggesting a role for the β2-subunit in the organization of actin-dependent structures during neuronal differentiation.

Single-molecule study of VEGFR2 spatiotemporal organization on the endothelial cell surface.
B. Da Rocha-Azevedo1, A. Dasgupta1, S. Lee1,2, T. Kim1, K. Jaqaman1;
1 Biophysics, UT Southwestern Medical Center, Dallas, TX, 2 Korea University, Seoul, South Korea

Vascular Endothelial Growth Factor Receptor 2 (VEGFR-2) is a receptor tyrosine kinase that plays an essential role in the formation of blood vessels in mammals. Activation of VEGFR-2 in endothelial cells (ECs) leads to critical changes in cell behavior such as cell sprouting, polarization, migration and proliferation. The classic model of VEGFR-2 activation involves binding of the growth factor VEGF, followed by dimerization of VEGFR-2 leading to autophosphorylation, which activates complex downstream signaling pathways. Alternative models predict that VEGFR-2 can be in a pre-dimerized state without VEGF. Yet, little is known about the spatial distribution, dynamics, and oligomerization status of VEGFR-2 in its native membrane environment in live endothelial cells. To fill this gap in our knowledge, we have undertaken a quantitative single-molecule study of VEGFR-2 in live microvascular ECs. Specifically, we labeled endogenous VEGFR-2 using Fab fragments of a neutral anti-VEGFR-2 monoclonal antibody, and imaged using total internal reflection fluorescence microscopy. The imaged molecules were then detected and tracked, allowing us to characterize VEGFR-2 movement as well as...
possible interactions as captured by trajectory merging and splitting events. These studies revealed a mix of freely diffusing, confined and immobile VEGFR-2 molecules, with mobility slowing down upon VEGF addition. They also revealed VEGFR-2 trajectory merging and splitting events both in the absence and presence of VEGF. While there were more merging and splitting events in the presence of VEGF, their existence in its absence provides evidence in live cells for the model of pre-dimerization. We hypothesized that pre-dimerization primes the cell to respond to VEGF, as previous studies indicate that the affinity of VEGF to dimeric VEGFR-2 is higher than to monomeric VEGFR-2. We tested this hypothesis in two ways. First, we expressed in CHO cells genetically modified VEGFR-2 constructs that have an increased or decreased tendency for pre-dimerization, and measured VEGF binding via single-cell imaging. We found that, for the same level of VEGFR-2 surface expression, VEGF binding was indeed proportional to the degree of pre-dimerization tendency. Second, we grew ECs long-term in the almost complete absence of VEGF, and monitored the behavior of VEGFR-2 on the cell surface. These experiments revealed that under these conditions ECs presented more VEGFR-2 on their surface, with higher mobility when compared to cells grown in VEGF-containing medium. Together, these experiments and analyses suggest that ECs indeed might modulate the spatiotemporal organization of VEGFR-2 on the cell surface to modulate their sensitivity and response to VEGF. A 3D culture system identifies a new mode of cetuximab resistance in colorectal cancer and provides means to overcome cetuximab resistance.
B. Singh1, G. Bogatcheva1, R.J. Coffey1,2, R. Graves-Deal1;
1Medicine, Vanderbilt University Medical Center, Nashville, TN, 2Veterans Affairs Medical Center, Nashville, TN

A human colorectal cancer (CRC) cell line, HCA-7, when cultured in 3D in type-1 collagen forms two kinds of colonies; either hollow single-layered polarized cysts or solid spiky masses. Individual colonies of both morphologies were isolated and propagated; the lines thus derived retained their cystic and spiky morphologies and were termed CC and SC, respectively. In 3D cultures, CC are sensitive to the EGF receptor (EGFR) neutralizing antibody, cetuximab, while SC are resistant (PNAS 114: E2852-61, 2017). Additionally, when injected subcutaneously in nude mice, CC form well-differentiated tumors, while SC form poorly-differentiated, invasive tumors. Interestingly, in SC, MAPK pathway members were found to be upregulated. We further show that inhibition of MAPK signaling with MEK inhibitor, U0126, restores cetuximab sensitivity in SC. In an RTK array we found upregulation of MET and RON phosphorylation in SC compared to CC. A small molecular inhibitor, crizotinib targeting both MET and RON restored cetuximab sensitivity in SC. Thus, with this 3D system, we have identified a new mode of cetuximab resistance and provided means to overcome cetuximab resistance. We are currently studying the effect of cetuximab/crizotinib combination on inhibition of proliferation, colony morphology, and apoptosis induction in 3D CC and SC cultures. We are also investing other CRC cell lines in 3D for their dependence on this mechanism of cetuximab resistance. As such, this represents a potentially powerful system to identify additional therapeutic sensitivities and disease-relevant genes for CRC.

Alternative Dopamine Signaling in Macrophages.
E. Nickoloff1, K. Runner1, R. Nolan1, P. Gaskill1;
1Pharmacology and Physiology, Drexel University, Philadelphia, United States

Throughout the HIV epidemic, drug abuse has been an important comorbidity in HIV infection. All drugs of abuse significantly elevate CNS dopamine levels, and dopamine has been shown to play a significant role in modulating immune cell function. Previous data from our lab have shown that in macrophages, elevated dopamine concentrations significantly increase HIV infection of these cells. These increases are mediated by activation of both D1-like and D2-like dopamine receptors present on the macrophage surface. However, most studies of dopamine receptor signaling have been done in neurons, and the signaling pathways mediated by dopamine receptors in macrophages remain unclear. To define more precisely the signaling pathways mediating the dopamine-induced increase in HIV infection, we examined the dopamine-mediated cAMP production pathway in primary human macrophages. We detected transcripts of all five dopamine receptor subtypes with qRT-PCR, showing D1-like receptors expressed at a significantly higher level than D2-like receptors in this cell type. To determine if D1-like receptors signaled through the Gas pathway as previously described in neurons, we utilized a sensitive cAMP assay to assess the ability of dopamine to stimulate adenylate cyclase in primary human macrophages. We were unable to observe any increase in cAMP in our cells after 5, 10, 15, or 30 minute treatments with dopamine or the D1-specific agonists SKF-38393 and A68,930. In contrast, isoproterenol increased cAMP in a dose-dependent manner, indicating adenyl cyclase was active in these cells. We looked downstream of cAMP activation and found dopamine treatment does not increase levels of phosphorylated PKA, confirming this pathway is inactive. However, dopamine treatment increased levels of phosphorylated PKC. Taken with our previous data, these findings suggest dopamine signaling in macrophages occurs primarily through an alternative signaling pathway, potentially mediated by Gsα/11 or Gβγ. Significantly, these studies suggest a novel signaling pathway associated with the dopamine mediated increase in HIV infection in macrophages. Improving our understanding this signaling mechanism, and how it interacts with the HIV infection process, may indicate new targets or therapeutic strategies to more effectively ameliorate the effects of HIV in the CNS of HIV-infected drug abusers.

The phosphatase PTPRG inactivates AXL sequestered in membrane lipid domains by the tumor suppressor OPCML.
J. Antony1,2, E. Zanini1, Z. Kelly1, R. Huang2, J. Thiery2, H. Gabra1,3, C. Recchi3;
1Surgery and Cancer, Imperial College London, London, United Kingdom, 2National University of Singapore, Singapore, Singapore, 3Clinical Discovery Unit, Early Clinical Development, AstraZeneca, Cambridge, United Kingdom

In ovarian cancer, the pro-metastatic RTK AXL promotes motility, invasion and poor prognosis. Here we observed that the reduced survival caused by AXL overexpression could be moderated by the expression of the GPI-anchored tumor suppressor OPCML. We subsequently discovered that AXL interacts with OPCML, preferentially so when AXL is activated by its ligand Gas6. As a consequence, AXL accumulates in cholesterol-rich lipid domains, where OPCML resides. Here phospho-AXL is brought in proximity to the lipid domain restricted phosphatase PTPRG, which dephosphorylates the RTK/ligand complex. This prevents AXL-mediated transactivation of other RTKs (cMET and EGFR), thereby inhibiting sustained
phospho-ERK signaling, induction of the EMT transcription factor Slug, cell migration and invasion. From a clinical perspective, we show that OPCML enhances the effect of the phase II AXL inhibitor R428 in vitro and in vivo. We thus unveil a novel mechanism by which two spatially restricted tumour suppressors, OPCML and PTPRG, coordinate to repress AXL onco-genic signalling.

Automated imaging-based technique for simultaneous monitoring of Ca\(^{2+}\) and DAG biosensors enables detailed characterization of GPCR signaling pathways.

J.E. Clayton\(^1\);
\(^1\)Applications, BioTek Instruments, Winooski, VT

G protein coupled receptor (GPCR)-mediated pathways are critical for cells to respond to intercellular and environmental cues and are a major focus of drug discovery efforts. The molecules that activate GPCRs, and the resulting signaling cascades triggered by associated G proteins, are diverse. Activation of the G\(_q\) sub-family of G proteins increases phospholipase C (PLC) activity, converting phosphatidylinositol 4,5-bisphosphate (PIP\(_2\)) into inositol 1,4,5-triphosphate (IP\(_3\)) and diacylglycerol (DAG), both of which function as second messengers. IP\(_3\) triggers release of intracellular Ca\(^{2+}\) stores which regulate calcium-dependent proteins, while membrane-bound DAG activates the signal cascade via protein kinase C.

Here we describe an automated imaging-based approach to characterize the IP\(_3\)/DAG signaling pathway using multiplexed R-GECO Ca\(^{2+}\) and DAG fluorescent biosensors from Montana Molecular. This method produces detailed kinetic profiles of Ca\(^{2+}\) flux and DAG levels following activation of G\(_q\)-coupled receptors within the same population of cells. Background subtraction and image analysis tools enable detection of changes in Ca\(^{2+}\) and DAG levels that is up to 8 times more sensitive than techniques relying on bulk fluorescence measurements.

Carbachol induced stimulation of G\(_q\)-coupled hM1 receptors in HEK-293 and HeLa cells expressing DAG and R-GECO biosensors was used to demonstrate the ability of this system to detect and quantify changes in DAG levels and IP\(_3\)-induced Ca\(^{2+}\) flux. Addition of 30 \(\mu\)M carbachol to HEK-293 resulted in a 9-fold increase in R-GECO fluorescence over baseline. Maximum intracellular Ca\(^{2+}\) concentration was reached within one second of carbachol addition and returned to baseline after approximately 60 seconds. DAG fluorescence levels in the same population increased 2.6-fold over 11 seconds before falling back to baseline over a period of 3 minutes.

HeLa cells exhibited a similar Ca\(^{2+}\) flux profile in response to 30 \(\mu\)M carbachol compared to HEK-293, with a 10-fold increase in R-GECO fluorescence. However, a much smaller increase in DAG levels was detected, with levels increasing 1.2-fold over baseline. Analysis of single cell kinetics revealed that HeLa cells exhibit multiple Ca\(^{2+}\) spikes following stimulation by carbachol that decrease in intensity, with an average interval of 20 seconds. In contrast, stimulated HEK-293 exhibit a single sustained spike in intracellular Ca\(^{2+}\) levels.

The RhoGAP SPV-1 acts through CDC-42 to regulate calcium signaling in the C. elegans spermatheca during embryo transits.

1Bioengineering, Northeastern University, Boston, MA, 2Biology, Northeastern University, Boston, MA, 3Mechanobiology Institute, Singapore, Singapore, 4Cell and Developmental Biology, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel

Biological tubes are essential components of many animal body systems, and the proper regulation of contractility in these tubes is vital for many life processes. The spermatheca, a 28-cell contractile tube and valve in the reproductive system of the nematode C. elegans, provides an ideal model for detailed studies of such tubes. During embryo transits the spermatheca is stretched significantly by oocyte entry, remains distended for a regulated period of time while the eggshell forms, and finally initiates coordinated contraction of the cells, opening the valve and expelling the egg. Spermathecal contractility is controlled by calcium signaling and Rho signaling, and these two signaling pathways control cellular contractility in many other biological contexts, suggesting that mechanisms at work in the spermatheca potentially represent fundamental biological responses to cell and tissue level deformations in biological tubes.

The RhoGAP SPV-1 was previously identified as a key regulator of contractility in the spermatheca, acting through RHO-1. When spv-1 is lost the spermatheca contracts immediately upon oocyte entry, leading to faster embryo transits. While it is known that calcium signaling is necessary for spermathecal contraction, it was unknown if SPV-1 affects calcium signaling, so we examined this using the genetically encoded calcium sensor GCaMP. We find that the loss of spv-1 results in a more rapid onset of calcium signaling upon oocyte entry, and elevated calcium levels throughout embryo transits. Overexpressing spv-1 results in the opposite calcium phenotype, with delayed onset of calcium signaling and decreased calcium levels throughout embryo transits. Studies using a mutated spv-1 which lacks RhoGAP activity exhibit calcium signaling similar to the loss of spv-1, indicating that SPV-1 controls calcium signaling primarily through GTPase activity. SPV-1 has significant GAP activity toward RHO-1 and CDC-42, so we used constitutively active versions of these GTPases to further explore how SPV-1 regulates calcium signaling. We find that increasing RHO-1 activity alters the timing of embryo transits without recapitulating spv-1 mutant calcium signaling, while increasing CDC-42 activity approaches spv-1 mutant calcium signaling without significantly altering the timing of embryo transits. These results reveal a previously unknown role for CDC-42 in the spermatheca, and show that in addition to regulating contractility, SPV-1 in the spermatheca also coordinates the activities of multiple GTPases and regulates calcium signaling. Ongoing work seeks to identify effectors that CDC-42 uses to regulate calcium signaling and to understand how the calcium signaling of individual cells is coordinated to generate tissue level responses.
Flares of active Rho and F-actin locally reinforce the tight junction barrier in response to mechanical stress.

The epithelial barrier is important for generating specialized compartments in multicellular organisms. The barrier property of vertebrate epithelia is dependent on tight junctions, which restrict the flow of ions, water, and small molecules between epithelial cells. Epithelia are subject to a number of cell- and tissue-scale forces, such as cell divisions, extrusions, wound healing, and morphogenetic events. During these events, cell-cell junctions must remodel to accommodate changes in cell shape and mechanical force. However, very little is known about how tight junctions are able to maintain barrier function during these events. In order to examine this question, we developed a highly sensitive barrier assay compatible with live imaging. When we applied this barrier assay to gastrula-stage *Xenopus laevis* embryos, we found that the epithelial barrier is not uniform across space and time. Instead, small barrier breaches occur—often around dividing cells—and persist for minutes before barrier function is restored.

We have previously reported that “flares” of active Rho accumulate at cell-cell junctions, particularly in situations where the cell-cell junctions are compromised. Because Rho flakes occur on similar time scales and at similar locations as barrier breaches, we investigated whether the two may be correlated in space and time. Indeed, we found that local barrier breaches are followed by local increases in Rho activity. As Rho returns to baseline levels, the barrier function is restored. Thus, we hypothesized that Rho may be involved in restoring barrier function on subcellular scales. To further investigate this possibility, we examined fluorescently-tagged tight junction proteins ZO-1 and Occludin with respect to Rho.

Intriguingly, we observed local discontinuities in ZO-1 and Occludin prior to the flare, and both proteins remained locally increased over baseline, or reinforced, following the flare. In order to investigate how active Rho contributes to reinstatement of the barrier and reinforcement of ZO-1, we perturbed actin polymerization and junction contraction using pharmacological tools. Both junction contraction and actin polymerization appear to contribute to ZO-1 reinforcement, as disruption of either results in only partial ZO-1 reinforcement. When both junction contraction and actin polymerization are lost, ZO-1 fails to be reinforced, and the barrier function is not reinstated. Taken together, these data indicate that transient breaches of the tight junction barrier arise in response to mechanical force, and Rho flakes serve to rapidly repair these breaches, preserving the overall barrier function of the epithelium.

Cytokines augment GEF-H1 expression through a cytoskeleton-dependent self-regulatory cycle in the tubular epithelium.

Transforming Growth Factor β1 (TGFβ1) is a major pro-fibrotic cytokine that along with tissue injury promotes epithelial phenotype shifts such as Epithelial-Mesenchymal Transition (EMT). While EMT supports wound healing and cell migration, thereby promoting tissue regeneration, it also plays a
central role in the development of organ fibrosis and cancer metastasis. Cytoskeletal remodeling mediated by Rho family small GTPases is a central event in EMT-associated cell reprogramming, in large part due to its effects on Myocardin Related Transcription Factor (MRTF), a coactivator of Serum Response Factor (SRF). Thus, the Rho- Rho kinase (ROK)-MRTF axis has a major role in pathologies such as inflammation, fibrosis and cancer. However, the context-dependent control of Rho regulators, including Guanine Nucleotide Exchange Factors (GEFs) during EMT remains less explored. We previously found that in tubular cells proinflammatory and profibrotic stimuli activate RhoA through the exchange factor GEF-H1. Here we show that prolonged stimulation of LLC-PK1 tubular cells with TGFβ1, or mechanical stress (cell stretch) or the proinflammatory cytokine Tumor Necrosis Factor-α (TNFα) elevates expression of GEF-H1. Tubular GEF-H1 expression was also increased in unilateral ureteral obstruction (UOO), a mouse model of kidney fibrosis, as shown using laser capture microdissection and micro-PCR. Silencing or inhibiting RhoA, ROK or MRTF reduced basal GEF-H1 expression in LLC-PK1 cells and prevented the TGFβ1- and TNFα-induced elevation. Conversely, Jasplakinolide that induces actin polymerization and activation of MRTF elevated GEF-H1 expression. TNFα and TGFβ activated a luciferase coupled GEF-H1 promoter construct through ROK, and MRTF silencing reduced this effect. Interestingly, silencing of endogenous GEF-H1 also reduced the activity of the promoter construct, suggesting a feedback regulation. Finally, TNFα augmented TGFβ-induced expression of the EMT marker smooth muscle actin (SMA) in a GEF-H1- dependent manner. In summary, our study shows that GEF-H1 expression is elevated by pro-fibrotic stimuli through cytoskeleton remodeling and the RhoA/Rho kinase/MRTF pathway, and this can further augment EMT. Such a self-regulatory positive feed-back cycle might play a key role in the further progression of kidney fibrosis.

RhoGDI Mediates Spatiotemporal Patterning of GTPase Activity During Cell Wound Repair.
A.E. Golding¹, W.M. Bement¹,²,³;
¹Graduate Program in Cell and Molecular Biology, University of Wisconsin-Madison, Madison, WI,
²Department of Zoology, University of Wisconsin-Madison, Madison, WI, ³Laboratory of Cell and Molecular Biology, University of Wisconsin-Madison, Madison, WI

The RhoGTPases experience constant flux as they move through the GTPase cycle. GTPases associated with membrane lipids are activated by GEFs and inactivated by GAPs. A third regulator, RhoGDI, is believed to extract inactive GTPase from the membrane and drive it into a soluble form within the cytoplasm. To better understand RhoGDI function in vivo, we have employed the Xenopus laevis system in which cell damage elicits rapid formation of concentric zones of Rho and Cdc42 activity around wounds. Overexpression of RhoGDI negatively regulates Rho and Cdc42 activity. Simultaneous overexpression of RhoGDI with PKCβ, previously shown to positively regulate Cdc42 activity during cell wound repair, rescues Cdc42 activity but not Rho activity. However, in the presence of non-phosphorylatable S90A RhoGDI, PKCβ is unable to rescue Cdc42 activity. These results suggest that the phosphorylation of RhoGDI by PKCβ promotes localized Cdc42 activity during cell wound repair. To better understand how RhoGDI contributes to the spatiotemporal patterning of GTPases, I generated a RhoGDI mutant designed to bind but be unable to extract GTPases from the membrane. The mutant RhoGDI localizes more strongly to wounds than wild-type and, remarkably, decreases Rho but increases Cdc42 activity. In contrast to the textbook model of RhoGDI function, these results suggest that RhoGDI extracts both active and inactive Cdc42 from membranes. If this is indeed true, RhoGDI can directly control GTPase patterning via extraction of active GTPases.

¹Pharmacology, UNC-Chapel Hill, Chapel Hill, NC, ²Cell Biology, UT Southwestern Medical Center, Dallas, TX

RhoGEFs directly activate Rho family GTPases leading to the regulation of cell shape through alterations in cytoskeletal dynamics. Consequently, cellular morphodynamics requires the exquisite spatiotemporal activation of diverse RhoGEFs acting in concert. Here, we describe a general strategy to produce RhoGEF biosensors. A pair of fluorescent proteins was inserted in a region of the RhoGEF where relief of autoinhibition altered FRET between the fluorescent pair. The design was optimized using high-content screening to produce Vav2 and Asef biosensors where activation causes changes in FRET emission ratios of 210% and 110%, respectively. The optimized Vav2 biosensor is responsive to Src kinase and epidermal growth factor receptor (EGFR), while the Asef biosensor reports activation by APC. The design strategy works for diverse RhoGEFs, including: LARG, b-Pix, Tim and Tiam1.

We used the RhoGEF biosensors together with updated versions of our Rho family GTPase biosensors to examine the relative dynamics of GTPases and RhoGEFs during constitutive migration of MDA-MB-231 breast cancer cells. The RhoGEFs Asef and Vav2, and the GTPases Rac1, Cdc42 and RhoA were all active at the edge of protruding/retracting regions of the cell. Asef, Vav2, Rac1 and Cdc42 had activation patterns that positively correlated with edge velocity, while RhoA showed a negative correlation. We modified our GTPase biosensors to enable simultaneous imaging of RhoGEF and GTPase activity. This revealed that the activity of Asef and Vav2 are closely correlated with Rac1 at the cell edge. Partial correlation analysis of simultaneous imaging data was used to dissect the role of Asef and Vav2 in regulating Rac1 activity. Rac1 activation relevant to protrusion initiation was specifically dependent on Asef. This was confirmed using shRNA knockdown of Asef. This study demonstrates that partial correlation analysis of multiple biosensors can be used to reveal how upstream molecules regulate different target proteins without disruption of normal biological processes.

Cancer metastasis comprises multiple steps of cell migration that requires active remodeling of the cytoskeleton for cells to invade the surrounding tissues. Rho small GTPases are key molecular switches that control such processes and are known to contribute to cancer progression. Among them, RhoA,
Rac1 and Cdc42 specifically promote actomyosin contractility, lamellipodia and filopodia formation, respectively. They are activated by guanine exchange factors (GEFs) and inactivated by GTPase-activating proteins (GAPs). Mutations in Rho are frequent only in a few cancer types, but deregulation of Rho signaling is often associated with tumorigenesis at the level of their gene expression or activation through their regulators or downstream effectors. Intriguingly, RhoA and Rac1 often act antagonistically and have distinct spatiotemporal activity profiles in lamellipodia. However, it is unclear whether the distinct spatiotemporal activity of Rho/Rac can be synchronized by a single protein that is common to both GTPases, which would help in facilitating a more efficient control in cell dynamics. We hypothesize that such an integrator for Rho/Rac signaling could exist by targeting and regulating both RhoA and Rac1 in close proximity.

Expression of the BPGAP1 (or ARHGAP8) is often elevated in primary colorectal tumors, invasive cervical and breast cancer. It is a multi-domain RhoGAP that inactivates RhoA and induces cell protrusions and cell migration via the interplay of its BH domain, Proline-Rich Region and RhoGAP domain. Consistent with its pro-metastatic potential, BPGAP1 translocates the actin regulator, cortactin, to lamellipodia where BPGAP1 also interacts with the inactive form of Rac1, raising the possibility that BPGAP1 could coordinate and integrate Rac1 and RhoA signaling in cell motility. Mechanistically, stimulation by growth factor EGF releases BPGAP1 autoinhibition, exposing its BH domain to recruit the RacGEF, Vav, to activate Rac1 and promote polarized cell motility, cell spreading, invadopodia formation and cancer extravasation. Importantly, BPGAP1 controls local Rho activity that influences Rac1 binding to BPGAP1 and its subsequent activation by Vav1. BPGAP1 therefore acts as a dual-functional scaffold that recruits Vav to activate Rac1 while inactivating RhoA to synchronize both Rho and Rac signaling in cell motility. As EGF receptor, Vav, Rho, Rac and BPGAP1 are all associated with cancer metastasis, BPGAP1 offers a crucial checkpoint for EGFR-BPGAP1-Vav-Rac-Rho signaling axis and possible regimes in cancer intervention.

Metastasis is responsible for 90 percent of cancer related deaths. One of the first steps in metastasis is the local invasion of tumor cells into the surrounding tissue. Invadopodia are actin-based protrusions that mediate the matrix degradation necessary for the invasion, dissemination and metastasis of tumor cells. Here, we demonstrate that Rac3 GTPase is critical for integrating the adhesion of invadopodia to the extracellular matrix (ECM) with their ability to degrade the ECM in breast tumor cells. We identify two signaling pathways important for the regulation of integrin activation at invadopodia and the delivery of matrix metalloproteinase to invadopodia, through the upstream recruiter Calcium and integrin binding protein 1 (CIB1) and the downstream effector G-protein coupled receptor kinase interactor 1 (GIT1). We then show that the activation dynamics of Rac3 at and surrounding the invadopodia core are controlled by two upstream GEFs, Vav2 and BPIX. These GEFs play key roles in
regulating the spatiotemporal dynamics of Rac3 activity, impacting GIT1 localization. Furthermore, we show that the GTPase activating function of GIT1 toward the vesicular trafficking regulator Arf6 GTPase is required for invadopodia matrix degradation. Importantly, Rac3 also regulates the ability of breast adenocarcinoma cells to invade, disseminate and metastasize in vivo. The Rac3-dependent mechanisms that we show here are critical for balancing proteolytic activity and adhesive activity, and to achieve a maximally invasive and metastatic phenotype.

Cdc42 Regulates Dynein and Actin in Terminal Differentiation of Human Erythroblasts.

Mammalian erythroblasts undergo enucleation through a process thought to be similar to cytokinesis. We have reported that dynein and microtubule-organizing centers (MTOCs), that are known to be crucial for proper cytokinesis, mediate organization of the mitotic spindle apparatus that separates the chromosomes during mitosis in erythrocyte progenitors. We showed that dynein inhibition impairs nuclear polarization, thereby blocking enucleation (Kobayashi I. et al. Exp. Hematol. (2016) 44: 247). It is well known that the nucleus is actively extruded by actomyosin in contractile ring. These results suggested to us that an upstream effector in the signal transduction pathway responsible for regulation of dynein, such as the small GTPase Cdc42, may play an important role during terminal differentiation of human erythroblasts. We therefore investigated the effect of the Cdc42 inhibitor, CASIN, 2-[(2,3,4,9-Tetrahydro-6-phenyl-1H-carbazol-1-yl) amino]ethanol, on cytokinesis and enucleation of human colony-forming unit-erythroblasts (CFU-Es, Day7) and mature erythroblasts (Day10) derived from purified CD34+ cells. We assessed the effect of this Cdc42 inhibitor on proliferation and enucleation ratio of CFU-Es and on the distribution of dynein and actin filaments during terminal differentiation of human erythroblasts. CASIN inhibited proliferation of CFU-Es and blocked their enucleation in a dose-dependent manner (0 – 25 μM). Whereas dynein adopted an island-like distribution in the cytoplasm of non-treated CFU-Es, in contrast, in CASIN treated cells, dynein was concentrated near the nucleus as a dot and co-localized with γ-tubulin. The cell number in cell cycle G2/M phase was decreased by CASIN treatment in CFU-Es but not in Day10 cells. Phalloidin staining revealed that formation of actin filaments was inhibited by CASIN in both CFU-Es and Day10 cells. In the CASIN-treated Day10 cells, formation of the actomyosin contractile ring was also inhibited. Notably, the expression of CD71 and glycoporphin A (GPA) in both CFU-Es and Day10 cells and the morphology of erythroblasts were not significantly affected by CASIN treatment. Our data confirm that Cdc42 plays an essential role in both cytokinesis and cell polarization through regulation of dynein and actin filament organization during terminal differentiation of human erythroblasts.
This work was supported by JSPS KAKENHI Grants 15K09448 (WN), 15K19540 (KU), 17K16177 (YG) and 15K09516 (HW) and by a private donation from Dr. Ken Satoh, Satoh Naika Clinic, Sakata 998-0013, Japan.
MAPK pathways play diverse roles in cell differentiation, proliferation, and the response to stress. Different MAPK pathways induce different responses yet can be regulated by shared components. Misregulation of MAPK signaling by inappropriate cross talk has been linked to cancer and other diseases. In the model system budding yeast, three MAPK pathways (filamentous growth or fMAPK, mating and HOG) share components such as the polarity control Rho GTPase Cdc42, p21 activated (PAK) kinase Ste20 and MAPKKK Ste11. We developed methods to directly compare yeast MAPK pathways that share components. Using this system, we showed that each pathway has a unique modality. In particular, the fMAPK pathway was a ‘low and slow’ pathway that sensitized the cell to a variety of inputs, including positional cues and the integrity of the mother bud neck. Testing a library of CDC42 alleles in this system identified pathway-specific versions of Cdc42. Pathway-specific inputs came in part from scaffold-type adaptors (Bem1 and Bem4) that interact with Cdc42. Bem1 and Bem4 failed to interact with versions of Cdc42 specifically compromised for fMAPK signaling. Bem4 preferentially associated with versions of Cdc42 that mimic the closed or GDP-locked conformation that also are sequestered by the guanine nucleotide exchange factor (GEF) Cdc24. Thus, Bem4 may stabilize the interaction between GDP-Cdc42 and Cdc24 to promote GTPase activation. Bem1 associates preferentially with versions of Cdc42 that mimic the GTP-locked or active conformation. Thus, Bem1 may promote subsequent steps in MAPK activation, such as the interaction of GTP-Cdc42 with effector proteins. In support of this idea, a version of Bem1 that was unable to associate with the PAK kinase Ste20 was defective for fMAPK signaling. Bem4 also interacts with the MAPKKK Ste11. Thus, the Bem1-Ste20 and Bem4-Ste11 interactions may promote fMAPK signaling and account for their unique roles in fMAPK regulation. Another control point was PM recruitment of Cdc42 and fMAPK specific components. Bem4 promoted the plasma membrane (PM) localization of Cdc42, and overexpression of the Rho GDP dissociation inhibitor Rdi1 dampened fMAPK activity. Our results indicate that one aspect of MAPK regulation is to boost and sustain Cdc42 activity. Consistent with these results, MAPK activation rescued the temperature sensitivity of a subset of cdc42 alleles. In conclusion, differential regulation of Cdc42 by different scaffold-type adaptors contributes to the unique modality of the fMAPK pathway and may provide a model for how other GTPases are directed to specific pathways to perform specific functions.
by guanine nucleotide exchange factors (GEFs), it is still unclear whether and how RhoA is activated by GEFs at the bleb membrane. Here, we report that a GEF termed MYOGEF can promote bleb retraction through activating RhoA at the bleb membrane. Our results further demonstrate that ezrin, a key regulator of bleb retraction, binds and recruits MYOGEF to retracting bleb membranes. CRISPR/Cas9- or RNAi-mediated depletion of ezrin disrupted the localization of MYOGEF at the bleb membrane. Results from yeast two-hybrid and immunoprecipitation assays indicate that amino acid residues 640-752 in MYOGEF are required for interactions with the amino-terminal region of ezrin that contains a FERM domain. Consistently, a truncated MYOGEF fragment lacking the ezrin-binding region failed to localize to the bleb membrane. In addition, ectopic expression of the MYOGEF fragment lacking the ezrin-binding region slowed down bleb retraction and induced the formation of extended blebs even though ezrin was still recruited to the bleb membrane, suggesting that the ezrin-MYOGEF interaction plays a critical role in promoting bleb retraction. Importantly, CRISPR/Cas9-mediated depletion of MYOGEF or ezrin resulted in deficiency in bleb retraction as well as interfered with RhoA activation and actomyosin cortex reassembly at the bleb membrane. Overall, our findings suggest that, by interacting with ezrin, MYOGEF is recruited to the retracting bleb membrane, where MYOGEF activates RhoA and stimulates the reassembly of the cortical actomyosin network at the bleb membrane, thus promoting bleb retraction.

Complex Colony Morphology as a Multicellular Behavior with Macroscopic Benefits.
J. Chow¹, P.J. Cullen¹, D.M. Ferkey¹;
¹Biological Sciences, SUNY Buffalo, Buffalo, NY

Individuals can work together in many settings to provide a benefit to the population. How individuals work together to accomplish biological tasks is not clear. One rudimentary cooperative behavior that occurs across microbial species is biofilm/mat formation. During this process, cells remain connected to each other by adhesion molecules and/or an extracellular matrix. In pathogens, biofilm/mat formation is required for virulence. One aspect of biofilm/mat formation is the development of complex colony morphology (CCM), which impacts the surface architecture of a biofilm. In the budding yeast S. cerevisiae, CCM involves the development of ruffled ridges across the colony surface. It is not known how cells form this structure or what its function(s) might be. To begin to address this question, CCM was examined in wild-type cells and various mutants by fluorescence microscopy and scanning electron microscopy (SEM). Fluorescence microscopy revealed that ruffles are composites of multiple groups of cells. SEM showed that individual cells within a ruffle align to the axis of the ruffle. Time-lapse photography of CCM development showed how surface architecture changes over time and the role of adhesion during development. The Rho GTPase Cdc42p and its cognate MAP kinase pathway regulated the development of CCM through the mucin Flo11p. Cdc42p’s regulation of apical growth also appeared to play a role. Comparative RNaseq analysis of biofilms with exaggerated CCM and biofilms that fail to make CCM was explored. CCM benefitted cells in a mock predator-prey experiment. Thus, our results provide an example of a role for Rho GTPases, like Cdc42p, in coordinating collective behaviors to produce macroscopic structures that can provide a protective benefit.

Breaking and entering: a pore-ensics analysis.
J.G. Lam1,2, S. Vadla3, S. Pathak-Sharma3, E. McLaughlin3, X. Zhang3, J.A. Swanson4, S.M. Seveau1;  
1Microbial Infection and Immunity, The Ohio State University, Columbus, OH, 2Microbiology, The Ohio State University, Columbus, OH, 3Center for Biostatistics, The Ohio State University, Columbus, OH, 4Microbiology and Immunology, University of Michigan Medical School, Ann Arbor, MI

Gaining entry into a host cell provides a survival advantage to any capable pathogen and this process contributes to the progression of infection. The typical mechanisms of gaining entry include passive phagocytosis by professional phagocytes or active entry into host cells via receptor-mediated endocytosis or introduction of effector molecules into the host cell to modulate endocytic processes. Interestingly, recent evidence indicates that pathogens can also induce host plasma membrane damage as a means to gain entry. Adenovirus HAdV-C2 and eukaryotic parasite Trypanosoma cruzi, the etiologic agents of acute respiratory disease and Chagas disease, have been shown to induce host plasma membrane damage via membrane lytic protein VI or through mechanical disruption, respectively, to take advantage of the subsequent host membrane repair machineries in order to gain entry into the target cells. Our lab recently evidenced that the intracellular pathogen Listeria monocytogenes can use its pore forming toxin listeriolysin O (LLO), a virulence factor thought to only be used to promote bacterial escape from the endocytic vacuole, to disrupt the host plasma membrane and mediate entry. This study was directed at characterizing the signaling cascade downstream of LLO-mediated membrane damage that leads to bacterial entry. Using siRNA, chemical inhibitors, and a live-cell fluorescence resonance energy transfer (FRET) imaging approach, we were able to dissect the spatiotemporal activities of key signaling molecules involved in LLO-mediated entry. Our findings indicate that pore-formation on the plasma membrane leads to an influx of Ca2+, which induces the translocation and activation of a conventional protein kinase C at the plasma membrane and activation of the central F-actin regulator, the Rho GTPase Rac1. Transduction of this signal results in the activation of Arp2/3 and formation of F-actin-mediated membrane protrusions that internalize the bacterium. Using a high-throughput membrane repair assay recently developed in our lab, we showed that the entry signaling pathway was dispensable for membrane repair indicating that although membrane damage may act as an initial step to entry, this novel pathway is characteristically distinct from membrane repair.

 Snf4 promotes Snf1/AMPK GEF activity for Arf3 activation during glucose starvation.
Y. Chen¹, J. Hsu¹, F.S. Lee¹;  
¹Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan, ²Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan

Upon nutrient deprivation, several fungi, including S cerevisiae, undergo invasive growth depicting a developmental switch to penetrate into agar for the exploration of sufficient nutrients. Our previous study indicated that Arf3 is required for yeast invasive growth and that Arf3 is highly activated in response to glucose depletion. We further identified a serine/threonine protein kinase, Snf1/AMPK, acts as a guanine nucleotide exchange factor (GEF) for Arf3p activation upon glucose deprivation. Snf1/AMPK has been identified as an obligate heterotrimer, containing a catalytic α subunit and two regulatory subunits (β and γ). In yeast, the kinase activity of Snf1 (α subunit) is tightly regulated by its activating γ subunit Snf4 and regulatory β subunits Sip1, Sip2 and Gal83. The regulation of Snf1 kinase activity is
much understood; however, how Snf1 acts as GEF to activate Arf3 is unknown. In this study, we address
the regulation of Snf1 GEF activity on Arf3 activation. We show that γ subunit Snf4, but not β subunits,
associated with inactive Arf3 and Snf1 in response to glucose depletion. We further demonstrate that
Snf4 is required for Arf3 activation by directly interacting Snf1 C-terminal GEF domain to efficiently
promote Snf1 GEF activity. These results reveal the regulatory role of Snf4 for Snf1 functions in releasing
its N-terminal kinase domain and enhancing C-terminal GEF activity during glucose starvation.

Deregulation of Rho GTPase Family Members in Myelodysplastic Syndromes and Acute Myeloid
Leukemia.
L. Bueno de Paiva³, F.V. Pericole³, C.O. Torello³, A.J. Ridley², S.T. Saad¹, M. Lazarini¹,³;
¹Hematology and Blood Transfusion Center, University of Campinas, Campinas, Brazil, ²Randall Division
of Cell and Molecular Biophysics, Kings College London, London, United Kingdom, ³Department of
Pharmaceutical Sciences, Federal University of São Paulo, São Paulo, Brazil

The Rho GTPase family is composed of twenty proteins, of which RhoA, Cdc42 and Rac1 are the most
studied. In hematopoietic cells, Rho GTPases have been reported to participate in self-renewal,
differentiation and stem cell interaction with the bone marrow niche. In recent years, abnormal gene
expression of Rho GTPases has been found in many cancers, but most of the family members have been
poorly studied in myeloid malignancies. We aimed to characterize the expression of Rho GTPases in
myelodysplastic syndromes (MDS) and acute myeloid leukemia (AML). Gene expression of ten Rho
GTPases (RhoA, Cdc42, Rac1, RhoB, RhoC, Rac2, Rac3, RhoG, RhoQ and RhoH) was analyzed in six
myeloid cell lines and in bone marrow samples by quantitative PCR using TaqMan assays. Bone marrow
aspirates were collected from patients with MDS (n=35), AML with myelodysplasia-related changes
(AML-MRC) (n=9), de novo AML (n=30) and from healthy donors (n=13). Comparisons were performed
with Mann-Whitney U test and the data is showed as median [max-min]. The study was approved by the
Local Ethical Committee Board. All the Rho GTPases evaluated were expressed in the myeloid cell lines.
A similar pattern of expression was observed between genes from the same subfamily: Rho subfamily,
Cdc42 subfamily and Rac subfamily. When analyzing the expression of Rho GTPases in primary cells, we
observed a reduction of Cdc42 transcripts in MDS patients (0.48 [2.47-0.08]) in comparison with healthy
donors (0.97 [7.08-0.17], P=0.02). Cdc42 showed a tendency to decrease in MDS patients with less than
5% blast cells in the bone marrow (0.53 [1.19-0.08]), P= 0.058 and showed a significant reduction in
MDS patients with higher blast number (0.45 [2.47-0.08], P=0.045). RhoB expression was increased in
AML-MRC (7.78 [23.00-1.07]), compared to healthy donors (2.25 [15.25-0.94], P=0.03). RhoC was
upregulated in AML-MRC (23.45 [84.87-1.41]) and in de novo AML (12.28 [99.22-0.80]) compared with
healthy donors (1.53 [34.66-0.59]), P=0.008, P=0.002, respectively. The other Rho GTPases evaluated
were not altered in MDS or in AML. We also analyzed the correlation of Rho GTPases in patient samples.
Rac2 strongly correlated with RhoA (r=0.70, P<0.0001) and RhoG (r=0.83, P<0.0001). Rho GTPases
appear to have a dual role in cancer and may execute both oncogenic and tumor suppressor activities.
Therefore, Rho GTPase expression is cancer type-specific. Herein we provide first evidence of
downregulation of Cdc42 in MDS, and upregulation of RhoB and RhoC in AML. Since these proteins are
involved in critical hematopoietic cell functions, further studies will be important to elucidate the
relation of their deregulation to the physiopathology of myeloid malignancies. Supported by FAPESP,
CNPq and CAPES.

Investigation of RhoA binding proteins using BioID system.
1Department of Agrobioscience, Kobe University, Kobe, Japan, 2Department of Biomedical Engineering, University of California, Davis, Davis, CA, 3Biosignal Research Center, Kobe University, Kobe, Japan, 4Analytical Laboratory, Kobe Pharmaceutical University, Kobe, Japan, 5Department of Cellular and Molecular Medicine, University of Ottawa, Ottawa, Canada, 6Department of Medicine, McGill University, Montreal, Canada

RhoA belongs to the Rho family of small GTPases and acts as a molecular switch to convert extracellular stimulation by growth factors into cellular signals. Many effector and regulatory proteins of RhoA are known, but, due to rapid activation and deactivation cycle of RhoA, it is difficult to comprehensively analyze the activation state specific binding proteins of small GTPases. To identify cell-type specific signaling molecules via activation of RhoA, we have employed a proximity-dependent biotin identification (BioID) method to compare RhoA (WT) with its active mutant RhoA (G14V). BirA-fused RhoA proteins were ectopically expressed in 293T cells, and biotinylated proteins were purified with Tamavidin 2-REV beads and analyzed by nanoLC/MS/MS. In this study, 147 biotinylated proteins were detected in BirA-RhoA (WT) and 212 proteins in BirA- RhoA (G14V). The emPAI score estimating protein abundance from peptide counts in mass spectrometry were analyzed with OPLS-DA by multivariate analysis to compare the profiles. In this analysis, Ste20-like kinase, SLK was calculated with a higher emPAI score than other proteins, and its biotinylination was confirmed at a lysine residue in the C-terminal region of SLK. In a previous report, SLK was reported to phosphorylate Ser188 of RhoA in vascular smooth muscle cells. Therefore, we verified the role of the interaction between RhoA and SLK using a muscle hypertrophy model of C2C12 cells, carried out in C2C12 myotubes during IGF-I treatment for 48 hours. In the C2C12 myotubes, the level of SLK proteins was increased with differentiation, and IGF-I-treatment enhanced SLK phosphorylation at Ser189, which is an autophosphorylation site related to kinase activity of SLK. Overexpression of RhoA (G14V) enhanced, while inhibition of RhoA activation by dominant-negative mutant RhoA (T19N) suppressed the IGF-I-dependent SLK phosphorylation. Pretreatment with the Rho kinase (ROCK) inhibitor Y-27632 also suppressed the IGF-I-dependent SLK phosphorylation. On the other hand, an increase in phosphorylation of RhoA Ser188 was not observed in the C2C12 myotubes. Furthermore, pretreatment with the SLK inhibitor (Erlotinib) inhibited the IGF-I-stimulated increase in myotube diameter and the expression of myosin heavy chain. Our results indicate that a RhoA-SLK pathway may be involved in regulating muscle hypertrophy in C2C12 cells.

Paclitaxel induces post-translational modifications of RhoGDI alpha as a mechanism to regulate RhoA activity.
H. Horita1, A. Law1, K. Middleton1;
1RD Department, Cytoskeleton Inc., Denver, CO

Communication between the microtubule and microfilament systems have been shown previously, and are thought to be critical for coordinated cellular function. Studies utilizing stabilizing and depolymerizing microtubule agents have been shown to regulate stress fiber formation in part through RhoA dependent mechanisms. A recent study showed low doses of paclitaxel inhibits RhoA function;
however, the mechanism by which microtubule stabilization or destabilization regulates RhoA activity is not fully understood. RhoA activity is regulated by several mechanisms including RhoGDI alpha interaction, which inhibits RhoA activity. RhoGDI alpha is regulated by post-translational modifications such as SUMOylation (SUMO) and acetylation (Ac). Ac of RhoGDI alpha has been shown to inhibit binding to RhoA; thus, promoting RhoA activity. Conversely, SUMO-1 modification of RhoGDI alpha enhances RhoGDI alpha-RhoA complex formation and inhibits RhoA activity. Interestingly, paclitaxel has been shown to alter the SUMO 2/3 state of RhoGDI alpha in mitosis. Thus, we asked whether paclitaxel regulates RhoGDI alpha PTMs as a mechanism to alter RhoA activity. Physiologic and endogenous SUMO 2/3 modified RhoGDI alpha was detected in response to 6 hr paclitaxel treatment. The RhoGDI alpha SUMO 2/3 modification was validated with desumoylase inhibitor, as well as inhibition of the SUMO ligase with 2-D08. RhoA activity was measured over a timecourse of paclitaxel treatment, and surprisingly, there was a rapid increase in RhoA activity at early time points prior to the decrease observed at 6 hr of paclitaxel treatment. The significant decrease in RhoA activity observed at 6 hr correlated with the increase in SUMO 2/3 RhoGDI alpha modification, and suggests that SUMO 2/3 modification of RhoGDI alpha may have a similar role to SUMO-1 modification of RhoGDI alpha. As RhoGDI alpha SUMO 2/3 levels were not detectable at early time points, this PTM could not be responsible for the early change in RhoA activity. However, a paclitaxel induced increase in Ac of RhoGDI alpha did correlate with the increased RhoA activity. Of particular interest, the Ac RhoGDI alpha signal disappeared as the SUMO 2/3 signal appeared, which supports previous in vitro findings of competition between these two types of PTMs on RhoGDI alpha. Importantly, data shown here suggests that crosstalk between RhoGDI alpha Ac and SUMO 2/3 modification occur physiologically in response to paclitaxel, and trapping RhoGDI alpha in an Ac state with TSA treatment prevented SUMO 2/3 modification of RhoGDI alpha in response to paclitaxel. Collectively, these data identify additional regulatory mechanisms between the microtubule and microfilament system, which functions through regulating RhoGDI alpha's PTM state.

**Intermolecular steric inhibition of Ephexin4 is relieved by Elmo1.**

K. Kim¹,², J. Lee¹,², S. Lee¹,², H. Moon¹,², B. Park¹, D. Kim¹,², Y. Joo¹, D. Park¹,²,³,⁵

¹School of Life Sciences, Chonnam National University Medical School, Gwangju, South Korea, ²Research Center for Cellular Homeostasis, Ewha Womans University, Seoul, South Korea, ³Aging Research Institute, Chonnam National University Medical School, Gwangju, South Korea, ⁴Department of Internal Medicine, Chonnam National University Medical School, Gwangju, South Korea, ⁵Department of Biomedical Science and Engineering, Chonnam Institute of Science and Technology, Gwangju, South Korea

Ephexin4, a guanine nucleotide-exchange factor for RhoG, promotes engulfment of apoptotic cells and cancer cell migration in a RhoG-dependent manner, which is synergistically augmented by Elmo1, an Ephexin4-interacting protein. However, the underlying molecular mechanism remains elusive. Here, we report a mechanism by which Elmo1 cooperates with Ephexin4 to activate RhoG. We found that Ephexin4 activity was increased by elimination of its SH3 domain which intermolecularly interacts with the N20 region of Ephexin4. This interaction prevented RhoG from binding to Ephexin4 and thus inhibited RhoG activation. Moreover, we also found that Elmo1 associated with the SH3 domain as well as the N20 region and competed with the SH3 domain for binding to the N20 region, interrupting the interaction of the SH3 domain with the N20 region and thereby promoting RhoG binding to Ephexin4. In addition, the activity of Ephexin4 lacking the SH3 domain was comparable to that of Ephexin4 with
Elmo1. Taken together, the data suggest that Elmo1 relieves the steric hindrance of Ephexin4 generated by the intermolecular interaction of the SH3 domain and makes Ephexin4 more accessible to RhoG.

GTPase Steering by an Enzymatic Corral.  
T.A. Burke¹, N.R. Davenport¹, W.M. Bement¹;  
¹Laboratory of Cell and Molecular Biology, The University of Wisconsin at Madison, Madison, WI

Dynamic arrays of actin filaments and myosin-2 ("actomyosin") drive a broad variety of dynamic biological processes ranging from cell division to wound repair. Such arrays are controlled by the Rho GTPases, proteins that exert their effects on actomyosin by stimulating "effector" proteins when in their active (GTP-bound) state. Traditionally, information flow from the Rho GTPases to the cytoskeleton has been viewed as linear, with GTPase activators (GEFs) stimulating a given GTPase, which then activates effectors which, in turn, modify actomyosin. Subsequently, the process is terminated by inactivation of GTPases by inhibitor proteins (GAPs). However, it is becoming apparent that control of actomyosin arrays entails rapid flux of GTPases from the active to inactive stages that is somehow subject to continual modulation via feedback from the actomyosin itself. Here we test a feedback model in which circular, ring-like waves of Rho activity that direct cell wound repair in the Xenopus oocyte model are driven forward by a self-organizing "enzymatic corral" that forms at their trailing edge. Preliminary results indicate that 1) trailing edge Rho inactivation depends on an F-actin binding protein known as Cortactin and 2) Cortactin exerts its effects on Rho activity by serving as a binding site for two GAPs (RG1 and RG8, RG1/8). Both Cortactin and RG1/8 localize behind the Rho zone, perfectly situated to facilitate the trailing-edge inactivation. As predicted, Cortactin and RG1/8 functionally affect Rho levels. Over-expression of RG1/8 dramatically diminishes the Rho zone. Expression of a Cortactin truncation missing its SH3 domain (implicated in RG1/8 recruitment) causes increased Rho levels, and expression of the SH3 domain in isolation not only causes an outward spreading of Rho activity, but imparts gaps in the usually contiguous ring of RG1/8. F-actin assembly and turnover likely play a crucial role in cortical formation as well. Inhibition of the Arp2/3 complex with the small-molecule inhibitor CK-666 significantly depletes Cortactin from behind the Rho zone, and pharmacological stabilization of F-actin with Jasplakinolide delocalizes Cortactin resulting in an accompanied failure of RG1/8 localization

The dual Rho GEF/Rac GAP protein Bcr regulates p38 MAPK signaling and cell proliferation.  
S.E. Kohrt¹, A.D. Dubash¹;  
¹Biology, Furman University, Greenville, SC

The Rho GTPase family of proteins (including Rho and Rac) control many cell functions including cytoskeleton rearrangement, cell growth, cell to cell adhesion, and cell migration. These proteins cycle between active GTP bound and inactive GDP bound states. Guanine nucleotide exchange factors (GEFs) activate GTPase signaling by exchanging GDP for GTP. GTPase activating proteins (GAPs) inhibit the activity of the G-proteins by hydrolyzing GTP to GDP. Mutations or deregulated signaling have been linked to multiple phenotypes of tumorigenesis for both the Rho and Rac signaling pathways. Though the roles of Rho and Rac in tumorigenesis are extensively studied, less is known about which GEFs or GAPs regulate tumorigenic signaling. The proteins Bcr and Abr are of interest as they contain both a Rho GEF (DH/PH) and a Rac GAP domain, giving them the dual ability to both activate Rho and inhibit Rac
signaling. Bcr has recently been shown to regulate the terminal differentiation of keratinocytes via control of Rho GTPase signaling. Interestingly, we have observed an increase in p38 MAPK activity in a range of skin and breast cancer cells in response to Bcr knockdown. p38 mitogen-activated protein kinase (MAPK) is a transcription factor which controls many biological functions including cell growth and apoptosis. We therefore hypothesize that Bcr-mediated Rho GTPase signaling controls cell proliferation via coordination of p38 MAPK activity. In this study, we show that knockdown of Bcr results in a significant decrease in Raf-mediated anchorage-independent growth in soft agar. Our preliminary evidence using pharmacological modulators of Rho and Rac activity suggest that these proteins are involved in mediating p38 MAPK signaling via Bcr. Future studies will determine if regulation of p38 MAPK signaling by Bcr is responsible for its effect on Raf-mediated anchorage-independent growth. Taken together, these data have highlighted a novel link between the Rho GEF/Rac GAP Bcr and coordination of cell proliferation.

An artificial cell-like system linking cell size and GTPase signaling pathways.
P. Torre1, M. Good1, J.G. Bermudez1;
1Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Signaling pathways in human cells are organized in the cytoplasm and have a pivotal importance in defining cell shape and leading tissue morphology. Rho-GTPases signaling proteins are involved in the formation of actin-based structures, such as filopodia and lamellipodia, which are required for cell motility and polarity, and acto myosin filaments that mediate cell division. The interplay of activation and inactivation of GTPases signaling is controlled by Exchange Factors (GEFs) and GTPase activating proteins (GAPs). GEFs and GAPs form patterns of activation by diffusing, oscillating and concentrating in specific subcellular positions. In this study, we test the hypothesis that GTPase activation is patterned by cellular geometry. Our approach is to overcome the complexity of living cells by encapsulating minimal GTPase networks in artificial cell-like systems. Here, I describe my progress in building this system, including the 1) the reconstitution and the in vitro characterization of pathways regulating Cdc42, RhoA, and Rac1 GTPases, 2) the encapsulation and spatial patterning of GTPase regulators in water in oil emulsions. The latter will enable us to determine how pathway organization and cell geometry control the timing and the pattern of Cdc42 activation. Furthermore I propose a model for feedback can lead to pattern of Cdc42 activation.

Cytoskeleton-Membrane Interactions: Septins

Oligomerization properties and structural plasticity of shs1 capped-rod in interaction with membranes.
C. Taveneau1, G. Pehau-Arnaudet2, A. Di Cicco1, D. Levy1, A. Bertin1;
1Institut Curie, Paris, France, 2Institut Pasteur, Paris, France

Saccaromyces Cerevisiae express five mitotics septins (Cdc10, Cdc3, Cdc12, Cdc11 and Shs1) leading to the formation of two octamers capped by shs1 or/and cdc11 with different structural properties1,2. During cytokinesis, both of them assemble into a filamentous collar at the mother-bud neck in contact with the plasma membrane. This structure is essential for normal morphogenesis and a proper
cytokinesis. Furthermore, Cdc10 is known to interact specifically with phosphatidylinositol-4,5-bisphosphate PI(4,5)P2 in vitro, promoting then filament polymerization and organization on monolayers of one of the octamer.

As cdc11 rods organization and properties are well characterized both in solution and lipid monolayer, we decided to focus on shs1 rods characterization in presence of membrane mimetics studied by (cryo) electron microscopy and cryo-tomography. We highlighted a direct interaction between shs1 subunit and some phosphoinositides, including PI(4,5)P2. This interaction is not as selective as the one characterized for cdc11 octamer. This result led us to dock phosphoinositides polar heads with modeled shs1/cdc11 gtpase domain. The resulting models brought new features concerning shs1/cdc11 interaction with lipids, especially regarding the selectivity of phosphoinositides by septins. Moreover, it appears that presence of membrane stabilizes the NC-interface between shs1 subunits, promoting then the self-assembly of the octamers into paired-filaments and sheets of filaments unseen in solution. The interaction between shs1 rods and the membrane leads to a distortion and a flattening of vesicles, probably in a dynamic way. As a matter of fact, different steps of distortion as well as different organization of shs1 octamers towards these local distortions were observed by cryo-tomography. Finally, it has been proposed that both shs1 and GTP could orchestrate the assembly of cdc11 octamers into the hourglass structure observed during cytokinesis in Saccharomyces Cerevisae. We bring here some clues comforting this hypothesis in vitro, in presence of membrane.

Membrane reshaping by curvature sensitive septin filaments.
C. Taveneau, A. Beber, H. Isambert, P. Bassereau, D. Levy, P. Milhiet, S. mangenot, A. Bertin; 1Department of physical chemistry, Institut Curie, Paris, France, 2Structure and Dynamics of nucleoproteic and membrane assemblies, Structural Biology Center, Montpellier, France

Septins are cytoskeletal proteins that assemble into a variety of supramolecular organizations from paired filaments to bundles, ring like structures or gauzes of orthogonal filaments. Septins are bound to the inner plasma membrane through specific interactions with phosphoinositides. Septins are essential for cytokinesis, participate in the formation of diffusion barrier and might be involved in membrane deformation and rigidity.

Both positive and negative micron-scale curvatures are present at the cleavage furrow (Gaussian “horse saddle” curvatures). To mimic specific curvatures and geometries, we have used PDMS substrates covered with a supported lipid bilayer doped with PI(4,5)P2. “Wavy” PDMS patterned substrates displaying both positive (“bumps”) and negative (“valleys”) curvatures were utilized. Using Scanning electron Microscopy, we have seen that Septin filaments have a preference for negative micrometric size curvatures. On positively curved geometries, septins spontaneously align on the top of the bumps and orient towards null curvature. Besides, this curvature preference is closely related to the ability of septins to reshape and deform membranes. Indeed, bound to Giant Unilamellar Vesicles, septins induce...
striking deformations with regular spikes and hollow micrometric deformations at the surface of liposomes, as visualized by fluorescence microscopy. Smaller vesicles (LUVs of 100-300 nm in diameter), highly positively curved, are flattened by Septin filaments as shown in 3D by cryo-electron tomography. By cryo-EM, we visualize both the septin filaments and the deformed vesicles. In addition, on supported lipid bilayers, septins induce a dramatic reorganization of the lipids in the membrane and deformation of the bilayers as visualized by Atomic Force Microscopy coupled to fluorescence microscopy. Finally, a theoretical model has been generated and accounts for both the visualized deformations and curvature sensitivity which are relevant to describe cytokinesis in vivo.

Dynamic exchange of septin complexes in plasma membrane filaments.
I.M. Mucha-Kruczyńska¹,², M. Baňko², E. Platonova², H. Ewers¹,²;
¹Institute for Chemistry and Biochemistry, Freie Universität Berlin, Berlin, Germany, ²Randall Division of Cell and Molecular Biophysics, King's College London, United Kingdom

Septins are a family of cytoskeletal GTP-binding proteins which are highly conserved in eukaryotes. They play a key role in a number of essential biological processes such as cytokinesis, cell polarity and exocytosis. Septin molecules form linear non-polar hetero-oligomeric complexes, which further coalesce into filaments, rings and other higher-order structures. Defects in septin organization and expression have been linked with various pathological conditions, including neurodegenerative diseases and multiple types of cancer. However, despite the growing number of studies, the exact architecture and mechanism of septin filament formation in cells remains unknown. Here we created a genome-edited cell line in which septin 2 is quantitatively coupled to EGFP to investigate septin filaments in vivo and with single molecule microscopy techniques.

We introduce a rat cell line in which all SEPT2 is endogenously tagged with EGFP. We characterize it using live-cell imaging, RT-PCR, and migration and proliferation assays. We visualize a network of ~500 nm-long septin filaments at the plasma membrane by Single-Molecule Localization Microscopy via GFP-specific nanobodies and resolve a systematic ca. 35nm spacing between consecutive SEPT2-EGFP localizations, suggesting the direct assembly of filaments from complexes. Combined with our immunoprecipitation, immunofluorescence and mass spectroscopy data, we identify the septin complex as an octamer consisting of septins 2, 8 or 11, 7 and 9. Using dual color super-resolution imaging we demonstrate that septins 2 and 7 are incorporated into the same filaments and their positions alternate along a filament in a regular fashion confirming an end-to-end arrangement of septin complexes.

We have found that bleached septin filaments recover their fluorescence in vivo and postulate that septins can dynamically exchange within their higher-order structures. To determine the basic unit of septin exchange we have performed stepwise-photobleaching during the turnover of septin structures in the generated cells. We present that by counting the number of EGFP bleaching steps we can identify the newly-recruited septin structures to the plasma membrane. Furthermore, by following the EGFP
fluorescence we resolve septin filaments during their formation in cells. Based on the obtained data we suggest that in filaments septins exchange as single complexes and there is no preferential addition of new septin subunits to the filament ends.

Here we have established a new genome-edited mammalian system for biochemical and microscopy studies of septins. In this cell line, septin complexes assemble into actin-independent filaments in a dynamic fashion. Our data present unprecedented insight into the assembly of septins in live mammalian cells.

Deciphering the regulatory role of Septin9 N-terminus in mammalian septin polymerization.
F. Soroor1,2, W.S. Trimble1,2,  
1Cell Biology Program, Hospital for Sick Children, Toronto, ON, 2Department of Biochemistry, University of Toronto, Toronto, ON

Septins are GTP-binding cytoskeletal proteins conserved from yeast to man. In humans there are 13 genes, many of which undergo alternative splicing, giving rise to a large number of isoforms, although the significance of these isoforms remains unknown. The 13 genes fall into 4 subfamilies and it is thought that two copies of a member of each family assemble in an ordered array into hexamers or octamers that serve as the building blocks for larger filaments. In the case of octamers, SEPT9 is located at the terminal positions, indicating that SEPT9-SEPT9 interactions are critical for polymerization. However, the mechanisms that control septin polymerization are not understood. Moreover, SEPT9 undergoes alternative splicing to produce 5 N-terminal splice variants. Importantly, mutations in SEPT9 N termini have been linked to hereditary neuralgic amyotrophy and changes in the relative expression of SEPT9 splice variants have been associated with cancer progression. Since the N termini constitute the interaction surface involved in octameric septin polymerization, it is possible that different isoforms may have different polymerization properties.
To begin to examine the factors regulating septin polymerization, we developed in vitro polymerization assays using septin complexes purified from mammalian cells. Stable mammalian cell lines were generated expressing GFP-FLAG-His6-tagged versions of SEPT9i1, SEPT9i3, SEPT9i4 or SEPT9i5 under the control of an inducible promoter. Ectopic expression of each isoform caused a reduction in the levels of endogenous isoforms as they compete to cap the limited numbers of octameric complexes. Blue native PAGE revealed that the expressed GFP-FLAG-His6 tagged version of Sept9 capped the hexamers to form octamers that are detectable with GFP antibody. Immunopurification using anti-FLAG antibody conjugated to beads allowed isolation of the mammalian septin complexes from these cell lines, as confirmed by Coomassie blue staining after SDS-PAGE and Western blot. Isolated complexes were imaged using fluorescence microscopy and electron microscopy. The majority of septin complexes isolated from this cell line were rod shaped, 32-35nm long and 4-5nm in diameter, consistent with the predicted size for septin octamers. In-vitro polymerization was promoted by dialysis against low salt buffer and micron-long septin filaments and higher order structures were visualized with EM and fluorescence microscopy. Now that we have established a reliable system to produce functional mammalian septin octamers for in-vitro polymerization, we will isolate mammalian septin octamers that are distinguished by different SEPT9 isoforms to determine the importance of isoform specificity on the formation of filaments and higher ordered structures.
Mechanisms controlling micron-scale membrane curvature recognition by septins.
K. Cannon1, A.S. Gladfelter1;
1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Shape is an important feature of cells and can be described in terms of membrane curvature. It is relatively well understood how cells generate different shapes, but comparatively little is known about how cells recognize their own shape and use information about their geometry. In yeast and mammalian cells the septin cytoskeleton localizes to sites of micron-scale membrane curvature. How septins recognize micron-scale membrane curvature are not understood. Septins can differentiate between different curvatures in vitro in a minimal system composed of supported lipid bilayers on beads and rods of different diameters, allowing dissection of the mechanisms of septin curvature sensing. We predict that the basis for curvature sensing involves a combination of membrane binding affinity, filament polymerization rates and higher-order structure formation that are tuned by association with different curvatures. There is some support for a polybasic patch that septins use to bind lipid membranes, however what surfaces of septins are capable of membrane binding are not established. Primary sequence analysis revealed an amphipathic helix at the C-terminus Cdc12. Amphipathic helices are used by many proteins that sense curvature on the nanometer scale because of their ability to insert into membranes. We investigated the role of this amphipathic helix in membrane binding and curvature sensing by mutating either the polar or hydrophobic face of the helix, followed by measuring septin adsorption onto lipid-coated beads. In both cases, we found septin adsorption was significantly reduced indicating that this region of the protein can modulate association with curved membranes. Previous work identified a role for septin polymerization in robust curvature sensing. Saturation binding curves on beads of optimum curvatures show that septin adsorption is a highly cooperative process. This cooperativity in assembly on curved surfaces could emerge from polymerization and/or higher-order assembly of filaments. Using scanning electron microscopy imaging of septins assembled on rods of different diameters, we found that septin filament orientation is dependent on the local curvature. On rods, filaments arrange in parallel arrays orthogonal to the positive curvature axis at low radii, at a variety of angles at intermediate radii and parallel to the curvature axis at larger radii. This indicates that curvature influences the arrangement and orientation of septin filaments within a higher-order structure and supports that cooperativity could exist at multiple stages of the curvature-dependent assembly process. This work provides insight into how the septin cytoskeleton binds membranes and uses cooperative assembly to distinguish micron-scale membrane curvatures.

Analysis of septin assembly using optogenetics and in vitro reconstitution.
B. Woods1, A.S. Gladfelter1;
1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Cells build micron-scaled structures from relatively small, nanometer-scaled proteins. The septin cytoskeleton is particularly adaptable in its ability to form micron-scale structures in a variety of shapes, sizes, and functions. Septins are conserved from fungi to mammals and self-assemble into heterooligomeric, rod-shaped complexes 17-32 nanometers in length. These “rods” can polymerize into filaments (hundreds of nanometers long) at the plasma membrane or associated with other cytoskeletal proteins. Septin filaments can be arranged into higher-order assemblies such as laterally associated...
bundles, crosslinked lattices, wrapped gauzes, and curved rings. Higher-order assemblies serve as platforms for protein localization including the polymerization of other cytoskeleton proteins, scaffolds for cell signaling events during morphogenesis, and possibly even act as protein diffusion barriers. How are septin filaments arranged into higher-order assemblies? And how are different assemblies positioned at distinct cortical locations? Genetic studies in multiple model systems have identified a substantial network of factors proposed to regulate septins, including kinases and cell polarity proteins. However, little is known mechanistically about how these septin regulators help form higher-order septin assemblies at the molecular level. To investigate which candidate regulators might position and shape septin assemblies, we used optogenetics in both budding yeast and the filamentous fungus Ashbya gossypii. Optogenetics enable tunable subcellular targeting of a protein of interest to a specified cortical site using focused light. Our results suggest that polarity proteins, such as Cdc42, can both position and shape septin assemblies. In parallel experiments, we reconstitute septin assembly on supported lipid bilayers using purified, recombinant septin complexes co-incubated with recombinant regulators. These combined approaches are revealing how septin filaments can be shaped and patterned into different geometries to build distinct higher-order septin assemblies.

The role of focal adhesion-localized calcium sparks in the sensing of extracellular matrix mechanical properties.
A.Y. Moalim¹, S.V. Plotnikov¹;
¹Department of Cell and Systems Biology, University of Toronto, Toronto, ON

The ability of individual cells to sense and integrate multiple extracellular cues underlies many types of cellular behavior including proliferation, differentiation, and migration. Recently, it has been established that mechanical cues such as extracellular matrix (ECM) stiffness are sensed by cells to direct both normal and pathological phenotypes. Several cellular structures, including integrin-based focal adhesions (FAs), have been shown to be essential for ECM stiffness sensing. Nevertheless, the exact molecular mechanism of ECM stiffness sensing remains elusive. Here we show that mouse embryo fibroblasts increase cell area as substrate stiffness increases and that calcium is necessary for this mechanosensitive response, particularly at high ECM stiffness. Furthermore, fibroblasts plated on stiff substrates display local fluctuations of extracellular calcium entry within FAs, i.e. calcium sparks, indicating that calcium sparks may mediate the detection of stiff ECM. Chemical perturbations showed that these calcium sparks occur via FA-localized stretch-activated ion channels under the control of cellular actomyosin contractility, indicating an intimacy between these mechanosensing-critical calcium sparks and the mechanical activity of the cytoskeleton. Analyzing the properties of calcium sparks at both the small scale along individual FAs and at the large scale across the whole cell clarified the relationship between calcium spark dynamics, FA turnover, and cell migration. Critically, chemical and genetic manipulation allowed us to narrow down the stretch-activated ion channel responsible for sparks and critical for ECM stiffness detection. Thus, we present FA-localized calcium sparks as a means for cells to detect ECM stiffness by converting the mechanical activity of the cell against the ECM to a discrete intracellular biochemical signalling event.

Substratum stiffness modulates proliferation downstream of Wnt3a by regulating integrin-linked kinase and frizzled-1.
S. Han¹, M. Pang², C.M. Nelson¹²;
¹Molecular Biology, Princeton University, Princeton, NJ, ²Chemical and Biological Engineering, Princeton University, Princeton, NJ

The Wnt/β-catenin signaling pathway controls a variety of cellular behaviors, aberrant activation of which is closely associated with tumor progression in several types of cancer. The same cellular behaviors are also affected by the mechanical properties of the extracellular matrix (ECM), which induces signaling through integrins and integrin-linked kinase (ILK). However, it remains unclear how cells integrate mechanical signals such as ECM stiffness with biochemical signals such as Wnt. Here, we investigated the mechanisms by which cell proliferation is regulated by ECM stiffness and Wnt signaling. We found that treatment with Wnt3a increased the proliferation of cells cultured on stiff substrata, with compliances characteristic of breast tumors, but not on soft substrata, with compliances comparable to that of normal mammary tissue. Depleting ILK rendered cells unresponsive to Wnt3a on both substrata. Ectopic expression of ILK permitted Wnt3a to induce proliferation of cells on both soft and stiff substrata. These results suggest that ILK is required for proliferation downstream of Wnt3a on stiff substrata and sufficient to permit proliferation downstream of Wnt3a on soft substrata. We further showed ILK regulates expression of the Wnt receptor Frizzled-1 (Fzd1), suggesting the presence of a positive feedback loop between Wnt3a, ILK, and Fzd1. These findings suggest that tissue mechanics regulates the cellular response to Wnt under physiological and pathological microenvironmental conditions.

Stopping Transformed Growth with Rigidity Sensing Modules: Turning a Devil into an Angel.
B. YANG¹, H. Wolfenson², N. Nakazawa³, S. Liu³, J. Hu³, M.P. Sheetz¹²;
¹Mechanobiology Institute, National University of Singapore, Singapore, Singapore, ²Department of Biological Sciences, Columbia University, New York, NY, ³Department of Mechanical Engineering, Columbia University, New York, NY

The growth of non-transformed cells depends upon rigid matrices (anchorage-dependent growth). In contrast, a hallmark of cancer cells is their ability to grow on soft surfaces (transformed phenotype), i.e. on soft agar. One plausible explanation for transformation is that it results from depletion of the rigidity-sensing apparatus. Recent findings reveal that rigidity sensing depends upon a modular complex of cytoskeletal proteins and tyrosine kinases that produce sarcomere-like local contractions. Depletion of any one of several cytoskeletal proteins in the sensing module blocks local contractions and rigidity sensing. It also promotes growth on soft surfaces. To test if this is relevant to cancer, we analyzed different transformed cancer cell lines and discovered that they all lacked rigidity sensing. Further, different cytoskeletal proteins involved in mechanosensing were depleted in each cancer. Restoration of normal cytoskeletal protein levels, either of myosin-IIA in Cos7 cells (Cos7-IIA) or of tropomyosin 2.1 (Tpm2.1) in MDA-MB-231 cells (231-Tpm) restored normal anchorage-dependent growth and rigidity sensing. Importantly, reciprocal depletion of Tpm2.1 and myosin-IIA from the Cos7-IIA and 231-Tpm cells, respectively, blocked rigidity sensing and enabled transformed anchorage-independent growth.

Monday-392
Thus, depletion of any one of multiple cytoskeletal components of rigidity-sensing modules enables transformed growth in metastatic and non-metastatic cells.

Myofibroblast Differentiation of Fetal Fibroblasts is Inhibited in Response to ECM Rigidity and TGF-b1.
R.J. Jerrell¹, M.J. Leih¹, A. Parekh¹,²,³,⁴;
¹Otolaryngology, Vanderbilt University Medical Center, Nashville, TN, ²Vanderbilt-Ingram Cancer Center, Vanderbilt University Medical Center, Nashville, TN, ³Biomedical Engineering, Vanderbilt University, Nashville, TN, ⁴Cancer Biology, Vanderbilt University, Nashville, TN

During dermal wound healing, extracellular matrix (ECM) rigidity and transforming growth factor-b1 (TGF-b1) induce fibroblasts to differentiate into myofibroblasts in the wound bed. Myofibroblasts generate large contractile forces using stress fibers rich in a-smooth muscle actin (a-SMA) that are transduced via focal adhesions to excessively contract and remodel the ECM leading to scarring and fibrosis. In contrast, injured fetal skin heals scarlessly without myofibroblast activity suggesting that fetal fibroblasts exert smaller contractile forces due to their unique wound environment. However, fetal wounds have less TGF-b1 and are more compliant than adult wounds. Therefore, it remains unclear whether the lack of myofibroblast differentiation is a result of inherent properties of fetal fibroblasts or biochemical and biomechanical differences in fetal wounds. In this study, we tested whether physiologic wound rigidities and TGF-b1 can mediate actomyosin contractility in fetal fibroblasts and promote myofibroblast differentiation. Using traction force microscopy and polyacrylamide gels (PAAs) that mimic the biomechanical stages of healing wounds, we found that traction forces and focal adhesion formation by fetal fibroblasts were impaired on rigid PAAs that mimic late stage granulation tissue when compared to their adult counterparts. On rigid PAAs with TGF-b1 stimulation, we found that fetal fibroblasts exhibited no differences in traction forces, focal adhesions, or a-SMA while all three increased for adult fibroblasts indicating myofibroblast differentiation. Overall, our data indicate that fetal fibroblasts exhibit a unique contractile phenotype that prevents myofibroblast differentiation due to altered mechanical responses to ECM rigidity and TGF-b1.

Plasma Membrane and Cell Surface Mechanics in Embryonic Stem Cells.
H. De Bell¹, M. Winzi², J. Guck², C. Lamaze³, K. Chalut³, E.K. Paluch¹;
¹LMCB, University College London, London, United Kingdom, ²Cellular Machines, Technical University Dresden, Dresden, Germany, ³Laboratoire Trafic, Signalisation et Ciblage Intracellulaires, Insitut Curie, Paris, France, ⁴Cambridge Stem Cell Institute, Wellcome Trust/Medical Research Council, Cambridge, United Kingdom

Embryonic Stem Cells (ESCs) are able to generate any tissue in a given organism; this ability is called pluripotency. Membrane mechanical properties, such as tension, have been shown to influence cell behavior and differentiation in many systems. However, very little is known about plasma membrane dynamics and mechanics in ESCs. Here, we investigate the link between the mechanical properties of the plasma membrane and the molecular factors that lead to exit from pluripotency. Using optical tweezers, we show that naïve mouse ESCs have a higher effective membrane tension compared to cells exiting pluripotency. We show that naïve cells have a higher expression and level of activation of protein regulating membrane-to-cortex attachment and that affecting these proteins results in defects in exiting
pluripotency. We also observe an increase in expression and differential localization of caveolae components as ESCs exit pluripotency. Caveolae are membrane tension sensing lipid raft and have been suggested to play an important role in other stem cell types, such as human mesenchymal stem cells, and are sensitive to change in membrane tension. Together, our data show that membrane organization and tension change during exit from naïve pluripotency in mouse ESCs. We are currently investigating the impact of these changes on cellular fate transitions.

**Fibrillar Force Generation by Fibroblasts Depends on Microenvironmental Stiffness.**

V. Maruthamuthu\(^1\), M. Eftekharjou\(^1\), D. Palmer\(^2\), B. McCoy\(^1\);
\(^1\)Mechanical Aerospace Engineering, Old Dominion University, Norfolk, VA, \(^2\)Biological Sciences, Old Dominion University, Norfolk, VA

Fibroblasts in connective tissue interact with a fibrillar extra-cellular matrix (ECM) that often restricts their shape along one-dimension (1D, along the fiber). At the same time, the fibroblast responds to and affects the mechanical nature of its microenvironment which consists of the inter-woven fibrillar ECM, other matrix components and cells. To simultaneously constrain a fibroblast along 1D and still let it mechanically interact with an extended microenvironment of defined stiffness, we plated NIH 3T3 fibroblasts on micropatterned 1.5 \(\mu\)m-wide fibronectin lines on polyacrylamide gels of stiffness (Young’s modulus) 4, 7 or 15 kPa. The cells adhered to the fibronectin lines, exhibiting 1D cell-matrix adhesions marked by paxillin and vinculin. We observed that cell lengths only modestly increased with hydrogel stiffness, at a rate of 3 \(\mu\)m/kPa. We then used traction force microscopy to quantify the cellular traction force transmitted to and deforming the substrate and the associated strain energy. We found that the strain energy stored in the substrate increased with substrate stiffness, more than doubling between the lower (4 kPa) and higher substrate stiffness (15 kPa) considered here. Finally, we assessed whether Arp2/3, which plays a key role in fibrillary cell migration, also affected force generation in this context. Pharmacological inhibition of Arp 2/3 modestly increased cell length but decreased the strain energy associated with traction force exertion. Thus, our data show that fibrillar force generation by fibroblasts is dependent on the stiffness of the microenvironment and on nucleation promoting factors such as Arp2/3.

YAP is a mechanosensitive transcriptional activator with a critical role in cancer, regeneration, and organ size control. Here we show that force applied to the nucleus directly drives YAP nuclear translocation by decreasing the mechanical restriction of nuclear pores to molecular transport. We demonstrate that the
nucleus only connects mechanically to the cytoskeleton above a threshold in substrate rigidity, allowing forces exerted through focal adhesions to reach the nucleus. This leads to nuclear flattening, which increases YAP nuclear import by decreasing the mechanical restriction of nuclear pores to molecular transport. This restriction is further regulated by the mechanical stability of the transported protein. Control of YAP translocation by nuclear force is independent of focal adhesions, the actin cytoskeleton, substrate rigidity, cell-cell adhesion, and the Hippo pathway. Our results unveil a mechanosensing mechanism mediated directly by nuclear pores, demonstrated for YAP but with potential general applicability in transcriptional regulation.

Modulation of T cell Priming by Dendritic Cell Stiffness.
D. Blumental\textsuperscript{1,2}, V. Chandra\textsuperscript{1,2}, J.K. Burkhardt\textsuperscript{1,2}; \textsuperscript{1}Pathology and Laboratory Medicine, Children’s Hospital of Philadelphia, Philadelphia, PA, \textsuperscript{2}Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Priming of T-cell responses by dendritic cells (DCs) is essential for protective immunity to pathogen invasion and cancer. T cell activation requires intimate cell-cell interactions at a site termed the immunological synapse (IS) and mounting evidence indicates that this process involves mechanotransduction. In response to inflammatory stimuli, DCs undergo a maturation process during which their phenotype changes from one specialized for pathogen surveillance to one optimized for T cell priming. During maturation, T cell stimulatory ligands are upregulated, and cytoskeletal proteins are reprogrammed to downregulate antigen uptake and facilitate migration to lymphoid tissues. We hypothesized that maturation also alters the biophysical properties of the DC cortex, and that these properties represent an unexplored control point for T cell priming. Using atomic force microscopy, we show that upon LPS-induced maturation, DC stiffness increases from \textasciitilde2kPa to \textasciitilde4kPa in an actin-cytoskeleton dependent process. Using inhibitors and DCs from KO mice, we identify several actin regulatory pathways downstream of Rho GTPases involved in modulating DC stiffness. Interestingly, activating T-cells with agonist-coated acrylamide hydrogels of different compliance reveals a threshold for T cell activation within the range of 1-4 kPa, similar to the range over which the DC stiffness changes. The specific stiffness at which T cells are activated depends on the concentration of the stimulating molecules, indicating that mechanical cues are integrated with other stimulatory and co-stimulatory signals. Finally, by engineering DCs with altered stiffness, we show that the stiffness of mature DCs directly correlates with their ability to prime ex-vivo T-cells. Taken together, these findings indicate that the stiffness of the DC cortex provides a novel form of co-stimulation that has yet been considered.

Force Dynamics During T Cell Activation.
D.A. Garcia\textsuperscript{1}, A. Upadhyaya\textsuperscript{1}; \textsuperscript{1}Physics, University of Maryland, College Park, MD

T cell activation is an essential step in the adaptive immune response. The binding of the T cell receptor (TCR) with antigen triggers signaling cascades and cell spreading. Physical forces exerted on the TCR by the cytoskeleton have been shown to induce signaling events. While cellular forces are known to depend on the mechanical properties of the cytoskeleton, the biophysical mechanisms underlying force induced activation of TCR-antigen interactions unknown. Here, we use traction force microscopy to
measure the force dynamics of activated Jurkat T cells. The movements of beads embedded in an elastic gel serve as a non-invasive reporter of cytoskeletal rheological properties and molecular motor dynamics. We examined the statistical structure of the force profiles throughout the cell during signaling activation. We found two spatially distinct active regimes of force generation characterized by different time scales and rheological properties of the cytoskeleton. Typically, the interior of the cells was found to be more active than the periphery. Inhibition of myosin motor activity altered the correlation time of the bead displacements indicating additional sources of stochastic force generation. Our results indicate a complex interaction between myosin activity and actin polymerization dynamics in producing cellular forces in immune cells.

B cell mechanosensing: is it a myth?

S. Shaheen¹, Z. Wan¹, Z. Li¹, W. LIU¹;
¹ School of Life Sciences, Institute for Immunology, Tsinghua University, Beijing, China

Mechanosensing capability of lymphocytes plays an important role in shaping the initiation of an immune response. Although it is evident that B lymphocytes use such capabilities to discriminate the stiffness features of the substrate presenting antigens, but the underlying molecular mechanism remains unexplored. Here, through a combination of molecule imaging, genetic ablation and pharmacological approaches, we demonstrated that B cells with genetic ablation of each of the early BCR signaling molecules, Lyn, Syk, PLCγ2, Btk, BLNK or PKCβ, lost the capability to discriminate substrate stiffness during initiation of B cell activation, while exogenous addition of each molecule rescued the defects, suggesting B cell discrimination of substrate stiffness is dependent on the BCR signaling. In marked contrast, BCR signaling-independent BCR accumulation in the initiation of B cell activation is insensitive to substrate stiffness. Mechanistically, we showed that PMA induced activation of PKCβ can bypass the requirements on Btk and PLCγ2 for the substrate stiffness discrimination ability of B cells. Importantly, we excluded the contribution of PKCβ mediated NF-κB activation to the discrimination capabilities of B cells, instead we provided evidence for a model that PKCβ-dependent activation of focal adhesion kinase (FAK) is required in these events by the FAK-mediated potentiation of B cell spreading and adhesion responses. FAK inactivation or deficiency impaired B cell discrimination against substrate stiffness. As supporting evidence for this model, we showed that the presence of adhesion molecules, ICAM-1 or VCAM-1, greatly enhanced B cell’s capability to discriminate substrate stiffness. In contrast, integrin inactivation, drastically impaired the capability of B cell to discriminate substrate stiffness. Lastly, rheumatoid arthritis (RA) patient B cells strikingly exhibited disordered capability to discriminate substrate stiffness in contrast with B cells from healthy controls. All these data shed light on the precise molecular mechanism of how B cells discriminate substrate stiffness through a BCR signaling and PKCβ mediated FAK activation dependent manner in the process of B cell activation, improving our understanding of the sophisticated mechanosensing capability of B cells.

The lamellipodium is a myosin independent mechanosensor.
1Institute for Biophysical Dynamics, University of Chicago, Chicago, IL, 2Department of Physics, University of Chicago, Chicago, IL, 3James Franck Institute, University of Chicago, Chicago, IL, 4Department of Biology, University of Rochester, Rochester, NY, 5Department of Physics Astronomy, University of Rochester, Rochester, NY, 6Department of Chemistry, University of Chicago, Chicago, IL, 7Interdisciplinary Scientist Training Program, University of Chicago, Chicago, IL

Numerous cellular processes have been shown to be sensitive to changes in the mechanical properties of their extracellular environments. Here we show that cell spreading is acutely impacted by the stiffness of the substrate and displays a biphasic behavior with a transition stiffness between ~5-8 kPa. While this has long been thought to depend on cells' ability to generate tension, here we demonstrate that this behavior is independent of myosin activity. Cells on soft substrates actively try to spread, but display impaired nascent adhesion formation. Addition of Mn2+, surprisingly, recovers the ability of cells to spread on soft substrates, in addition to the other morphological characteristics of cells on rigid surfaces. Using a computational model to simulate integrin catch-bond kinetics with the extracellular matrix, we find that changes to both the unloaded and peak force lifetimes by addition of Mn2+ regulate the fraction of bound integrins. Together these data suggest that actin retrograde flow driven forces in the lamellipodium disrupt integrin binding on soft substrates, thereby impairing clustering required to form nascent adhesions and inhibiting cell spreading. These results illustrate that nascent adhesion formation can act as a myosin independent mechanism to control cell spreading, and thereby potentially other stiffness sensing processes.

Control of cell morphology, stiffness, and differentiation by substrates with independently tunable elasticity and viscous dissipation.
1Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA, 2School of Medicine, University of Pennsylvania, Philadelphia, PA

The mechanical properties of extracellular matrices control the function of cells during development, homeostasis, and wound healing. Studies of cellular responses to biomimetic soft materials have been largely restricted to soft hydrogels and elastomers that have stiffness values independent of time and extent of deformation, so the effective stiffness can be unambiguously related to its effect on cells. Real tissues, however, often have loss moduli that are 10 to 20% of their elastic moduli and therefore behave as viscoelastic solids on a timescale relevant to mechanical sensing. The response of cells to a time-dependent viscous loss is largely uncharacterized because appropriate viscoelastic materials are lacking for quantitative studies. Here we report the synthesis of soft viscoelastic solids in which the elastic and viscous moduli can be independently tuned to produce gels with viscoelastic properties that closely resemble those of soft tissues. Systematic alteration of the viscous and elastic components in viscoelastic substrates demonstrated the time dependence of cellular mechanical sensing and the influence of viscous dissipation on the mechanical signals to which cells respond.
Microtubule-based control of motor-clutch system mechanics in glioma cell migration.
L.S. Prahl1,2, P.F. Bangasser1,2, M. Hemmat1,2, S.S. Rosenfeld2,3,4, D.J. Odde1,2;
1Biomedical Engineering, University of Minnesota, Minneapolis, MN, 2Physical Sciences-Oncology Center, University of Minnesota, Minneapolis, MN, 3Cancer Biology, Cleveland Clinic, Cleveland, OH, 4Medical Oncology, Mayo Clinic, Jacksonville, FL

Microtubules are attractive chemotherapy targets for microtubule-targeting agents (MTAs), which disrupt cell migration in nanomolar doses. Cell migration mechanisms have been largely studied in the context of coordinated actomyosin self-assembly and force generation, and cell-substrate adhesion dynamics, while the mechanisms by which MTAs block cell migration are poorly understood. Focusing on MTAs that bind to two clinically relevant binding sites on tubulin – the taxane site and vinca site – we show that both types of MTAs disrupt stiffness sensitive glioma cell polarization and random motility on compliant hydrogels. Measuring traction force, actin retrograde flow, and microtubule dynamics, we identify dose-dependent mechanisms for each class of MTA: paclitaxel (a taxane site binding MTA) promotes microtubule polymer assembly and decreases strain energy, while vinblastine (a vinca site binding MTA) disassembles polymer and increases actin retrograde flow and strain energy. Results from a stochastic motor-clutch model suggest that MTA site-specific mechanisms are achieved by disrupting a balance between actomyosin contraction and adhesion, rather than a direct mechanical role of microtubules in traction force generation. Finally, we employ a cell migration simulator that incorporates actin protrusion dynamics, force balances, and mass conservation principles to investigate other cell systems-level effects of MTAs. Interestingly, slowing the extension rate of individual protrusions suppresses stiffness sensitivity of simulated cell polarization and random motility, as observed in experiments, providing a systems-level theoretical basis for the actions of MTAs in controlling cell migration.

Sea anemone as a model to study inner ear hair bundle mechanotransduction and Usher proteins interactions.
V. Michel1,2,3, C. Sabourault4, C. Petit1,2,3,5,6;
1UMRS1120, INSERM, Paris, France, 2Université Pierre et Marie Curie - Paris 6, Sorbonne Universités, Paris, France, 3Neuroscience - Généétique et Physiologie de l’Audition, Pasteur Institut, Paris, France, 4UMR7138, Equipe Symbiose Marine, Université Côte d’Azur, Nice, France, 5Syndrome de Usher et Autres Atteintes Rétino-Cochléléaires, Institut de la Vision, Paris, France, 6Collège de France, Paris, France

Cnidarians use a very specialized structure to capture their preys and protect themself : the nematocyst. Nematocyt discharge is controlled by a mechanosensitive actin made structure located on the tentacles : the hair bundle. Hair bundles of sea anemones are structurally close ancestors of vertebrate hair bundles and may constitute a valuable model to study inner ear vertebrate hair bundle functions. It has been previously shown that some molecules crucial for vertebrate hair bundles shaping and function are present in sea anemone. In the inner ear of superior vertebrates, including human, USH1 and USH2 proteins (defective in the Usher syndrome type 1 and type 2, respectively associating deafness and blindness) are localized in the auditory hair bundle, the mechanosensitive structure receptive to sound stimulation. The presence of a homolog of cadherin 23, i.e. the USH1D protein in vertebrates, has been
demonstrated some years ago in sea anemone. Here we show that other USH1-protein homologues could also be observed by in situ immunohistochemistry within sea anemone *Anemonea viridis* hair bundles, by using antibodies designed against specific vertebrates USH1 proteins. In parallel, by using scanning electron microscopy approach, we have done a morphological comparison between the different types of sea anemone hair bundles structures and frog and mouse inner ear mechanoreceptor neurons hair bundles.

*Magnetic Bead Pulling Forces on Soft Substrates Calibrated Using Traction Force Microscopy.*

V. Maruthamuthu 1, J. Bush 1, J. Poole 1; 1Mechanical Aerospace Engineering, Old Dominion University, Norfolk, VA

Localized application of exogenous forces on soft biomaterials and cells is the essential first step in studying their response to mechanical perturbations. Here, we demonstrate the in situ determination of magnetic bead pulling forces on a soft substrate using traction force microscopy. A magnetically permeable pencil-shaped probe was machined and its tip electro polished. An adapter was used to mount the needle, along with permanent neodymium magnets, to a micromanipulator. Magnetic beads were coated with Protein A and allowed to bind to an Fc coated 100 Pa polyacrylamide gel. We found that magnetic beads bound to the polyacrylamide gels (via protein A to Fc bonds) and moved, but did not detach from the gel when approached by the probe within a magnetic bead-probe distance of tens of microns. We could thus determine the force-distance plot showing the force exerted on the magnetic bead by the magnet probe – and thus exerted by the magnetic bead on the soft polyacrylamide substrate – as a function of the distance between the probe tip and the magnetic bead. We have thus devised a set-up where localized traction forces can be applied on soft materials like cells using a magnet probe. We demonstrated that forces of 1-10 nN can be locally exerted – a range ideal for cellular mechanobiology studies. Application of this method for the in situ measurement of localized exogenous forces exerted on cells can enable dissection of cellular force transmission and transduction pathways.

*Normal extracellular matrix restricts cancer cell proliferation via mechanosensitive epigenetic reprograming.*

R. Kaukonen 1, A. Isomursu 1, A. Mai 1, H. Sihto 2, H. Joensuu 2,3, J. Ivaska 1,4; 1Centre for Biotechnology, University of Turku, Turku, Finland, 2Laboratory of Molecular Oncology, Translational Cancer Biology program, University of Helsinki, Helsinki, Finland, 3Department of Oncology, Helsinki University Central Hospital, Helsinki, Finland, 4Department of Biochemistry and Food Chemistry, University of Turku, Turku, Finland

Interactions between cells and the extracellular matrix (ECM) are integral for tissue regulation and homeostasis. While cancer stroma plays a well-characterized role in tumor progression, emerging evidence is now starting to point to a specific contribution of the ECM itself. Moreover, the tumor-suppressive properties of normal, non-cancerous stromata remain poorly understood. We show that the ECMs generated by normal (NF) and cancer-associated fibroblasts (CAF) are physically distinct and regulate cancer cell proliferation. Normal, soft ECM triggers the downregulation and nuclear exit of histone demethylase JMJD1a, leading to localized H3K9 hypermethylation and persistent growth

Monday-399
inhibition in carcinoma cells. Mechanoresponsive targets of JMJD1a include Hippo pathway transcriptional coactivators YAP/TAZ, wherein active JMJD1a directly binds and demethylates the WWTR1 (TAZ) promoter to drive TAZ expression. JMJD1a localization is unperturbed by the actomyosin targeting drugs cytochalasin D and blebbistatin, indicating that JMJD1a activity is independent of intracellular contractility and inside-out mechanosignaling. Finally, we explore upstream mechanotransduction pathways and coregulatory transcription factors that may help modulate the JMJD1a-mediated mechanosensitive transcriptional regulation. Taken together, the results show that soft ECM, like normal stroma, restricts cancer cell proliferation through stiffness-dependent epigenetic modulation, underlining the significance of biophysical tumor-stroma interplay.

Using proximity based biotin identification (BioID) to identify mechano-sensitive interactions surrounding α-catenin.
J.S. Cheah¹, S. Yamada¹;
¹Biomedical Engineering, University of California, Davis, Davis, CA

Protein-protein interactions are the molecular basis of cell signaling. Recently, proximity based biotin identification (BioID) has emerged as an alternative approach to traditional co-immunoprecipitation. In this protocol, a mutant biotin ligase promiscuously labels proximal binding partners with biotin, and resulting biotinylated proteins are purified using streptavidin conjugated beads. This technique does not require preservation of protein complexes in vitro, making it an ideal approach to identify transient or weak protein complexes. Using MDCK epithelial cells expressing BirA* tagged α-catenin, we analyzed the biotinylation of proteins surrounding α-catenin, a component of the E-cadherin complex at cell-cell contacts. To effectively release biotinylated proteins bound to streptavidin conjugated beads, we designed a series of experiments to determine optimal binding and elution conditions. Interestingly, the presence of SDS and IGEPAL-CA630 during the incubation with streptavidin conjugated beads was the key to how effectively biotinylated proteins eluted from the beads with excess biotin and heating. High SDS concentration during binding of biotinylated proteins to streptavidin conjugated beads promoted efficient release of the proteins from the beads, whereas high IGEPAL-CA630 concentration prevented efficient release. Using mass spectrometry analysis along with this protocol, we identified potential force sensitive binding partners of α-catenin. This proximal biotinylation analysis is applicable to a wide range of proteins to identify their force sensitive binding partners and ultimately uncover the force sensitive interactome.

The epithelial circumferential actin belt regulates YAP/TAZ through nucleocytoplasmic shuttling of Merlin.
K. Yamashita¹, K.T. Furukawa¹, N. Sakurai¹, S. Ohno¹;
¹Department of Molecular Biology, Yokohama City University, Yokohama, Japan

Circumferential actin belts underlying the adherens junctions of columnar epithelial cell monolayers control intercellular surface tension and cell shape to maintain tissue integrity. Yes-associated protein (YAP) and its parologue TAZ are proliferation-activating transcriptional coactivators that shuttle between the nucleus and cytoplasm in a context-dependent manner. In most cases, nuclear localizing YAP/TAZ promotes cell proliferation through activating transcription factor TEAD. Previous studies suggest the
importance of stress fibers, one of the major actin cytoskeleton, on the regulation of YAP nuclear localization; however, the effect of the circumferential actin belt, the epithelial cell-specific actin cytoskeleton, on YAP localization remains to be clarified. In low-density cultured columnar epithelial cells, where proliferation is promoted by nuclear YAP/TAZ, circumferential actin belts are poorly organized. On the other hand, in high-density cultured columnar epithelial cells, where proliferation is suppressed, nuclear localization of YAP/TAZ is inhibited, and circumferential actin belts are well developed. By manipulating actin fiber tension in columnar epithelial cell monolayers, we demonstrate that circumferential actin belt tension suppresses YAP/TAZ nuclear localization and their activities at high cell density. In addition, we revealed that this suppression of YAP/TAZ nuclear localization requires Merlin, an F-actin binding protein associated with adherens junctions. Overexpression of wild-type Merlin suppressed YAP/TAZ nuclear localization, however, a Merlin mutant lacking NESs failed to suppress YAP/TAZ nuclear localization, suggesting that Merlin nuclear export sequences (NESs) are critical for its function. Merlin physically interacts with YAP/TAZ, and nuclear export sequences of Merlin are required for the suppression. Together with the observation that the association between E-cadherin and Merlin was diminished by tension in circumferential actin belts, our results support a novel mechanism whereby contraction of the circumferential actin belt promotes Merlin release from E-cadherin, released Merlin undergoes nucleocyttoplasmic shuttling and mediates nuclear export of YAP/TAZ through formation of the Merlin-YAP/TAZ complex.

Mechanosensing in endothelial cells involves novel heparin receptor transmembrane protein 184A.
B.E. Tsoulosi1, C.J. Brown2, S.N. Farwell1, L.J. Lowe-Krentz1;
1Department of Biological Sciences, Lehigh University, Bethlehem, PA

Endothelial cells (ECs) make up the blood vessel interface and provide a semi-permeable barrier between blood and tissues. Blood flow through the vessels exerts dynamic physical forces, such as fluid shear stress (FSS), that dictate vascular patterning during embryonic development, regulate vessel size and integrity throughout adulthood, and maintain EC function at the molecular level. Several proteins act as mechanosensors to transduce information about the intensity, duration, and direction of FSS. Mechanotransduction is a coordinated process that leads to changes in gene expression and ultimately promotes decreased proliferative signaling, cytoskeletal changes, and realignment in the direction of flow. PECAM-1, VE-cadherin, and VEGFRs expressed at adherens junctions form a complex that senses shear and initiates many signaling pathways that lead to actin stress fiber formation. Luminal glycosylated proteoglycans such as syndecans (SDC) and glypicans interact directly with growth factors and plasma proteins in the blood to transduce force directly to the cytoskeleton. Although much is known about the complex primary mechanosensing systems required to sense and respond to FSS, knowledge of mechanisms underlying the integration of these systems and the involvement of potential cofactors is incomplete. Our laboratory has identified a novel receptor, transmembrane protein 184A (TMEM184A), that is expressed in vascular cells and binds specifically to heparin. TMEM184A is required for heparin-induced effects on proliferative signaling, inflammation, and cytoskeletal dynamics in vitro. We hypothesize that TMEM184A is also involved in mechanosensing through interactions with endogenous heparan sulfate proteoglycans (HSPGs). Using immunofluorescence microscopy and immunoprecipitation, we show that TMEM184A interacts with VE-cadherin, VEGFR2, and HSPGs in primary bovine and rat aortic ECs. Upon onset of laminar FSS (5 min – 2 hours), TMEM184A traffics to the surface and clusters similarly to HSPGs. Overall surface TMEM184A expression changes to evenly

Monday-401
distributed punctate clusters in cells acclimated to FSS (up to 24 hours). ECs that overexpress TMEM184A align normally and have enhanced VE-cadherin expression at adherens junctions. Degradation of endogenous HS with heparinase results in decelerated clustering of TMEM184A and impaired cell elongation and alignment. These data support TMEM184A functioning as a modulator of mechanotransduction. Further investigation is needed to confirm this potential role for TMEM184A during EC responses to physiological FSS.

**Mechanical behaviors of catch bonds under varied loads.**  
B. Chen\(^1\);  
\(^1\)Engineering Mechanics, Zhejiang Univ., Hangzhou, China

Within the framework of two-state models, we construct two types of catch bonds that have a similar force-lifetime profile upon a constant force-clamp load. However, when a single catch bond of either type is subjected to varied forces, we find that they can behave very differently. We further find that a cluster of catch bonds of either type generally becomes unstable when subjected to a periodically oscillating force. These results suggest that it is necessary to further differentiate those bonds that are all phenomenologically referred to as “Catch bonds”.

**Mechanosensitivity in LIM domain proteins.**  
J.D. Winkelman\(^1\), C.A. Anderson\(^2\), D.R. Koval\(^2,3\), M.L. Gardel\(^1,4,5\);  
\(^1\)Institute for Biophysical Dynamics, The University of Chicago, Chicago, IL, \(^2\)Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, \(^3\)Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL, \(^4\)James Franck Institute, The University of Chicago, Chicago, IL, \(^5\)Physics, The University of Chicago, Chicago, IL

The actin cytoskeleton is used to build major load-bearing structures in the cell including stress fibers, muscle sarcomeres and the cytokinetic ring. These structures generate and respond to mechanical forces while maintaining tension homeostasis. The LIM (Lin11, Isl-1 & Mec-3) domain superfamily is heavily associated with these load-bearing structures and a many LIM domain proteins have been implicated in various studies probing mechanoresponsive elements of the mammalian cell. Zyxin and Paxillin are well-studied members of this family and are known to rapidly localize to strain sites in these stress-bearing elements where they aid in tension homeostasis. Zyxin LIM domains are necessary and sufficient for localization to stress fiber strain sites in mammalian cells. Surprisingly, the LIM domains from fission yeast Paxillin-like 1 (Pxl1) are also sufficient for its localization to strain sites in mammalian cells as well as the contractile ring in fission yeast. This suggests that LIM recognition of strain sites existed in the common ancestor of yeast and humans and is a conserved LIM domain function. To detect sequence signatures in LIM and determine when mechanosensitivity arose in evolution, we are screening for this function in mammalian LIMs as well as LIM domains across the phyllogenetic tree. To study the molecular mechanism of LIM mechanosensitivity, we have reconstituted LIM domain localization to stressed actin networks containing purified alpha-actinin and Myosin II. We observe that LIM localization requires Myosin II activity. We hypothesize that Pxl1 and Zyxin LIM domains recognize a stress-induced deformation of either Actin or Alpha-actinin.

ADP-ribosylation of vimentin induces changes in morphology and motility of microglia through enhancing phosphorylation of vimentin at Ser56 and disassembly of vimentin filaments.
L. Xie¹, F. Yang¹, C.Y. Chung¹,²;
¹The School of Pharmaceutical Science and Technology, Tianjin University, Tianjin, China,
²Pharmacology, Vanderbilt University, Nashville, TN

Microglia are the immune effector cells in the central nervous system (CNS). Pathological stimuli such as neuronal injury induce transformation/activation of resting microglia with ramified morphology into a motile amoeboid form. It has been shown that ADP-ribosylation by poly (ADP-ribose) polymerase (PARP) is required for TNF-α-induced microglial activation and our goal is to get mechanistic insights how ADP-ribosylation contributes to dramatic changes in morphology and motility of microglia. Through the use of highly specific AF1521 macrodomain beads that can bind to ADP-ribose, poly-ADP-ribosylated (PARylated) proteins were pulled down from lysates of resting or activated microglia. SDS-PAGE showed a few prominent bands eluted only from activated microglia, and these proteins were identified by Mass Spectroscopy. Surprisingly, the most prominent PARylated band was vimentin which is a type III intermediate filament (IF) protein. We found that ADP-ribosylation of vimentin is required for the disassembly of vimentin filaments and the change of morphology upon activation of microglia with LPS. Vimentin gets phosphorylated at, at least, five different serine/threonine residues and vimentin assembly/disassembly have been reported to be affected by these phosphorylations. We found that veliparib (ABT-888), a PARP inhibitor, blocks the increase of phosphorylation of vimentin at Ser56, suggesting that ADP-ribosylation is required for Ser56 phosphorylation. Further investigation revealed that U0126, an ERK1/2 inhibitor, significantly reduced the ADP-ribosylation of vimentin, indicating that ERK1/2 activation upon microglia activation plays a role in the regulation of PARP activity. These results suggest that ADP-ribosylation of vimentin takes an important part in the regulation of changes in the morphology and motility of microglia upon activation.

The role of vimentin intermediate filaments in confined cell migration.
A.E. Patteson¹, P.A. Janmey¹;
¹Physiology, University of Pennsylvania, Philadelphia, PA

The ability of cells to deform and migrate through tight constricting spaces in tissues is important for biological processes, such as embryogenesis, wound healing, and cancer metastasis, and depends on the mechanical properties of the cell cytoskeleton. Migratory and invasive cells often express and upregulate the intermediate filament protein vimentin. Yet, little is known about the role of vimentin in three-dimensional (3D) cell motility. To this end, we fabricate micro-fluidic channels of varying size and ligand surface coatings and use time-lapse imaging to visualize cell migration in a knocked-out model of vimentin in mouse embryo fibroblasts (mEFs). Unlike two-dimensional flat surfaces where vimentin-null mEFs exhibit impaired migratory behavior, their migration in micro-channels is enhanced, outpacing wild-type mEFs. In particular, vimentin-null cells enter channels more quickly and move at faster speeds compared to wild-type cells in collagen type 1 coated channels. The impeding effects of vimentin on cell
motility is strongest in small channels where cell deformations are highest; however, the use of fibronectin surface coating equalizes the 3D motility of the two cell types. Live nuclear staining reveals that the cell nucleus in vimentin-null cells undergoes higher deformations and rates of damage than wild-type cells. Our results demonstrate that vimentin hinders cell motility through small pores and suggest that vimentin networks serve a protective role during migration by providing mechanical resistance to large strains that can cause nuclear damage. This work may be of significant importance in understanding the links between vimentin expression and invasive cell behavior.

**A role for 14-3-3 in recruitment of keratin filaments to mechanically sensitive cadherin junctions.**

R.A. Mariani¹, G.F. Weber¹;

¹Biological Sciences, Rutgers University-Newark, Newark, NJ

Intermediate filament cytoskeleton forms vital networks that are increasingly being shown to be subject to dynamic change, despite early characterization as static elements in cells. Dramatic remodeling of the keratin intermediate filament network has been described as an essential process required for collective cellular movements that occur during early developmental morphogenesis of the frog *Xenopus laevis*¹. Transduction of mechanical forces across cell junctions in these tissues results in rapid reorganization of cytosolic keratins to the junctions through a mechanism that is at present not understood. Although previous research has demonstrated that 14-3-3 proteins facilitate dynamic protein exchange within keratin filaments², it remains to be seen whether these proteins have a role in network reorganization across cellular compartments.

In this work we propose that 14-3-3 proteins regulate keratin reorganization dynamics in *Xenopus* mesendoderm. Utilizing immunofluorescence, we found that 14-3-3 proteins display different expression and sub-cellular localization across the tissues of the gastrulating embryo and co-localize with keratins at cell-cell junctions in migrating mesendoderm. Employing LC/MS-MS, we identified Keratin 19 as a novel intermediate filament target of 14-3-3 proteins in the whole embryo and more specifically mesendoderm tissue. We subsequently used co-immunoprecipitation of endogenous proteins to demonstrate that 14-3-3 proteins associate with Keratin 19 as well as C-cadherin. To gain insight into the relationship between 14-3-3 proteins and keratin reorganization, we induced expression of a well-described ‘R18’ 14-3-3 inhibitor³. Performing FRAP experiments with Keratin 19-GFP as the target in migrating mesendoderm explants, we found that inhibition of 14-3-3 results in reduced recruitment of keratin proteins to bleach zones. Additionally, dissociation and reassembly of explanted mesendoderm tissue demonstrated that R18-mCherry expressing cells fail to recruit keratin filaments to newly assembled cell-cell junctions. Taken together, these findings indicate that 14-3-3 acts on keratin intermediate filaments and is involved in their reorganization to sites of cell adhesion. These results imply the possibility of a novel role for 14-3-3 as a transmitter of mechanosensitivity to cytoskeletal scaffolds at cellular sites that experience tension.

*Influence of nebulin on the assembly mechanics of desmin intermediate filaments.*

M.A. Caragea1, D.A. Hernandez1, R. Kirmse1, H. Herrmann1, G.M. Conover1;
1Department of Chemistry, Texas AM University, College Station, TX, 2Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, 3Molecular Genetics, German Cancer Research Center, Heidelberg, Germany

Desmin intermediate filaments bind to nebulin, an integral actin-binding sarcomere protein, forming a direct physical link between the intermediate filament cytoskeletal network and the Z-discs of myofibrils in muscle cells. As the main intermediate filament protein in myocytes, desmin maintains the structural organization of sarcomeres by providing their alignment and integrating their function to that of the mitochondria. Our research investigated how nebulin impacts the assembly of desmin and desminopathy–associated desmin mutants in vitro. Three dimensional electron-microscopy in vitreous ice shows that nebulin appears to organize desmin filament bundles into networks. Atomic force images taken 10 minutes after initiation of assembly showed that the mean length of mutant desmin E245D was shorter with or without nebulin as compared to that of WT desmin. Force displacement measurements showed that nebulin binding dramatically decreased the elasticity of mutant desmin networks. Networks assembled from equal amounts of wildtype and mutant desmin filaments and nebulin were significantly more fluid as compared to wildtype desmin-nebulin networks. Together, our results indicate that nebulin binding to desmin has a significant influence on the assembly properties of desmin. This influence likely is to efficiently coordinate sarcomere function within the myofibril during its changing physiology.

*Adaptive Multiple Orientation Analysis for the Segmentation of Intermediate Filament Networks.*

M. Kittsipikul1, T. Shimi1, A.E. Goldman1, R.D. Goldman1, K. Jaqaman2;
1Cell and Molecular Biology, Feinberg School of Medicine, Northwestern University, Chicago, IL, 2Biophysics, University of Texas Southwestern Medical Center, Dallas, TX

Intermediate filaments (IF) typically form complex overlapping cytoplasmic and nucleoplasmic networks and meshworks in mammalian cells. In order to accurately detect and analyze these networks, we propose a computational image analysis method that can detect ridge-like structures with variable orientation resolution. IF often join together in junctions that involve two or more directions. These junctions may be physical in nature or due to two dimensional projections of three dimensional structures. Multiple orientations can complicate the segmentation and detection of these cellular structures. Many existing methods cannot distinguish between two structures that meet at small acute angles. Methods such as Canny-based ridge detection or anisotropic diffusion are limited both in terms of the number of orientations that can be detected at a point in an image and their orientation resolution. Since the number of structures and their orientations may not be known a priori, we propose a method where the orientation resolution can be directly selected as a parameter such that an arbitrary number of joining structures can be detected. Furthermore, the method can adaptively select the minimum orientation resolution needed. By doing so, we improve the spatial localization of the detected orientations. Our method is based on steerable wavelets and applies concepts from the analysis of scale-space to the orientation dimension to form a variable resolution orientation space. This

Monday-405
orientation space analysis is orthogonal to scale analysis and thus can also be combined with existing methods that evaluate scale. As a test, we apply our method to light microscopy images of IF including elongated structures formed by vimentin and keratin as well as meshwork-like structures formed by nuclear lamins. The method is able to accurately detect junctions in these structures directly while providing multiple orientation information that can be used in post-processing and analysis. In summary, we have developed a method that can be used to analyze images where an arbitrary number of IF structures intersect by employing an adaptive algorithm for orientation resolution. Our method can distinguish intersecting structures and yields multiple orientation information along with the orientation resolution required. The resulting analyses are being used to determine IF functions, especially their roles in cellular mechanics and motility.

This work was supported in part by NIGMS (2R01GM106023-05) to Yixian Zheng and Robert Goldman, CPRIT recruitment award (R1216) to Khuloud Jaqaman, and training funds from NICHD (5U54HD087351) and NCI (3T32CA080621) provided to Mark Kittisopikul.

The Effects of Vimentin Serine 72 phosphorylation in OxLDL uptake mechanism in macrophage.
S. Kim1, Y. Park1;
1school of medicine, Ewha womans university, seoul, South Korea

Oxidized low density lipoprotein (oxLDL) is a form of modified LDL which causes atherosclerosis, a chronic inflammatory disorder of arterial wall. Atherosclerosis is initiated by lipid-laden macrophages called foam cells. Although foam cell formation is a critical initial stage of atherosclerosis, the mechanism by which macrophages uptake oxLDL is not clearly defined. It is recently reported that vimentin, a type of intermediate filament protein in macrophages, is a component of intracellular lipid droplet in adipocytes and involves in vesicular trafficking. In this study, we aimed to reveal the function of vimentin in foam cell formation and atherosclerosis.

We generated Apoe-/- mice lacking vimentin and Ldlr -/- mice reconstituted with Vim-/- bone marrow and fed western diet for 15weeks. Apoe-/-Vim-/- mice showed less atherosclerotic lesion formation than Apoe-/- mice. In accordance, Ldlr -/- mice with Vim -/- bone marrow showed 15% less lesion formation than Ldlr -/- mice with Vim +/+ bone marrow. We demonstrated that Vim -/- mouse peritoneal macrophages uptake less oxLDL and foam cell formation than Vim +/+ mouse peritoneal macrophages, which was proven by Dil-oxLDL uptake assay and oil-red O staining of macrophages incubated with oxLDL. Despite less uptake of oxLDL in Vim -/- macrophages, there was no difference in the expression of CD36 which is known to mediate oxLDL uptake between Vim +/+ and Vim -/- macrophages. However, there was significant difference in CD36 localized in plasma membrane between Vim +/+ and Vim -/- macrophages. CD36 localized in plasma membrane measured by flow cytometry and subcellular fractionation assay was 50% less in Vim -/- macrophages than in Vim +/+ macrophage.
We also found that oxLDL induced vimentin (Ser72) phosphorylation. Vimentin (Ser72) phosphorylation was dependent on protein kinase A (PKA). H-89, a specific PKA inhibitor, decreased vimentin phosphorylation and oxLDL uptake in macrophages. Moreover, CD36 null macrophages didn’t exhibit phosphorylation ser72 on vimentin induced by oxLDL. To evaluate the role of vimentin phosphorylation at Serine 72, we generated phosho-mimetic vimentin and transfected into Vim -/- bone marrow-derived macrophages and performed Dil-oxLDL uptake assay. We observed that mimicking phosphorylation at serine 72 of vimentin increased oxLDL uptake and membrane CD36 localization. We revealed that vimentin involves in oxLDL uptake of macrophages and vimentin (Ser72) phosphorylation via PKA induced by oxLDL mediates this process. Our study suggests a mechanism of macrophage foam cell formation which may aid to establish a new therapeutic strategy.

Keratin intermediate filament recruitment to cell-cell contacts is dependent on proper actin localization and function.

H.Ü. Mücahit\(^1\), G.F. Weber\(^1\), A.J. Rodriguez\(^1\);

\(^1\)Biology, Rutgers University, Newark, NJ

Cell-cell adhesion assembly and maturation within epithelial cells is a highly dynamic process involving several adhesive complexes and their respective cytoskeletal anchors. Of these, adherens junctions, associated with the actin cytoskeleton, are responsible for adhesion initiation while desmosomal junctions, tethered by keratin intermediate filaments, are the final complex to assemble. Although these structures were once thought to be distinct, recent literature suggests that the interaction between actin and keratin cytoskeletal systems, as well as their adhesion complexes, is required for proper cell-cell adhesion. However, the extent of these associations is still not fully understood. It remains unknown whether keratin intermediate filaments are recruited during adherens junction assembly or as a result of desmosomal junction assembly. To answer this question, we characterized the temporal sequence of keratin intermediate filament recruitment during cell-cell adhesion assembly. To examine the relationship between both cytoskeletal systems and the adherens junction complex, we disrupted actin cytoskeletal translation at cell-cell contact sites during adhesion assembly and show that keratin intermediate filament recruitment is reduced at the cell periphery in correlation with E-cadherin. Additionally, we demonstrate that inhibition of acto-myosin tension increases keratin intermediate filament cytoplasmic localization and disrupts keratin cytoskeletal organization. Thus, these data indicate that keratin intermediate filament recruitment and organization is dependent on the proper function and translation of the actin cytoskeleton in steady state and during adherens junction assembly, providing stronger evidence for extensive association between these complex structures.

Optogenetic perturbation of intermediate filament networks.

R. Sanghvi-Shah\(^1\), S. Paranjpe\(^1\), J. Baek\(^1\), R. Dobrowolski\(^1\), G.F. Weber\(^1\);

\(^1\)Biological Sciences, Rutgers University-Newark, Newark, NJ

Cytoplasmic intermediate filaments play important roles in simultaneously supporting mechanical integrity and influencing signal transduction pathways. The significance of cytoplasmic intermediate filament proteins has previously been examined largely through various genetic approaches, including knockdown, knockout and transgenic overexpression. However, few studies to date have attempted to examine the role of specifically the filamentous intermediate filament network in orchestrating various cell functions. To directly assess the role of the filamentous keratin network in regulation of cellular behavior, we created genetically-encoded photoactivatable (PA-) and constitutively active (CA-) versions of a peptide disruptor of keratin intermediate filaments (PA-dIF and CA-dIF, respectively). This genetically encoded construct consists of a peptide derived from the 2B2 region of keratin 8 fused to the photosensitive LOV2 domain from *Avena sativa* phototropin-1. To validate the ability of this construct to disrupt intermediate filament networks, we expressed PA-dIF and CA-dIF in multiple cell lines and tissues. Across multiple species and cell types, CA-dIF induces disruption of keratin networks. Upon 457nm photoradiation, PA-dIF disrupts keratin intermediate filaments and induces dynamic changes in cell shape and protrusive behavior. Marked remodeling of the keratin intermediate filament network
accompanieds collective cellular morphogenetic movements that occur during gastrulation and neurulation in the *Xenopus laevis* frog embryo. Disruption of keratin intermediate filaments by expression of CA-dIF in presumptive neuroectoderm results in a dramatic failure of neural tube closure. Expression of CA-dIF in presumptive mesendoderm causes marked reduction in head structures. Altogether our data show a fundamental requirement for keratin intermediate filaments in orchestrating morphogenetic movements during development that have yet to be revealed in other model systems. Moreover, our data validate the utility of a new genetically encoded photoactivatable tool for the disruption and examination of intermediate filaments.

The gap junction Nexus controls localization and mobility of neural proteins.

R.F. Stout,1,2 D.C. Spray2

1Biomedical Sciences, New York Institute of Technology College of Osteopathic Medicine, Old Westbury, NY, 2Dominick P. Purpura Department of Neuroscience, Albert Einstein College of Medicine, Bronx, NY

Gap junctions connect astrocytes and oligodendrocytes, providing bidirectional exchange of nutrients, metabolites and intracellular signaling molecules. Each of these glial cell types expresses a distinct set of gap junction (GJ) proteins (astrocytes: Cx43, Cx30, & Cx26 oligodendrocytes: Cx32, Cx47 & Cx29) and each connexin forms a supramolecular complex (the GJ Nexus) made up of GJ channels and molecules that interact with GJs. Nexus composition is also determined by the posttranslational modification state of the Cx proteins and cell physiological state. GJs also have important non-channel functions including cell-cell adhesion and control of autophagy. We recently used live cell confocal microscopy and Fluorescence Recovery After Photobleaching (FRAP) to show that cysteine (Cys) residues within the cytoplasmic carboxyl-termini (CT) of Connexin 43 and Connexin 32 (Cx43 and Cx32) produce stably arranged orthogonal GJ channel arrays (GJ plaques) in the membranes of cells joined by those connexin isoforms whereas Cx30 & 26 (which have no Cys residues in the CT) form highly fluid GJ plaques. Here we report for the first time that Cx47 (contains 3 CT Cys residues) forms stably arranged GJs- thereby completing exploration of macroglial GJ stability characteristics (leaving the postulated xenotypic Cx29::Kv channel for continuing studies). Our discovery that mutation of Cys residues to alanine in the CT of Cx43 and Cx32 produces a switch from stable GJ Nexuses to a fluid structures allowed us to employ this as a new tool to test how Nexus stability affects mobility and localization of other membrane proteins- since known protein interaction sites are preserved in the Cys mutants. Here, we used live cell microscopy for four dimensional and multi-color FRAP to test how the GJ Nexus controls subcellular morphology near the GJ plaque and Cx43 mobility affects mobility of other Nexus components. We found that GJs excluded many membrane proteins from the GJ plaque membrane area. Some membrane proteins did infiltrate the Nexus and localization of the tight junction protein occludin (Ocludin) to the GJ plaque area was higher than other membrane areas. Cx43-CT mediated Nexus stability had a substantial effect on mobility of some membrane proteins (Cx30 and Ocludin) but a minor effect on other Nexus components. We examined localization and mobility of other proteins at the Nexus that are critical for function of specialized cellular compartments in astrocytes- where GJs are preferentially localized- such as peri-synaptic astrocyte processes (EAAT2b) and the perivascular endfeet (AQP4, Nectin-2, TJP1). We continue to explore ways the GJ Nexus acts as intercellular channels and membrane organizing nodes to determine astrocyte and oligodendrocyte cellular physiology.

Molecular machinery of gap junction turnover.
M.M. Falk¹, J.T. Fong¹, R.M. Kells¹, W. Nimlamool¹, A.F. Thevenin¹;
¹Biological Sciences, Lehigh University, Bethlehem, PA

Gap junctions, one of four principle cell-cell junction types, provide direct cell-to-cell communication by forming clusters of membrane channels that bridge the plasma membranes of neighboring cells. Gap junctions and cell-to-cell communication are widespread in the animal kingdom and are a hallmark of multi-cellular life. Interestingly, gap junctions turn over with a short half life of only a few hours, however the reason for this short and for membrane channels untypical turnover kinetics is not known. One possibility is that channels, once accrued to a gap junction plaque permanently close, become non-functional and thus need to be replaced by newly synthesized functional channels. Similarly, to allow cell migration, cells will need to physically uncouple from their neighbors, and this uncoupling requires the coordinated, rapid removal of all cell-cell junction types, including gap junctions. Regulated turnover is important for gap junction function, as abnormal turnover characteristics can lead to severe pathological conditions. We have characterized the turnover of the major gap junction protein, connexin 43 (Cx43), on a molecular basis and characterized a sequence of posttranslational modifications that occur in sequence on Cx43 in gap junctions: (1) binding and release of the scaffolding protein ZO-1, (2) earlier and later phosphorylation/de-phosphorylation events on several regulatory serine residues located in the Cx43-C-terminal domain, and (3) Cx43 K63-poly-ubiquitination. These hierarchical regulatory events transition functional into non-functional gap junction channels that then can interact with clathrin/clathrin-adaptors to internalize and recycle gap junctions. These novel and exciting findings will be summarized in this presentation.

Desmoplakin bears tension under externally applied load but not during epithelial monolayer growth and homeostasis.
A.J. Price¹, A.R. Dunn¹,²;
¹Biophysics, Stanford University, Stanford, CA, ²Chemical Engineering, Stanford University, Stanford, CA

Desmosomes are intercellular adhesion complexes that link the intermediate filament cytoskeletons of neighboring cells. In humans, mutations in desmosomal proteins lead to cardiomyopathies and skin blistering diseases, suggesting that desmosomes play an important role in defining the mechanical properties of multicellular tissues. However, how and whether desmosomes bear mechanical load in living tissues was unclear due to limitations inherent in existing measurement techniques. In this study, we inserted a Förster resonance energy transfer (FRET)-based tension sensing module (TSMod) into desmoplakin-I (DPI), a scaffolding protein that links desmosomal adherins to intermediate filaments. In a model epithelial system consisting of Madin-Darby canine kidney (MDCK) cells, live-cell FRET measurements are consistent with negligible mechanical tension transmitted through DPI-TSMod in confluent monolayers, sparse cell colonies, and at the edge of expanding monolayers. However, we observed a significant decrease in FRET efficiency, consistent with mechanical tension transmitted through DPI-TSMod, in epithelial monolayers subjected to external mechanical stretch, particularly at cell-cell junctions oriented perpendicular to the axis of applied strain. These data support a model in which desmosomes bear mechanical loads from external deformations, but bear negligible mechanical loads arising from local, cell-generated forces. We suggest that, in simple epithelia, desmosomes have
evolved to protect tissues from mechanical disruption while still allowing the cellular movements and shape changes that are essential to tissue homeostasis.

Proximity Labeling Proteomics of Desmosomes Reveals Novel Components Essential for Epidermal Integrity.
K.A. Badu-Nkansah1,2, T.H. Lechler1,2;
1Dermatology, Duke University Medical Center, Durham, NC, 2Cell Biology, Duke University Medical Center, Durham, NC

Desmosomes are cell-cell adhesion structures that provide mechanical robustness to the epidermis and heart. Perturbation of desmosomes that occurs in genetic, autoimmune and infectious pathologies produce phenotypes that range from skin blistering diseases to cardiomyopathies. While the core components in desmosomes have been identified decades ago, more recent work has uncovered additional desmosome-associated proteins that have either regulatory and/or non-canonical functions. Here we used a combination of proximity biotinylation and quantitative mass spectrometry to identify novel desmosome-associated proteins. We performed separate analyses to enrich for proteins at the outer and inner dense plaques regions within desmosomes and identified many candidates with potential functionality within each region. Additionally, we found a significant overlap with proteins normally associated with both adherens junction and tight junction complexes. We show that this is due, in part, to differential promiscuity in the association of some proteins with adherens junctions, tight junctions, and desmosomes in different tissues. Lastly, we demonstrate that a subset of the identified proteins co-localize with core desmosome components and require these proteins for their localization. Finally, we performed functional evaluation of the role of signal adapter molecules, Crk and Crkl, two homologous proteins that were identified in our analysis. Loss of Crk/Crkl in cultured keratinocytes and in the mouse epidermis resulted in defects in keratin organization, impaired adhesion, and neonatal lethality. These data position Crk/Crkl as crucial regulators of the desmosome:keratin interaction which is essential for mechanical integrity of the skin and highlights the utility of the approach to identify novel regulators of the desmosome.

Increased cardiac arrhythmogenesis associated with gap junction remodeling with upregulation of RNA binding protein FXR1.
M. Chu1, S.M. Novak1, C. Cover1, A. Wang1, I. Chinyere2, E. Juneman2, D.C. Zarnescu3, P. Wong4, C.C. Gregorio1;
1Cellular Molecular Medicine, University of Arizona, Tucson, AZ, 2Sarver Heart Center, University of Arizona, Tucson, AZ, 3Molecular and Cellular Biology, University of Arizona, Tucson, AZ, 4Department of Biomedical Engineering, Pennsylvania State University, University Park, PA

Gap junction remodeling is well established as a consistent feature of human heart disease involving spontaneous ventricular arrhythmia. The mechanisms responsible for gap junction remodeling are still debated. Studies reveal that multiple transcriptional and post-transcriptional regulatory pathways are triggered in response to cardiac disease, such as those involving RNA-binding proteins. The expression levels of Fragile X mental retardation autosomal homolog 1 (FXR1), an RNA-binding protein, are critical to maintain proper cardiac muscle function; however, the connection between FXR1 and disease is not

Monday-410
clear. To identify the mechanisms regulating gap junction remodeling in cardiac disease, we sought to identify: 1) the functional properties of FXR1 expression, 2) direct targets of FXR1 in human dilated cardiomyopathy (DCM) biopsy samples and mouse models of DCM, and 3) how FXR1 regulates its targets, and the functional consequences of altering the levels of this important RNA binding protein. We discovered that FXR1 expression is significantly increased in tissue samples from human and mouse models of DCM. FXR1 associates with intercalated discs. The integral gap junction proteins Cx43, Cx45 and ZO-1 were identified as novel mRNA targets of FXR1 using a BioID proximity assay and RNA immunoprecipitation. Our findings show FXR1 is a multifunctional protein involved in translational regulation and stabilization of its mRNA targets in heart muscle. Additionally, introduction of 3xMyc-FXR1 via adeno-associated virus into mice leads to redistribution of gap junctions and promotes ventricular tachycardia showing functional significance of FXR1 upregulation observed in DCM. Furthermore, we have demonstrated that knocking out FXR1 in the heart leads to DCM. However, Cx43 expression is not changed in cardiac-specific FXR1 KO mice as observed in other DCM models, consistent with our observation that FXR1 directly regulates gap junction remodeling in DCM. Together this study provides a novel function of FXR1 namely that it directly regulates major gap junction components, contributing to proper cell-cell communication in the heart.

Dynamic Equilibrium of Endothelial Cell Junctions is Required for Vessel Morphogenesis.
J. Yang1, r. kilker1, A. Horowitz1;
1medicine, Thomas Jefferson university, philadelphia, PA

Intercellular junctions are maintained by complexes of cytoplasmic and transmembrane proteins stabilized by scaffold proteins. Multi PDZ (MPDZ, also known as MUPP1), which contains 13 PDZ modular domains and one L27 domain, is a major scaffold proteins localized at the endothelial cell (EC) junctions. It is thought to function as a paralog of Pals1-associated tight junction protein (PATJ) in the Crumbs polarity complex. Though the apical basal polarity complexes Crumbs and PAR are involved in the regulation of cell junction assembly during development, it is unknown which protein complex, if any, regulates EC junctional dynamics in response to physiological factors that alter vessel permeability, such as vascular endothelial growth factor (VEGF). We suggest that MPDZ serves as the backbone permeability, such as junctional protein complex which mediates the translocation of junction proteins to and from the junctions. We found that either depletion or absence of MUPP1 in mouse or human endothelial cells (ECs), respectively, resulted in acute loss of adherens as well as tight junction transmembrane and membrane-proximal proteins. Surprisingly, however, the in vitro permeability of confluent Mpdz-/-/6NJEC monolayers to fluorescently-conjugated dextran was lower than that of Mpdz+/+6NJ monolayers either in the presence or absence of VEGF. This finding suggests that MPDZ is required for conferring vascular plasticity rather than for maintaining EC junction integrity. In vivo, we observed that: (1) the typical radial symmetry of the major retina arteries and veins of the wild type mouse (Mpdz+/+6NJ) was lost in the Mpdz-/-/6NJ retina; (2) the diameter of the major vessels was twice larger in the Mpdz-/-/6NJ retina; (3) their branching frequency was substantially higher. The Mpdz+/+6NJ and Mpdz-/-/6NJ vessels differed also at the cellular level: EC pattern along Mpdz-/-/6NJ veins, but not along arteries, was irregular and their junctions were jagged. In agreement with the in vitro result, the in permeability of Mpdz-/-/6NJ skin vessels in response to VEGF was lower than that of Mpdz+/+6NJ vessels. VEGF treatment of Mpdz+/+6NJ EC monolayers caused a reduction in MPDZ abundance at the junctions, whereas the number and size of MPDZ in recycling endosomes and the trans Golginetwork (TGN) increased substantially. We detected by mass-spectrometry novel MPDZ-associated proteins, including TBC1D2, a Rab7 inhibitor that is likely to impede MPDZ trafficking to the
lysosomes. MPDZ was shown by others to associate with retromer and sorting nexin 3 (SNX3), which sort endocytosed cargo proteins and recruit them to the trans Golgi, respectively. Our findings indicate that EC junctions are maintained in a dynamic equilibrium by recycling between the plasma membrane and the TGN.

Miniaturized Permeability Assay for Whole Genome Screening.
C.M. Simonneau\(^1\), A. Horowitz\(^1,2\);
\(^1\)Medicine, Thomas Jefferson University, Philadelphia, PA, \(^2\)Cancer Biology, Thomas Jefferson University, Philadelphia, PA

Maintenance of vessel wall integrity is the primary function of endothelial cells. Unlike other frequently assayed cell activities such as proliferation or migration, permeability is a cell-group behavior. Current whole genome screening techniques can be readily applied to identify genes involved activities phenotyped by measuring cell proliferation rates, such as drug resistance. In contrast, a screen to identify genes involved in regulating endothelial cell junctions would require as many samples as the number of annotated genes in the genome, multiplied by the numbers of probes and technical replicates. This is so because screens, such as those using shRNA probes, require targeting several loci in each gene to achieve effective transcriptional inhibition. Currently, multi-well Transwell plates provide the largest number of monolayer permeability assay per plate (96 wells). To produce statistically valid results, each experimental group would have to contain as many as 106 samples – an impractical number for most if not all labs. To solve this problem, we have designed a permeability assay based on microcarrier beads averaging 150 μm in diameter. While microcarriers had been used to measure endothelial cell (EC) permeability in a chromatographic format (Haselton et al., 1989), we use each bead as a single assay. ECs are grown on these beads to confluence and are then challenged by any compound of interest. In one assay version, we treated cells grown on gelatin-coated commercially-available beads by thrombin, a protease that disrupts cell-cell junctions. To distinguish between microspheres coated by cells that respond to thrombin from others that do not, we added to the medium fluorescently-conjugated collagen-binding fibronectin fragment (fFN) that attaches to gelatin with high affinity. The fFN probe bound to the newly-exposed gelatin surface between adjacent thrombin-treated cells. On the other hand, only a low amount bound to the surface of beads that were not treated by thrombin. The difference in fluorescence intensity between the thrombin-treated and untreated cell samples is large enough to facilitate separation by fluorescence-assisted sorting between beads carrying thrombin-responsive versus non-responsive cells grown in the same volume. The relevant information can then be produced by sequencing the genomic DNA or the mRNA of each cell group.
Desmosomal Regulation of Gap Junctions via Ras: Implications for Cardiocutaneous Disease.

C.Y. Kam, A.D. Dubash, F. Sheikh, P.D. Lampe, S. Polo, K.J. Green;
Departments of Pathology, Northwestern University, Chicago, IL, Department of Biology, Furman University, Greenville, SC, Department of Medicine, University of California-San Diego, La Jolla, CA, Translational Research Program, Fred Hutchinson Cancer Research Center, Seattle, WA, FIRC Institute of Molecular Oncology, Milan, Italy, Department of Dermatology, Northwestern University, Chicago, IL

The mammalian heart is a vital organ comprising specialized muscle cells, or cardiomyocytes (CMs) that adhere to each other via intercalated discs, specialized junctions made up of elements from desmosomes, adherens junctions, and gap junctions. These junctions are crucial for integrating mechanical, chemical, and electrical signals to coordinate cardiac rhythmic contraction. Desmoplakin (DP) is an essential component of desmosomes, that tethers intermediate filaments to sites of cell adhesion. DP is a frequent target for mutation in cardiocutaneous disorders. In particular, DP mutations cause arrhythmogenic cardiomyopathy (AC), an inherited disorder characterized by replacement of healthy myocardium by fibro-fatty deposits that presents with or without cutaneous defects. During AC pathogenesis, a loss of electrical conduction between CMs can occur prior to fibro-fatty infiltration, an event that has been dubbed the “concealed phase”. Providing a possible explanation for the conduction defect, DP loss has been linked to decreased levels of the gap junction protein Connexin-43 (Cx43). However, the mechanism by which loss of DP decreases Cx43 expression is unknown.

We utilized *in vitro* and *in vivo* models of DP deficiency in heart and skin to elucidate the mechanism by which DP regulates Cx43 protein levels. Depletion of DP in rat CMs led to lowered Cx43 protein levels, consistent with prior *in vivo* studies. Gap junction dynamics are regulated by a number of phosphorylation sites on the Cx43 C-terminus. Systematic analysis of known Cx43 phospho-sites in DP-deficient CMs revealed a specific increase in the MAPK sites S279/282, previously shown to signal internalization and degradation of Cx43. Elevated phosphorylation was also conserved in cardiac and epidermal tissues from mice with conditional ablation of DP. Furthermore, elevated p-Cx43 to total Cx43 signal ratio is observed in a cardiac patient sample harboring a pathogenic AC mutation. DP depletion in CMs accelerated loss of Cx43, which was prevented by inhibitors of lysosomal, but not proteosomal, degradation.

RNA-sequencing analysis revealed Ras-GTPases as candidates for DP-dependent activation of the ERK1/2 MAPK pathway. DP loss led to elevation of K-ras transcript, protein, and activity. We utilized a novel reagent derived from the bacterium Vibrio vulnificus termed RRSP that is able to cleave Ras isoforms to test if dampening of Ras activity could ameliorate DP-dependent Cx defects. Cx43 levels were restored in CMs treated with RRSP, supporting a mechanistic connection between ERK activation and Cx43 expression. Collectively, our results reveal a novel mechanism for the regulation of Cx43 levels in cardiac disease caused by loss of DP and highlight a potential novel therapeutic for AC patients.

**Connexin 43 loss induces proliferation and invasion pathways in non-neoplastic breast epithelium.**

1Department of Biology, American University of Beirut, Beirut, Lebanon, 2Department of Basic Medical Sciences, Purdue University, West Lafayette, IN, 3Purdue University Center for Cancer Research, Purdue University, West Lafayette, IN, 4Department of Natural Sciences, Lebanese American University, Beirut, Lebanon

The loss of connexin 43 (Cx43) expression has been reported in breast cancer cell lines, in-vivo models and tissue biopsies, suggesting a tumor suppressive role for Cx43 in the breast. Our earlier studies demonstrated disruption of apical polarity and mitotic spindle orientation in 3-dimensional (3-D) culture of Cx43-silenced HMT-3522 S1 cells, non-neoplastic human mammary epithelial cells (S1 cells). The current study aims to investigate the role of Cx43 in proliferation and invasion pathways in non-neoplastic breast epithelium. Cx43 shRNA-transfected and control S1 cells were cultured under 2-D and 3-D conditions. Proliferation and cell cycle progression were monitored by cell counting (2-D) or measurement of acinus size (3-D) and flow cytometry. Motility and invasion were assessed by time-lapse imaging and transwell cell invasion assays. Western blotting, co-immunoprecipitation, immunofluorescence, gelatin zymography and pulldown assays were used to decipher the mechanism of Cx43 signaling. Cells in 2-D cultures were assayed on days 4, 6, 9, and/or 11, while those in 3-D cultures on day 11. Silencing Cx43 enhanced proliferation of S1 cells in 2-D and 3-D cultures, as shown by the increased cell counts and acinar size, respectively and throughout the culture period. Cell cycle entry was concomitantly enhanced, as indicated by the increased percentages of cells in S and G2/M phases and the reduced percentage of cells in G0/G1 phase. c-Myc and cyclin D1, but not β-catenin, were consistently upregulated in 2-D and 3-D (day 11) cultures of Cx43-silenced S1 cells. Cx43 associated with β-catenin in 2-D and 3-D cultures of S1 cells. β-catenin colocalized with Cx43 in 3-D cultures of S1 cells, and exhibited mislocalization in Cx43-silenced cells, suggesting involvement of Cx43 in the Wnt/β-catenin pathway. Furthermore, silencing Cx43 enhanced motility in 2-D cultures of S1 cells and distorted the characteristic spheroid morphology in 3-D cultures, indicating cell migration. In addition, matrigel-invasion and MMP-9 activity were enhanced. The expression and activity of Rho GTPases (RhoA, Rac1 and Cdc42) were upregulated in 2-D and 3-D cultures of Cx43-silenced S1 cells, suggesting implication of Cx43 in non-canonical Wnt signaling. We propose a role for Cx43 loss in triggering proliferation and invasion events in non-neoplastic breast epithelium downstream of disrupted Wnt signaling.

**Dynasore disrupts gap junction-mediated cell-cell communication.**

C.L. Bell, D.O. Osakue, S.A. Murray;

1Cell Biology, University of Pittsburgh, School of Medicine, Pittsburgh, PA

Dynamin, a mechanoenzyme, has been established to be a key player in scissoring vesicles from the plasma membrane. Further, gap junction plaque internalization is dependent on dynamin for detachment of gap junction buds into the cytoplasm. A dynamin GTPase inhibitor, dynasore, has been extensively used to study the role of dynamin in membrane scissoring and it has been demonstrated to decrease the scissoring of invaginated gap junction plaque membrane from the cell surface. To investigate if gap junction-mediated cell communication was altered following dynasore treatment,
fluorescence recovery after photobleaching (FRAP) techniques were used. In addition, live-cell imaging, immunocytochemistry and transmission electron microscopy (TEM) were used to demonstrate gap junction plaque location and morphology. With live-cell imaging, fewer annular gap junction vesicles were observed to be released into the cytoplasm in the dynasore treated populations compared to diluent treated controls. This corresponded to an increase in the number and size (area) of gap junction “buds” suspended from the gap junction plaques. Gap junction plaque invaginations were observed to remain on the cell surface and to undergo dynamic changes but not to be internalized to form annular gap junction vesicles in the dynasore treated cultures. Ultrastructural analysis revealed large numbers of invaginated gap junction structures with atypical morphology, including those with separations greater than the typical 2-4 nm space found at the gap junction plaque membrane. This would be consistent with undocking of the gap junction channels that compose the gap junction plaque and thus the loss of cell-cell communication. When dye communication was evaluated by FRAP analysis, control cells rapidly recovered fluorescence after photobleaching, while dynasore treated cells did not recover. The failure of dynasore treated cells to recover fluorescence compared to controls is consistent with the atypical gap junction morphology seen with TEM and the loss of cell communication. Cell communication was restored when dynasore was washed from cell cultures. Based on these findings, dynasore treatment, in addition to altering the scissoring and release of buds into the cytoplasm, impaired the capacity for gap junction-mediated dye communication. The disruptive effects of dynasore on cell communication may be important considerations needed in interpreting outcomes in studies that utilize dynasore to disrupt dynamin and study changes. This research was supported by NSF grant #MCB-1408986

Using concatemerization as a tool to investigate the dominant effect of the mutation N188T of Connexin46.

Y. Stahl¹, P. Schadzek¹, M. Preller²,³, A. Ngezahayo¹,⁴;
¹Institut für Biophysik, Leibniz Universität, Hannover, Germany, ²Institute of Biophysical Chemistry, Medical School (MHH), Hannover, Germany, ³Center for Structural Systems Biology, German Electron Synchrotron (DESY), Hamburg, Germany, ⁴Center for System Neuroscience (ZSN), Hannover, Germany

The mutation N188T of Connexin46 (Cx46) is associated with an autosomal dominant congenital nuclear pulverulent cataract. The aim of the project was to analyze how the N188T mutant might affect the formation of Cx46 gap junctions when concomitantly expressed with the wild type Cx46. As membrane proteins connexins are embedded in the membrane of the ER during synthesis. They oligomerize along the secretory pathway on the way to the plasma membrane to form hexamers called connexons or hemichannels, which are built into the plasma membrane of the cell. Connexons of adjacent cells dock with each other forming gap junction channels, which might be assembled in gap junction plaques. To study how Cx46N188T might affect the formation of gap junctions by Cx46, generated eGFP labelled Cx46-Cx46, Cx46N188T-Cx46N188T, Cx46-Cx46N188T and Cx46N188T-Cx46 concatemers were expressed in gap junction communication deficient HeLa cells. The concatemers were compared with the Cx46 and Cx46N188T monomers with respect to trafficking and formation of gap junction plaques using confocal laser scanning microscopy. First, ethidium bromide dye uptake experiments demonstrated that all constructs formed functional hemichannels in the membrane. To study the formation of gap junction plaques, randomly taken confocal laser scanning micrographs of cells expressing the eGFP-tagged variants were analyzed by ImageJ. The quantification revealed a three-step model that shows the highest number of gap junction plaques per cell pair in cells expressing the monomer and the homodimer Cx46, suggesting that the concatemerization per se did not alter the

Monday-415
formation of gap junction plaques. Cells expressing the Cx46N188T monomer and the Cx46N188T-Cx46N188T homodimer showed the lowest number of gap junction plaques per cell pair. For cells expressing Cx46-Cx46N188T or Cx46N188T-Cx46 heterodimer a number of plaques in between the pre-mentioned extremes was found. With respect to trafficking, retention of the protein in the ER was observed for the concatameric variants in which Cx46N188T was present, either in a homodimeric or in a heterodimeric variant. Although the monomeric variants and the homodimeric Cx46 did not significantly differ, a trend to retention in ER was perceived for Cx46N188T monomer. Taken together, the results show that the presence of Cx46N188T affected the trafficking as well as the formation of gap junction plaques by Cx46.

Understanding the Molecular Mechanisms Regulating Gap Junction Turnover and its Relevance to Disease in an Animal Model.
C.A. Hyland¹, A. Madaan¹, M. Falk¹;
¹Biological Sciences, Lehigh University, Bethlehem, PA

Cell to cell communication is a crucial cellular function of multicellular organisms. This cellular communication is established by gap junction channels. Gap Junctions are intercellular connections that directly link the cytoplasm of two adjacent cells. This provides a direct means of diffusion for various molecules, ions and electrical impulses between cells. Previous research supports several models explaining the mechanism of gap junction related pathologies. Specific mutations in gap junction proteins (connexins) have been mapped genetically and correlated to disease phenotypes. However, our understanding if and how gap junction turnover mechanisms may also lead to disease are still largely unknown. The Falk lab and others have previously characterized the gap junction turnover pathway and characterized a set of posttranslational modifications that include phosphorylation/dephosphorylation, ubiquitination, and binding/release of a scaffolding protein) that occur on key amino acid residues on connexin43 that regulate turnover. However, their implications in disease are still unclear. To explore how gap junction turnover is associated with disease phenotypes, an animal model must be utilized. The purpose of this research is to determine the molecular mechanisms regulating gap junction turnover and its relevance in disease in a zebrafish model system. To accomplish this, the CRISPR/Cas9 technology is employed to generate the proper mutations to define the molecular source of disease phenotypes. Currently, the CRISPR/Cas9 system has been established in our laboratory for this study, and a mutation that deletes a region of connexin43 that contains several of the key residues involved in gap junction turnover has been generated and injected into zebrafish embryos. The next steps will be to generate mutations that specifically target key phosphorylation residues and ubiquitination residues to investigate their potential relevance to disease.

Connexin43 (Cx43) and Zebrafish Fin Regeneration.
A.D. Hoptak-Solga¹;
¹Biological Sciences, Kutztown University, Kutztown, PA

I am interested in the mechanisms responsible for the control of bone growth in Zebrafish caudal fins. Zebrafish have the remarkable ability to re-grow missing caudal fin tissue upon amputation, making them an ideal model to study bone growth. There are several fin length mutants where bone growth is...
affected, including the short fin mutant (sof). Mutations in the gap junction gene connexin43 (cx43) cause sof mutants to develop short fins due to defects in segment length. Gap junctions serve as intercellular pathways for the exchange of small molecules between neighboring cells, particularly, the exchange of signals between bone cells (i.e. osteoblasts) that coordinate bone growth. Therefore, gap junctional intercellular communication (GJIC) may be responsible for the regulation of bony segment length. We know that sof mutants exhibit fins that are half the length of wild-type fins, have reduced levels of cx43 mRNA and a reduced amount of cell proliferation in the mesenchyme of regenerating fins. We have examined both functional (dye and ionic coupling, morpholino knockdown) as well as cellular processes (cell proliferation, cell differentiation, cell structure and protein expression) in an attempt to identify the cellular defect in the zebrafish sof mutant (Hoptak-Solga et al., 2008). Using a novel technique of targeted gene knockdown of cx43 in regenerating fins, we were able to recapitulate both the segment length as well as the cell proliferation defect of the sof mutants. We hypothesize that the level of GJIC within the population of dividing cells in the regenerating fin may regulate bone growth by regulating the level of cell proliferation. It is not known how a reduction in cell proliferation can lead to short fins, however, the level of cell-cell coupling may directly regulate the number of mitotic cells in the blastema which in turn controls bone growth. This research establishes a key role for Cx43 cell-cell coupling in the regulation of a proliferative cell population that is responsible for the regulation of bone growth (Hoptak-Solga et al., 2008). Understanding the role Cx43 plays in cell-cell communication in the regenerating fin will serve as a model to examine how cells can coordinate a response to re-grow missing tissue. It is hypothesized that defects in Cx43 may lead to aberrant channel structure in sof mutants. Future projects include an electron microscopic study of gap junction structure in both wild-type and sof mutants to determine if structure affects the function of channels and thus GJIC between cells.

Desmoplakin promotes cell migration via coordinated control of p38 MAPK and Rho GTPase signaling.
J.L. Bendrick¹, N.B. Haight¹, A.D. Dubash¹;
¹Biology, Furman University, Greenville, SC

Desmosomes are cell-cell adhesion complexes crucial for maintaining the integrity of tissues, especially those under high mechanical stress. One of the key components of desmosomes is desmoplakin (DSP), a plakin protein that links intermediate filaments to other proteins of the desmosome complex. Due to the vital nature of this connection for mechanical stability of the desmosome, DSP has been a frequent protein of interest for studying the stability of cell-cell adhesion. Although DSP also affects other types of cellular behavior (such as cell-matrix adhesion and cell migration), little is known about the mechanism by which this occurs. Our preliminary findings have shown that loss of DSP results in a dramatic increase in the rate of cell migration, as measured by performing wound healing assays (scratching a monolayer of cells and measuring the rate of wound closure over time). Some studies have indicated that DSP can modulate cellular signaling pathways known to affect cell migration, such as p38 MAPK and Rho GTPase signaling. We therefore hypothesize that DSP regulates the process of cell migration via coordinated effects on p38 MAPK and Rho/Rac activity in epithelial cells. Western blots demonstrated that DSP knockdown results in elevation of p38 MAPK activity (phosphorylation) in A431 epithelial cells, which supports similar findings previously shown in cardiomyocytes. Interestingly, both inhibition of p38 MAPK and an upstream activator, TAK1, were found to rescue the elevated rate of migration of DSP knockdown cells. Rac1 inhibition also rescued migration, suggesting a positive role for
Rac in promoting DSP-mediated migration. Preliminary evidence using GST-pulldown assays for GTP-bound Rac indicates that loss of DSP results in increased Rac activity, providing further support for this hypothesis. Conversely, inhibition of the Rho/ROCK pathway increased migration while activation of the same pathway rescued migration, suggesting that Rho signaling can abrogate DP-mediated migration. Further, we have characterized significant changes in actin cytoskeleton morphology (specifically increases in filopodia number and length) that are associated with the loss of DSP. Altogether, these findings indicate that DSP is responsible for coordinated control of p38 MAPK and Rho GTPase signaling pathways involved in cell migration. This study therefore sheds light on the mechanisms via which desmosomal proteins can induce changes in migratory properties via control of cellular signaling.

The MAL/SRF pathway regulates desmosomal gene expression and protein localization in cancer cells.

L. Eldredge1, A.D. Dubash1;
1Biology, Furman University, Greenville, SC

The desmosome (DSM) is a cell-cell adhesion complex required for the mechanical stability of tissues and regulation of other biological processes, such as proliferation and migration. Proteins from three families make up the complex: Transmembrane cadherins connect adjacent cells, plaque proteins stabilize attachment on the intracellular face, and desmoplakin (DSP) anchors the DSM complex to the IF cytoskeleton. Many studies have reported diverse mechanisms by which cancer progression alters DSM gene expression, but the signaling pathways that govern the expression and localization of DSM constituent proteins remain elusive. Recent work has identified the transcription factor serum response factor (SRF) as a regulator of mRNA levels and localization of DSM proteins such as the cadherin Desmoglein-1. Here, we treated several cancer cell lines with siRNA and a pharmacological inhibitor (CCG-1423) of SRF and its cofactor, MAL, to broadly investigate the role of these transcription factors in regulating DSM gene expression and protein localization. Our results demonstrate that abrogation of MAL/SRF signaling through both siRNA and pharmacological inhibition results in a decrease in DSP transcription, and a concomitant decrease in DSP protein levels. In addition, localization of DSP to borders is also reduced upon inhibition of MAL/SRF signaling. We observed similar changes for the plaque proteins Plakophilin-2 and Plakoglobin, but not for desmosomal cadherins. As DSP is required to maintain the strength of DSM attachments, we also investigated the role of MAL/SRF signaling on the adhesion strength between cells. Our data highlight a novel link between MAL/SRF signaling and DSP expression, and contribute to a growing understanding of the variety of signaling pathways involved in mediating DSM gene expression.

Investigating the Role of Connexin 32 in Cell Cycle, Cell Viability and Epithelial to Mesenchymal Transition of Normal Breast and Breast Cancer Cells.

A. Adak1, E. Ozcivici1, G. Mese1;
1Molecular Biology and Genetics, Izmir Institute of Technology, Izmir, Turkey, 2Bioengineering, Izmir Institute of Technology, Izmir, Turkey

Breast cancer is one of the most prominent cancer-related deaths among females. Among many molecules, connexins and gap junctional communication were shown to have role in breast cancer. Gap
junctions, formed from hemichannels of six connexins (Cx), facilitate intercellular communication between adjacent cells. Connexins, including Cx26, Cx32 and Cx43, were shown to be expressed during different stages of breast cancer. Cx32 was observed both in normal pre-menopausal breast tissue and patient tumor samples. In lymph node metastases, elevated levels of Cx32 was observed compared to primary breast cancer. However, the role of Cx32 in breast cancer is not known but elevation of Cx32 in lymph node metastasis may indicate its diverse functions in different stages of breast cancer. To verify this, in normal breast MCF10A and breast cancer MDA-MB-231 cell lines, connexin32 was overexpressed. The localization of the protein was compared with immunostaining method after transient Cx32 overexpression. In untransfected MDA-MB-231 cells, Cx32 localized in the nucleus and the cytoplasm, while it was mostly observed in the cytoplasm in MDA-MB-231 Cx32-EGFP cells. In untransfected MCF10A cells Cx32 localized in the nucleus, whereas Cx32 formed gap junctional plaques between the adjacent MCF10A Cx32-EGFP cells. Scrape loading assay for gap junction activity and dye uptake assay for hemichannel functionality were performed with stable cell lines. When Cx32 was overexpressed, the gap junction coupling significantly increased in MCF10A cells whereas it did not change in MDA-MB-231 cells. In both cell lines, the hemichannel activity did not alter as a result of Cx32 overexpression. The effects of Cx32 expression on cell viability and cell cycle profile were examined. Cx32 overexpression led to a significant decrease in cell viability in MCF10A cells but did not affect the viability of MDA-MB-231. Cell cycle analysis experiments indicated that the percentage of cells in G1 decreased and in G2 increased in Cx32 overexpressing MDA-MB-231, which may indicate that increase in Cx32 may lead to a G2 arrest in MDA-MB-231 cells. However, the overexpression did not alter cell cycle profile of MCF10A significantly. In addition, Cx32 overexpression in MDA-MB-231 cells caused upregulation of vimentin and SNAI2; downregulation of E-cadherin, leading to a shift towards epithelial to mesenchymal phenotype. Assessment of Cx32 role in migration and invasion would further support its importance in this process. Finally, determination of the differential role of Cx32 in breast cancer initiation and progression may help us to understand its diagnostic and/or therapeutic potential.

The cell-cell adhesion component PLEKHA7 regulates the pro-tumorigenic MIR17HG long non-coding RNA in colon epithelial cells.
M.C. Bridges1, J. Nair-Menon1, A. Kourtidis3;
1Regenerative Medicine and Cell Biology, The Medical University of South Carolina, Charleston, SC

The adherens junctions (AJs) are essential architectural elements of epithelial tissues. Compromised junctional integrity is frequently observed in colon cancer, one of the most predominant forms of cancer. Recently, we identified a novel mechanism whereby the AJs of non-transformed colon cells suppress aberrant cell behavior by recruiting the RNAi machinery, mRNAs, and miRNAs, via the AJs component PLEKHA7. Our current data reveal widespread dysregulation of PLEKHA7 and of this mechanism in colon cancer cell lines and patient tissues. Interestingly, RNA-CLIP and subsequent RNA-Seq identified association of PLEKHA7 with numerous long non-coding RNAs (lncRNAs). LncRNAs interact with the RNAi machinery in multiple ways. While a number of lncRNAs have been associated with tumorigenesis, the underlying mechanisms of their regulation during tumor progression are still unclear. We hypothesize that the AJs regulate the levels and function of lncRNAs via PLEKHA7 and its associated RNAi mechanism to suppress pro-tumorigenic colon cell behavior. Comprehensive examination of the junction-associated lncRNAs by RNA-seq identified several whose expression levels are indeed regulated by PLEKHA7. From this set, the top upregulated lncRNA upon PLEKHA7 depletion is MIR17HG (miR-17-92; Oncomir-1), an oncogenic polycistronic host transcript of a set of miRNAs that includes miR-17, miR-
18a, miR-19a, miR-19b, miR-20a, miR-92a. Notably, the mature forms of these miRNAs also co-precipitate with PLEKHA7. Although PLEKHA7 knockdown results in increased levels of MIR17HG, this is followed by increased expression of only a subset of its hosted miRNAs, namely miR-19a, miR-19b and miR-20a. Our data suggest that two PLEKHA7-associated miRNAs, miR-203a and miR-372, mediate suppression of this lncRNA by PLEKHA7 and by its associated RNAi machinery. Re-expression of PLEKHA7 in aggressive colon cancer cells that lack PLEKHA7 suppressed expression of MIR17HG, as well as anchorage independent growth of these cells. Our present data point towards a novel mechanism of lncRNA regulation that tethers epithelial tissue integrity with pro-tumorigenic cell transformation.

The role of calcium in Rho-dependent remodeling of epithelial tight junctions.
S. Varadarajan¹, R.E. Stephenson¹, T. Higashi², A.L. Miller³;
¹Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, ²Fukushima Medical University, Fukushima, Japan

In order for an epithelium to serve as an effective barrier, cell-cell junctions must be maintained during events that cause cell shape changes, such as morphogenetic movements and cytokinesis. During cytokinesis, the dividing cell and its adjacent cells undergo cell shape changes, thus generating tension changes at the junctions. Using live imaging in the epithelium of gastrula-stage *Xenopus laevis* embryos, we show that local loss of tight junction proteins (ZO-1 and Occludin) occur with increased frequency around dividing cells and their neighbors, resulting in a leaky barrier. These discontinuities are rapidly repaired by localized, transient activations of RhoA, which we call “Rho flares”. However, the mechanism underlying activation of Rho flares is unknown. Here, we show that transient influx of calcium (Ca²⁺) precedes activation of Rho flares. Because the frequency of Rho flares increases around cells undergoing cytokinesis, we hypothesized that a mechanical trigger may initiate Rho flares. One way Ca²⁺ may enter the cells at these sites is through a mechanosensitive cation channel (MSC) called Piezo1. Piezo1 can localize to the plasma membrane and opens in response to changes in membrane tension to allow Ca²⁺ influx. In ongoing work, we are testing whether Piezo1 is responsible for the Ca²⁺ influx at Rho flare sites. We find that embryos treated with the MSC blockers Gadolinium chloride (Gd³⁺) or GsMtx4 exhibit reduced Rho flares. Identifying the mechanism by which cells sense and respond to challenges to cell-cell junction integrity will help us gain a better understanding of diseases like Crohn’s Disease and Inflammatory Bowel Disease where barrier function is impaired.

Myosin-X filopodia during cancer cell invasion.
G. Jacquemet¹, I. Paatero¹, E. Peuhu¹, J. Ivaska¹;
¹Turku Centre for Biotechnology, University of Turku and Åbo Akademi University, Turku, Finland

The formation of metastases is responsible for 90% of deaths in patients with solid tumours. Consequently, there is a pressing need to develop therapeutic strategies that block the ability of cancer cell to disseminate throughout the body. We and others have made an intriguing discovery that cancer metastasis is associated with the development of specialized cellular protrusions called filopodia. In migrating cells, filopodia are “antenna-like” protrusions, which contain cell-surface adhesion receptors,
such as integrins, responsible for constantly probing the cellular environment. At filopodia, integrins modulate signalling pathways that support cell migration, survival and proliferation. Integrins are transported to filopodia via a motor protein called Myosin-X, a regulator of filopodia formation. We discovered that myosin-X contribute to cancer cell metastases in vitro and in vivo models and that myosin-X is highly expressed in patient samples (including breast, pancreatic, colorectal, glioma and lung carcinoma) where it correlates with poor prognosis. Mechanistically, we found that myosin-X-mediated transport of integrins, together with integrin signalling in filopodia are two important prerequisites for cancer metastasis. In particular, we identified a signalling pathway, downstream of integrin signalling, involving Src, L-type calcium channels, and calpain-1 that regulates filopodia stability and directional migration. We are now studying the role of myosin-X filopodia during the different steps of the metastatic cascade, in vivo, using both intravital and extravital microscopy strategies. Intravital microscopy, using zebrafish embryo, revealed that cancer cells use filopodia extensively in vivo during both local invasion and extravasation. In addition, ex-vivo live cell imaging of whole tumors (subcutaneous tumours dissected from mice) revealed that myosin-x regulate cell protrusions at the invading edges but may also contribute to stromal ECM organization.

Actin retrograde flow actively aligns and orients ligand-engaged integrins in focal adhesions. V. Swaminathan¹, J.K. Mathew², S. Mehta³, P. Nordenfelt⁴, T.I. Moore⁵, N. KOGA⁶, D. Baker⁷, R. Oldenbourg³, T. Tani³, S. Mayor⁷, T.A. Springer⁵, C.M. Waterman¹; ¹Cell Biology and Physiology Center, National Heart Lung and Blood Institute, Bethesda, MD, ²National Centre for Biological Sciences, Bangalore, India, ³Eugene Bell Center, Marine Biological Laboratory, Woods Hole, MA, ⁴Division of Infection Medicine, Lund University, Lund, Sweden, ⁵Program in Cellular and Molecular Medicine, Harvard Medical School, Boston, MD, ⁶Institute for Molecular Science, Okazaki, Japan, ⁷Department of Biochemistry, University of Washington, Seattle, WA

Integrins are transmembrane receptors that, upon activation, bind extracellular matrix (ECM) or cell surface ligands and link them to the actin cytoskeleton to mediate cell adhesion, mechanosensing and migration. How integrin activation and organization in adhesions mediate the cells ability to sense directional mechanical cues is unknown. One model for the structural transitions mediating integrin activation termed “the cytoskeletal force hypothesis” posits that force transmitted from the cytoskeleton to ligand-bound integrins acts as an allosteric stabilizer of the extended-open, high-affinity state. Since cytoskeletal forces in migrating cells are generated by centripetal “retrograde flow” of F-actin from the cell leading edge, where integrin-based adhesions are initiated, this model predicts that F-actin flow should align and orient activated, ligand-bound integrins in integrin-based adhesions. Here, polarization-sensitive fluorescence microscopy of GFP-αV 3 integrin chimeras in migrating fibroblasts shows that integrins are co-aligned with respect to the axis of FAs and the direction of F-actin flow in a specific orientation, and this alignment requires binding immobilized ligand and talin-mediated linkage to a flowing cytoskeleton. Polarization imaging and Rosetta modelling of chimeras engineered to orient GFP differentially with respect to the integrin headpiece suggest that ligand-bound αVβ3 integrin may be markedly tilted by the force of F-actin flow. These results show that actin cytoskeletal forces actively sculpt an anisotropic molecular scaffold in FAs that may underlie the ability of cells to sense directional ECM and physical cues.

Increase in the protein levels of an anti-sprouting factor and integrin receptor, Thy-1, with age in the supraoptic nucleus: implications for a role in collateral axonal sprouting.
T. Dalzell¹, S. Whiteman¹, M. Andersen¹, J. Askvig¹;
¹Biology, Concordia College, Moorhead, MN

It has been demonstrated that a young brain can overcome injury by axonal sprouting; however, it is well understood that the mature brain has a reduced capacity for functional or structural reorganization following injury. To this point, following injury, uninjured axons from the supraoptic nucleus (SON) undergo collateral axonal sprouting in the 35-day-old rat, but not in 125-day-old rats. Therefore, it appears that within the SON there are age-related changes that preclude the older rat from recovering following injury. Cell adhesion molecules have been previously demonstrated to play a role in axonal sprouting, both in a stimulatory and inhibitory manner. Thus, we compared protein levels of the integrin family of cell adhesion molecules and the integrin receptor, Thy-1, in 35 and 125-day-old SON using Western blot analysis. Our results demonstrated that in the 125-day-old SON, there was a significant increase in Thy-1 protein levels, which is an anti-sprouting factor that can interact with integrins. Conversely, there were no changes in the protein levels of alpha v, beta 3, or beta 5 integrin when comparing the sprouting (35-day-old rat) and non-sprouting SON (125-day-old rat). Additionally, there were no changes in protein levels of Thy-1 or the integrin proteins in the neural lobe (posterior pituitary), which is the site of axonal sprouting. Our results suggest that the observed increase in Thy-1 protein levels in the SON with age may contribute to an environment that prevents the collateral axonal sprouting in the SON of an older rat.

Spatiotemporal regulation of focal adhesions disassembly at the G2/M transition of the cell cycle.
H.R. Thiam¹, A.M. Pasapera-Limon¹, E.K. Degaga², J.S. Urbach³, C.M. Waterman¹;
¹NHLBI, National Institute of Health, Bethesda, MD, ²Department of Physics and The Institute for Soft Matter Synthesis and Metrology, Georgetown University, Washington, DC

A hallmark of metazoan cell division is the drastic shape change occurring during mitotic cell rounding. Recent studies have shown that such shape change is required for proper chromosome segregation as well as spindle positioning, orientation and stability. For a dividing cell to round up, it must reduce its contact area with the extracellular matrix (ECM). This can be achieved by increasing cell cortical tension beyond the cell-ECM adhesion strength or reducing cell-ECM adhesion, or both. Here, we tested the hypothesis that mitotic cell rounding may be mediated by reducing cell-ECM adhesion through focal adhesion (FA) disassembly prior to mitosis. Using TIRF-based live cell imaging of FA, nuclear and cell cycle marker, we showed that FA loss is a prophase event that starts before nuclear envelope breakdown and coincides with cyclin B1 nuclear translocation. Analysis of FA dynamics showed that during mitosis, the number of assembling FA decreased while the FA disassembly rate increased. Traction force microscopy showed that this loss of cell adhesion was accompanied by a rapid drop in traction forces right at the onset of cell detachment with no apparent pre-deadhesion peak, suggesting that FAs are not disassembled simply by increasing cell contraction beyond the adhesion strength. Inhibition of mitotic kinases showed that at mitotic onset, PLK1 activity is required for inhibition of FA assembly, while CDK1 activation drives FA disassembly. To examine the possible pathways governing FA
disassembly downstream of CDK1, we manipulated regulators of FA disassembly known from studies of cell migration, including myosin II, FAK, calpain and its cleavage target talin, and integrins. This showed that neither calpain, myosin II nor FAK activity are required for cell de-adhesion during mitosis. To determine the requirement for integrin inactivation in FA disassembly, we locked integrins in their active/high affinity ECM-binding conformation using either manganese or conformation specific antibodies. As expected, we found that integrin inactivation was required for mitotic deadhesion, but quite unexpectedly, we found that blocking integrin inactivation caused failure of cells to complete mitosis. Inhibiting integrin inactivation in cells expressing GFP-PCNA as a marker of cell cycle stage showed that integrin inactivation and subsequent FA disassembly inhibited entry into mitosis, with the GFP-PCNA localization pattern indicating a G2 block. Taken together, our data suggest that mitotic cells use a specific mechanism, distinct from the ones used by migrating cells but dependent on Cdk1 and Plk1 activity, to de-adhere at mitosis. Our data further suggest that integrin inactivation and FA disassembly are required for cell cycle progression in adherent cells.

**Extracellular Matrix Substrates Affect Focal Adhesion Kinase (FAK) Distribution in Prostatic Smooth Muscle Cells.**

D.A. Osorio Rodriguez¹, A.M. Santos¹, H.F. Carvalho¹;

¹Structural and Functional Biology, State University of Campinas, Campinas, Brazil

Smooth muscle cells (SMCs) shift between the contractile and the synthetic phenotype in response to different environmental cues. The extracellular matrix (ECM) triggers specific signaling pathways during development, homeostasis in adults and in disease. External stimuli from the ECM translate through the transmembrane receptors integrins, which bind specific ECM proteins. This allows the cell to recognize specific clues and respond to the surrounding environment. The integrin cytoplasmic domain interacts with several proteins in a complex called focal adhesion. FAK is one such 125-KDa protein-tyrosine kinase protein, responsible for transducing the ECM-integrin-cytoskeleton signaling. The aim of this work was to identify how collagen, laminin-rich matrigel and fibrin substrates regulate SMC phenotype and to map how these ECM substrates affects FAK subcellular distribution in these cells. SMCs were obtained by culturing ventral prostate explants from male Wistar rats, in DMEM medium supplemented with 10% fetal bovine serum, 1% penicillin/streptomycin, 10 nM dihydrotestosterone, and 5 μg/mL insulin. Subsequently, SMCs in the fourth-to-seventh passages were seeded on plastic, type I collagen, matrigel or fibrin substrates. After 48 hours in culture, the SMCs were fixed and then incubated with antibodies against smooth muscle alpha-actin (alpha-SMA) and FAK A17. Images were acquired using a confocal LSM780 microscope (Carl Zeiss). ECM substrates did not affect α-SMA expression though cell morphology differed markedly. SMCs seeded on plastic or type I collagen were well spread, and FAK was mainly located at the focal adhesion and in the cell nucleus. Cells seeded on fibrin or matrigel were elongated and had many cell processes, while FAK was found predominantly in discrete cytoplasmic dots. In contrast to the cells on plastic or collagen, most cells on fibrin and matrigel lacked nuclear staining for FAK. These observations suggest that ECM components regulate SMC behavior and that FAK might be involved in the maintenance of the SMC phenotype in the prostate, irrespective of the expression of alpha-SMA.

Alternative splicing of tenascin-C modulates cell-matrix interactions during inflammation and disease.
S.P. Giblin¹, K.S. Midwood¹;
¹Kennedy Institute of Rheumatology, University of Oxford, Oxford, United Kingdom

The extracellular matrix (ECM) is a complex network of proteins secreted by cells, which is essential for providing structural support and facilitating cell processes including adhesion, migration and survival. Tenascin-C is an immunomodulatory ECM protein that exhibits limited expression in healthy tissues, but is transiently elevated at sites of tissue injury, and is persistently expressed in chronic inflammatory diseases and tumours. Alternative splicing of tenascin-C’s 9 fibronectin type III-like domains (FnIII- A1, A2, A3, A4, B, AD2, AD1, C and D) generates enormous diversity in form; yielding 511 possible isoforms. Post-transcriptional modification of tenascin-C has been studied in cancer and during development where disease and tissue specific isoforms exhibit distinct adhesive, migratory and proliferative effects. However, little is known of how tenascin-C is expressed or alternatively spliced during inflammation. This study characterises inflammation and disease specific tenascin-C isoforms made by immune cells and fibroblasts, and investigates their functional relevance.

Biosynthesis and alternative splicing of tenascin-C was examined using standard curve qPCR, ELISA, Western blot and confocal immunocytochemistry in resting and activated primary human immune cells, dermal fibroblasts, and in synovial fibroblasts isolated from healthy controls and from osteoarthritis (OA) and rheumatoid arthritis (RA) patients. FnIII domains AD2-AD1, B-C-D and B-AD2-AD1-C-D were cloned, expressed and purified, and their impact on cell behaviour including adhesion, morphology and migration was assessed.

Basal tenascin-C expression was lower in myeloid and lymphoid cells than fibroblasts, and was induced in all following inflammatory stimulation. Tenascin-C expression was elevated in disease with RA and OA synovial fibroblasts containing higher levels than healthy controls. Alternative splicing following cell activation was cell-type specific: all FnIII except AD2 and AD1 were upregulated in dendritic cells and macrophages, in T-cells all FnIII were down-regulated and A1 was absent, and no change in splicing was observed in activated dermal fibroblasts. RA and OA fibroblasts predominantly expressed smaller isoforms, with FnIII-B and D specifically elevated in RA. Functional analysis revealed differences in the adhesion, morphology and migration of myeloid cells and dermal fibroblasts cultured on FnIII AD2-AD1, B-C-D, B-AD2-AD1-C-D and full length tenascin-C substrates.

For the first time, this study reveals differences in tenascin-C biosynthesis and alternative splicing by immune cells and fibroblasts following activation with inflammatory stimuli, and identifies cell-type specific responses to distinct FnIII that direct cell-matrix interactions.

Germline stem cell maintenance control by adipocyte collagen in adult Drosophila females.
L.N. Weaver¹, D. Drummond-Barbosa¹;
¹Biochemistry and Molecular Biology Department, The Johns Hopkins University, Baltimore, MD

Stem cells reside in specialized niches that are a source of local signals and also receive a variety of systemic inputs. In adult female Drosophila, germline stem cells (GSCs) are physically attached to a somatic niche composed primarily of cap cells through E-cadherin. Local signals produced by cap cells, including bone morphogenetic protein (BMP) signals, are required for proper regulation of GSC function.
In adult females, a prominent collagen IV-containing extracellular matrix is maintained around the GSC niche; however, it remains unknown what the cellular source of collagen IV is in the adult GSC niche or how it affects GSC function. In the adult female fat body, collagen IV proteins are abundant and highly regulated by diet, leading us to ask whether collagen IV function in adipocytes is required for GSC function. Adipocyte-specific knockdown of collagen IV in adult females leads to increased GSC loss over time. Interestingly, we found that collagen IV produced in adult adipocytes is transported to and incorporated into the extracellular matrix in the GSC region during adulthood. Although BMP signaling from the niche is not perturbed, E-Cadherin levels are decreased at the GSC-niche interface when collagen IV is knocked down in adipocytes. We are currently testing the hypothesis that adipocyte-derived collagen IV regulates integrin/focal adhesion kinase signaling in the GSC region to regulate E-Cadherin levels and GSC maintenance. To our knowledge, this is the first example of an extracellular matrix component produced in adult adipocytes being transported to a stem cell niche in a distinct, fully established adult tissue. These findings are a major step in advancing our understanding of the wide range of mechanisms for how adipocytes control the function of other organs, and are widely relevant considering the devastating impact of the current global obesity epidemic on our health.

BMP4-induced differentiation sensitizes glioblastoma tumor initiating cells to mechanical inputs.

J.H. Hughes1,2, S.Y. Wong1,2, S. Kumar1,3;
1Bioengineering, University of California, Berkeley, Berkeley, CA; 2UC Berkeley - UCSF Graduate Program in Bioengineering, Berkeley, CA; 3Chemical and Biomolecular Engineering, University of Berkeley, Berkeley, CA

Glioblastoma (GBM) is one of the most common and lethal primary brain cancers. Difficulty in treating this disease has been attributed to a rare but important subpopulation of cells that evade chemotherapeutic treatment, diffusely invade the surrounding tissue, and establish secondary tumors. These tumor-initiating cells (TICs) share characteristics with stem cells in that they self-renew and differentiate to produce the more specialized and heterogeneous cell populations that make up the bulk of the tumor. GBMs are typically stiffer than the surrounding brain tissue, and tumor cells follow stiffer structures such as vascular beds as they invade. Because of these observations, and because GBM is a disease of cell migration, we probed how these TICs respond to stiffness cues in their environment. In contrast to the majority of other cell types, TICs showed surprisingly little stiffness-dependent changes in cell shape and migration. By increasing cellular force generation via constitutive activation of RhoA, we were able to sensitize the TICs to mechanical cues. Furthermore, we found that TICs with heightened cellular force generation showed reduced invasion through three-dimensional materials, and when xenografted, produced small and circumscribed tumors, which translated into a 30% increase in survival time. Evidence from our lab and from others suggests that mechanosensitivity and differentiation state are correlated with TIC invasiveness and tumor generating potential. Others have demonstrated that bone morphogenetic protein 4 (BMP4) elicits a differentiation-like effect on GBM TICs and extends survival in a xenograft model. We therefore asked how the mechanosensitivity of these TICs changes as they are exposed to bone morphogenetic protein 4 (BMP4). We found that TICs treated with BMP4 showed increased mechanosensitivity of cell shape but not migration speed. To achieve a systems-level picture of the links between TIC differentiation state and mechanically-regulated signaling, we performed RNA sequencing. Interestingly, cells exposed to BMP4 on soft substrates showed a greater transcriptomic shift compared to those on stiff substrates, mirroring the observation that TICs exhibit a
“stiff” phenotype on soft gels and that sensitivity to soft gels is heightened upon BMP4 treatment. Of the genes differentially influenced by BMP4 treatment, pathways associated with cell-matrix interactions were particularly impacted. Immunoblotting and immunostaining confirmed differentiation-mediated changes in focal adhesion protein expression, including integrins and zyxin. Taken together, these findings suggest a link between differentiation, mechanosensitivity and invasion, and that mechanical signaling could be leveraged to control tumor progression.

Mechanical modulation of glycolysis through phosphofructokinase and its activators in a KRAS-dependent manner.
J. Park1, T. Isogai1, C.J. Burckhardt1, B. Gao1, R. Bachoo1, G. Danuser1;
1The Lyda Hill Department of Bioinformatics, University of Texas Southwestern Medical Center, Dallas, TX

Cells can actively sense the microenvironment by cytoskeletal remodeling and by actomyosin contractility. Both processes consume a significant amount of energy, which is supported by the cell’s metabolic activity. However, it is unclear if cells adjust their metabolism directly to the mechanical conditions of the environment. To begin to test such a link this study investigates metabolic changes as a function of extracellular matrix stiffness using untransformed human bronchial epithelial cells (HBECs) and non-small cell lung cancer cells (NSCLCs). We show that HBECs have more glucose metabolites and exhibit higher rates of glycolysis when placed on stiff substrate in comparison to soft substrate. Pharmacological inhibition of focal adhesion kinase and actomyosin contractility both disrupt glycolysis. Moreover, we show that expression of phosphofructokinase platelet (PFKP), 6-phosphofructo-2-kinase/fructose-2,6-biphosphatase3 (PFKFB3), and AMP-activated protein kinase (AMPK) are down-regulated upon decreased focal adhesion or intracellular tension, which could be partially rescued by proteasome inhibition. However, both mutant Kras-transformed HBECs and NSCLCs with the KRAS mutations assume consistent rates of glycolysis independent of cell substrate stiffness. Interestingly, the expression of PFKP is maintained by the mechanical desensitization driven by the Kras mutations. Knockdown of PFKP in Kras-mutant NSCLCs hindered tumor growth in mice as expected. Thus, while untransformed lung epithelial cells appear to adjust their metabolic activity in response to the mechanical properties of the microenvironment, Kras-mutated, transformed lung cancer cells loose this responsiveness, which may support the conditions of tumorigenesis and metastasis.

A Cautionary Tail: Changes in Integrin Behavior with Labeling.
C.G. Galbraith1, M.W. Davidson3, J.A. Galbraith1;
1OCSSB/BME, OHSU, Portland, OR, 2National High Magnet Laboratory, FSU, Tallahassee, FL

All mesenchymal cell migration depends upon integrin heterodimers forming connections between the extracellular matrix (ECM) and the cytoskeleton to enable the cell to pull itself forward. Critical to this function is the ability of integrins to increase their affinity in response to ECM and redistribute into structural and signaling hubs called adhesions. Decades of conventional fluorescence microscopy (TIRF, FRAP, FRET, FLIP) have shown that genetically expressed fluorescently labeled integrins correctly respond to ligand and form adhesions, and this ability to respond to a ligand is independent of which subunit of the heterodimer is labeled. However, when we imaged the cells using live-cell single
molecule super-resolution, we discovered differences in the behavior of the integrin molecule that depend upon which subunit is labeled. When we expressed either αβ3 or αβ1 integrins in the null backgrounds of CHO-K1 and CHO-B2 cells, respectively, we found that labeling the beta subunit decreased the mobility of individual integrins, increased the size of the adhesions, and increased the extent of cell spreading. These results are indicative of elevated integrin affinity, and the increased size of adhesions and cell spreading were nearly identical to results obtained when cells expressing unlabeled integrin were experimentally forced into a higher affinity state by Mn^{2+} treatment. Moreover, direct measures of integrin affinity made with quantitative immunofluorescence of an antibody targeted against a site that is only accessible when the affinity is elevated, indicate that labeling the beta subunit significantly increases the affinity of the integrin heterodimer in comparison to labeling the alpha subunit. Labeling the longer cytoplasmic tail of the beta subunit likely spreads the two subunits apart to change integrin conformation and enhance the response of the cell to a ligand. Thus, our dense-field, live-cell measurements of single molecule behavior can detect changes in receptor conformation, bringing to light a cautionary tail regarding molecular labeling.

Directly measuring integrin conformational change on the cell surface using Interferometric Photoactivation Localization Microscopy (iPALM).
T.I. Moore1,2; J. Aaron3; T. Chew4; H.F. Hess4; T.A. Springer4;
1Biological Chemistry and Molecular Pharmacology, Harvard Medical School, Boston, MA, 2Program in Cellular and Molecular Medicine, Boston Children’s Hospital, Boston, MA, 3Advanced Imaging Center, Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA, 4Janelia Research Campus, Howard Hughes Medical Institute, Ashburn, VA

Measuring protein conformational change has been the realm of soluble protein chemistry, NMR spectroscopy and X-ray crystallography. Here, we describe the use of super-resolution Interferometric Photoactivation and Localization Microscopy (iPALM) combined with a constrained photoactivatable fluorescent protein integrin fusion to measure the conformational change of the lymphocyte specific integrin LFA-1 on the cell surface. Our molecular scale measurements of the cell surface adhesion receptor agree with predicted distances derived from crystal structure models of bent and extended integrins. While measured LFA-1 conformation show that extension is ligand specific and inducible by small molecule allosteric modulators, adding additional support for the cytoskeletal force model of integrin activation.

A regulatory mechanism in the inside-out integrin signaling pathway.
P. Zhang1; J. Wu1
1Molecular Therapeutics Program, Fox Chase Cancer Cancer, Philadelphia, PA

Integrins are cellular receptors that regulate cell adhesion, migration, and proliferation. Abnormal integrin activity has been linked to many life-threatening diseases. Integrins are activated via an inside-out pathway, which is induced by the Rap1, and mediated by Rap1-interacting adaptor molecule (RIAM) and talin. Kindlin further enhances integrin activity. We have previously elucidated the structural basis of the interactions among these proteins. However, more detailed physiological information is still lacking in this signaling pathway, and many in vivo studies have indicated that alternative mechanisms
may exist. The current focus of our efforts is to identify new regulatory mechanisms in the inside-out pathway that fine-tune integrin activation by structural and biochemical approaches. We will present data regarding the structural and mechanistic basis of these regulatory events.

Polyphosphate protects organisms against DNA-damaging agents.
F. Beaufay¹, A. Franz¹, U. Jakob¹²;
¹Department of Molecular, Cellular, and Developmental Biology, University of Michigan, Ann Arbor, MI,
²Department of Biological Chemistry, University of Michigan, Ann Arbor, MI

Organisms are continually exposed to stressors that specifically target and damage DNA, including ultra violet radiation or chemical mutagens. We now discovered that polyphosphate (polyP), a linear polymer consisting of up to 1000 inorganic phosphate (Pi) molecules linked by high-energy ATP-like bonds, protects bacteria against a variety of different DNA damaging agents. We found that deletion of ppk, the polyP-synthesizing enzyme in E. coli, sensitizes cells against DNA damaging agents ranging from UV light to cisplatin, mitomycin C and phleomycin. Cells lacking polyP present significantly higher mutagenesis rates in response to cisplatin treatment in comparison to cells deleted for the polyP-degrading enzyme (ppx). These results agree well with quantitative polyP measurements, which revealed that E. coli accumulates large amount of polyP in response to cisplatin treatment. Preliminary results suggest that polyP protects cells using a mechanism that is independent of its known function as oxidative stress protecting agent, and independent of modulating DNA-repair systems. Instead, genetic studies suggest that polyP might protect DNA by chromosome compaction through interaction with histone-like proteins. Altogether, these observations provide new insights on the global function of PolyP upon stress and might open new ways of co-treatment when using DNA-damaging drugs.

GIV/Girdin Mediates Cell Survival during Endoplasmic Reticulum Stress.
P. Nguyen¹, R. Calderon¹, Y. Rodriguez¹, D. Bhandari¹;
¹Chemistry and Biochemistry, California State University Long Beach, Long Beach, CA

Endoplasmic reticulum (ER) stress is a form of cellular stress that is experienced both under normal physiological conditions such as in professional secretory cells and disease states such as cancer, diabetes and neuro-degeneration. Upon facing ER stress, cells initially try to restore normal function by activating a conserved signaling pathway called the Unfolded Protein Response (UPR). However, if the stress is overwhelming and cells are not able to recover within a reasonable time frame, the UPR ultimately commits cells to apoptosis. How cells make this life-or-death decision remains an exciting yet poorly understood phenomenon. Here, we show that GIV (Go-Interacting Vesicle associated protein aka Girdin), a multimodular signaling protein, helps promote cell survival during ER stress via activation of the Akt pathway. HeLa cells treated with various ER stressors activate the Akt pathway and this activation is significantly diminished upon shRNA-mediated depletion of GIV. Furthermore, GIV-depleted cells show a significant decrease in cell survival during ER stress. We also found that GIV interacts with one of the key ER chaperones in an ER stress dependent manner. Taken together, these findings suggest that GIV may play an important role in helping cells survive ER stress. Our current and future studies are
focused on delineating the exact mechanism by which GIV enhances cyto-protective Akt signals during ER stress. This project is supported by the NIH grant # SC2GM121246 (DB) and in part by the NIGMS Award # R25GM071638 (RC and YR). Cytosolic proteostasis through importing of misfolded proteins into mitochondria.

L. Ruan¹,², C. Zhou³, E. Jin², A. Kucharavy¹,², Y. Zhang³, Z. Wen³, L. Flores³, R. Li¹,²; ¹Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Department of Chemical and Biomolecular Engineering, Johns Hopkins University Whiting School of Engineering, Baltimore, MD, ³Stowers Institute for Medical Research, Kansas City, MO

Loss of proteostasis underlies ageing and neurodegeneration characterized by the accumulation of protein aggregates and mitochondrial dysfunction. Although many neurodegenerative disease-associated proteins can be found in mitochondria, it remains unclear how mitochondrial dysfunction and protein aggregation could be related. In dividing yeast cells, protein aggregates that form under stress or during ageing are preferentially retained by the mother cell, in part through tethering to mitochondria, while the disagggregase Hsp104 helps to dissociate aggregates and thereby enables refolding or degradation of misfolded proteins. Here we show that, in yeast, cytosolic proteins prone to aggregation are imported into mitochondria for degradation. Protein aggregates that form under heat shock contain both cytosolic and mitochondrial proteins and interact with the mitochondrial import complex. Many aggregation-prone proteins enter the mitochondrial intermembrane space and matrix after heat shock, and some do so even without stress. Timely dissolution of cytosolic aggregates requires the mitochondrial import machinery and proteases. Blocking mitochondrial import but not proteasome activity causes a marked delay in the degradation of aggregated proteins. Defects in cytosolic Hsp70s leads to enhanced entry of misfolded proteins into mitochondria and elevated mitochondrial stress. We term this mitochondria-mediated proteostasis mechanism MAGIC (mitochondria as guardian in cytosol) and provide evidence that it may exist in human cells.

Hsp104 disaggregase: protein refolder or phase converter?

H. Yoo¹, E. Pilipenko¹, D.A. Drummond¹; ¹Biochemistry and Molecular Biology, University of Chicago, Chicago, IL

In budding yeast, S. cerevisiae, many environmental stresses such as heat shock trigger aggregation of soluble proteins and RNA into massive particles, many of which are then recruited to stress granules (SGs). During the recovery period, a set of molecular chaperones called heat shock proteins resolubilizes the constituent proteins back to the cytosol. Although this aggregation has long been interpreted as resulting from stress-induced protein misfolding, recent results offer an alternative view. We recently demonstrated that poly(A)-binding protein (Pab1 in budding yeast), a classical marker for SGs, demixes into hydrogel droplets in vitro upon exposure to physiological stress conditions. Demixing involves phase separation and gelation, and is an adaptive response to stress. Here we show that the Hsp104 disaggregase system disperses Pab1 hydrogels with unparalleled efficiency relative to the model aggregate firefly luciferase. We isolate the precise proteins...
necessary for efficient dispersal. In an important methodological advance, we introduce a new fluorescence anisotropy assay for kinetic monitoring of the conversion of inert Pab1 hydrogels into soluble RNA-binding Pab1 monomers. Our assay reveals that hydrogel dispersal into functional monomers is markedly more rapid than disaggregation of a model misfolded protein. Our results raise important questions as to the identity of the native substrates of protein disaggregase systems, the mechanisms by which these systems recognize their substrates, and the molecular features which control the efficiency of molecular dispersal of phase-separated endogenous structures.

Ire1 RNase specificity separates transcriptional and post-transcriptional regulation of ER protein homeostasis.

W. Li¹, V. Okreglak¹, J. Peschek¹, P. Kimmig¹, P. Walter¹,²;
¹Department of Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA,
²Howard Hughes Medical Institute, University of California San Francisco, San Francisco, CA

The endoplasmic reticulum (ER) is the major folding compartment for most secretory and plasma membrane proteins in the cell. A conserved signaling pathway, the unfolded protein response (UPR), senses and modulates the folding capacity of the ER. To maintain ER protein homeostasis under ER stress conditions, the ER membrane embedded sensor, Ire1, binds unfolded proteins through its ER-lumenal domain and initiates two distinct mRNA processing programs through its cytoplasmic kinase/RNase domains. First, in both metazoans and S. cerevisiae, Ire1 catalyzes the unconventional cytoplasmic mRNA splicing of XBP1 (metazoans) or HAC1 (S. cerevisiae)—thereby initiating a transcriptional response that increases the ER folding capacity. Second, in metazoans and S. pombe, Ire1 selectively degrades ER-localized mRNAs—thereby post-transcriptionally reducing the ER’s protein folding burden through regulated Ire1-dependent mRNA decay. Thus, Ire1 homologs in S. cerevisiae and S. pombe are specialized to only one of the two functional outputs, while Ire1 in metazoans can perform both. To understand how Ire1 can regulate protein homeostasis through distinct RNA processing programs mechanistically, we characterized Ire1 from S. cerevisiae and S. pombe with in vivo and in vitro experiments. Surprisingly, despite relatively low sequence conservation in the lumenal domains, these domains share conserved ER-stress sensing mechanism. Conversely, despite high sequence conservation, Ire1 cytoplasmic domains recognize distinct RNA sequence and structural features, which leads to functional divergence in RNA processing. Finally, by applying our new findings, we successfully reconstituted unconventional mRNA splicing in S. pombe cells. Therefore, we engineered S. pombe into a metazoan-like Ire1 system, where unconventional mRNA splicing and selective mRNA decay co-exist. Our results provide new insights into a mechanistic understanding of Ire1 function and its interplay with RNA substrates.

Clustering of IRE1α depends on sensing the type and level of ER stress, but not on its RNase activity.
D. Ricci1, I. Marrocco1,2, M. Dibos1, D. Blumental1, J. Vargas1, S. Boyle1, Y. Iwamoto1, Y. Argon1,3;
1Pathology and Laboratory Medicine, The Children’s Hospital of Philadelphia, Philadelphia, PA,
2Department of Biological Regulation, Weizmann Institute of Science, Rehovot, Israel, 3University of Pennsylvania, Philadelphia, PA

The sensors of the Unfolded Protein Response (UPR) react to Endoplasmic Reticulum (ER) stress by transient activation of their enzymatic activities, which then initiate various signaling cascades in order to restore the cellular homeostasis. However, if the stress exceeds a tolerable threshold, the UPR sensors initiate programmed cell death and therefore play a fundamental role in determining the cell fate. Following ER stress, the ER transmembrane sensor Inositol-Requirement Enzyme 1 α (IRE1α) undergoes several molecular changes to transmit the stress signal to the cytosol: dimerization, auto trans-phosphorylation and, finally, activation of its RNase activity. In addition, IRE1α exhibits stress-induced clustering in the same transient fashion as its endoribonuclease activities. Neither the function nor the regulation of IRE1α clustering is well-understood, so we characterized the molecular requirements for clustering. Our data show that clustering depends on the stress sensing mechanism of IRE1α, because it is prevented by mutations in the dimerization or kinase domains, and because ablation of the ER luminal chaperone BiP causes massive and irreversible clustering of IRE1α. Although IRE1α kinase activity is required for clustering, sustained phosphorylation through okadaic acid treatment does not extend the clustering response, suggesting that phosphorylation is necessary for initiation but not dispersal of clusters. Surprisingly, the endoribonuclease activity is not necessary for clustering, since both active and inactive forms of IRE1α cluster irreversibly. Furthermore, clustering is dispensable for IRE1α endoribonuclease activity because the flavonoid luteolin binds to and activates IRE1α RNase activity without inducing clustering. The clustering response differentiates between distinct sources and magnitude of ER stress. The calcium pump inhibitor thapsigargin induces significantly less clustering than the inhibitor of glycosylation tunicamycin or the disulfide bond reductant dithiothreitol, and it also inhibits the tunicamycin-induced clustering. This suggests that ER calcium homeostasis is required for cluster formation. We propose that IRE1α clustering is a cellular tool to measure the type and strength of ER stress, since its magnitude and timing correlate inversely with the cells’ ability to cope with the stress.

Nuclear-import receptors reverse aberrant phase transitions of RNA-binding proteins with prion-like domains.
L. Guo1, J. Shorter1;
1Department of Biochemistry Biophysics, University of Pennsylvania, Philadelphia, PA

RNA-binding proteins (RBPs) with prion-like domains (PrLDs) phase transition to functional liquids, which can mature into aberrant hydrogels composed of pathological fibrils that underpin fatal neurodegenerative disorders. Several nuclear RBPs with PrLDs including TDP-43, FUS, hnRNPA1, and hnRNPA2 mislocalize to cytoplasmic inclusions in neurodegenerative disorders and mutations in their PrLDs can accelerate fibrillization and cause disease. Here, we establish that nuclear-import receptors specifically and potently chaperone and disaggregate wild-type and disease-linked RBPs bearing a NLS.
Karyopherin-β2 (Kapβ2) engages PY-NLSs to inhibit and reverse FUS, TAF15, EWSR1, hnRNPA1, and hnRNPA2 fibrillation, whereas importin-a plus KapB1 prevent and reverse TDP-43 fibrillation. Remarkably, Kapβ2 dissolves and liquidizes aberrant hydrogels formed by FUS and hnRNPA1 fibrils. Increased Kapβ2 expression prevents RBPs with PY-NLSs incorporating into stress granules, restores nuclear localization, and rescues degeneration caused by disease-linked FUS and hnRNPA2 in vivo. Thus, elevating nuclear import receptor expression could therapeutically restore RBP homeostasis and mitigate neurodegeneration.

Developing therapeutic protein disaggregases for Neurodegenerative Disease.
J.N. Lin³, P. Carman³, C.W. Gambogi³, N. Kendsersky², J. Shorter¹;
¹Department of Biochemistry Biophysics, University of Pennsylvania, Philadelphia, PA, ²Department of Pharmacology, University of Pennsylvania, Philadelphia, PA

The accumulation of abnormal protein aggregates in human brain is connected with neurodegenerative diseases such as Parkinson’s disease and Alzheimer’s disease. The mammalian protein-disaggregase system comprised of Hsp110, Hsp70, and Hsp40 (Hdj1 and Hdj2) can protect cells from proteinopathies. However, this disaggregate system has limitations and activity declines with age. Therefore, as a therapeutic strategy for neurodegenerative disease we propose to introduce an exogenous, synthetic disaggregate machinery, based on Hsp104, that converts amyloid to soluble, functional protein. Hsp104 is a hexameric AAA+ ATPase that is critical for stress tolerance in yeast by facilitating the resolubilization of stress-damaged, aggregated proteins. The homologues of Hsp104 are highly conserved in bacteria, fungi, and plants, but absent from metazoa. The disaggregate activity of Hsp104 can be enhanced by the presence Hsp70 and Hsp40. Hsp104 can dissolve α-synuclein, β-amyloid, and tau aggregates, but impractically high Hsp104 concentrations are needed. We aim to rationally design potentiated Hsp104 variants that can reverse protein misfolding at low concentrations. By investigating the mechanism of Hsp104 disaggregation and its structural basis, we will engineer and evolve potentiated Hsp104 variants that eradicate α-synuclein, β-amyloid, or tau misfolding and toxicity. We have exploited new cryo-EM structures of Hsp104 to engineer key interfaces to yield several novel Hsp104 variants with tunable activity, which can reverse protein aggregation in the presence or absence of human Hsp70 and Hsp40. These novel Hsp104 variants effectively rescue the aggregation and toxicity of diverse human neurodegenerative disease proteins and could have therapeutic utility. Moreover, our engineered Hsp104 variants provide key mechanistic insights into disaggregate function.

Modification of the ribosome as part of the adaptive response to oxidative stress in yeast.
J.A. Zinskie¹, D. Shedlovskiy¹, E. Gardner¹, D. Pestov¹, N. Shcherbik³;
¹Cell Biology and Neuroscience, Rowan University School of Osteopathic Medicine, Stratford, NJ

Living organisms are constantly exposed to a variety of environmental and internal stressors that are detrimental to their cellular physiology and viability. One such condition, oxidative stress, is caused by abnormal amounts of Reactive Oxygen Species (ROS) that can lead to damage to proteins, nucleic acids, and lipids. Although the mechanisms to neutralize ROS have been widely studied, the understanding of ROS-mediated signaling for these mechanisms is rather incomplete and sparse. We have uncovered a previously undescribed phenomenon of yeast ribosomes to respond to elevated levels of ROS through a
site-specific endonucleolytic cleavage of the 25S rRNA in the c-loop of the expansion segment 7 (ES7c) regions. ES7c is a putative regulatory region located on the surface of the 60S ribosomal subunit. This cleavage was detected at the early stages of stress and is not a part of cell death. Additionally, we have seen that low level exposure to oxidative stressors can lead to a protective effect against this cleavage when cells are exposed to higher levels of the stressor. We conclude that ES7c cleavage represents an early and sensitive marker of increased ROS levels in yeast cells and propose that changes in ribosomes may signify an adaptive response to oxidative stress.

Engineering potentiated Hsp104 variants with enhanced substrate-specificity to counter neurodegeneration.
K.L. Mack1, M.E. Jackrel1, J.E. DeNizio1, H. Kim2, K.A. Caldwell3, G.A. Caldwell4, J. Shorter1;
1Department of Biochemistry and Biophysics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, 2Department of Biological Sciences, University of Alabama, Tuscaloosa, AL

Hsp104, a hexameric AAA+ protein disaggregase found in yeast, dissolves amorphous aggregates and amyloid using energy from ATP hydrolysis. With the Hsp70 chaperone system, Hsp104 reactivates misfolded protein substrates. Interestingly, an Hsp104 homolog is absent from metazoa, and as such humans lack ample machinery to eradicate protein misfolding in the context of neurodegenerative disease. Therefore, Hsp104 is an ideal therapeutic candidate for directly targeting underlying protein misfolding. We previously engineered potentiated Hsp104 variants that disassemble neurodegenerative disease-associated substrates α-synuclein (implicated in Parkinson’s disease) and FUS and TDP-43 (implicated in amyotrophic lateral sclerosis). Though robust disaggregases, these Hsp104 variants are not substrate-specific and likely unfold essential proteins, causing off-target effects. Here, by targeting conserved pore loop residues that contact substrate in the central channel of Hsp104, we engineered substrate-specific Hsp104 variants capable of specifically suppressing α-synuclein toxicity in yeast proteinopathy models. These α-synuclein-specific Hsp104 variants only minimally suppress toxicity of FUS or TDP-43. Interestingly, we isolated two sets of α-synuclein-specific Hsp104 variants that differ in their ability to restore proper localization to and suppress toxicity of α-synuclein in yeast, and have different biochemical features. As such, these substrate-specific Hsp104 variants may selectively suppress α-synuclein toxicity through different mechanisms. Excitingly, some α-synuclein-specific Hsp104 variants inhibit dopaminergic neuron loss in a C. elegans model of Parkinson’s disease. Our findings reveal key insights to tuning Hsp104 to therapeutically target specific misfolded proteins.

Yeast FIT2 homologs mediate the crosstalk between lipid droplet biogenesis, the unfolded protein response and cytoplasmic proteostasis.
P.T. Shyu1, W. Gien1, G. Thibault1,2;
1School of Biological Sciences, Nanyang Technological University, Singapore, Singapore, 2Lee Kong Chian School of Medicine, Nanyang Technological University, Singapore, Singapore

Lipid droplets (LDs) have long been regarded as inert cytoplasmic organelles with the primary function of housing excess intracellular lipids. More recently, LDs have been strongly implicated in conditions of lipid and protein dysregulation. Moreover, these conditions are major contributors to the
pathophysiology of metabolic diseases and concomitantly activate cellular stress response pathways, namely the unfolded protein response (UPR) and heat shock response (HSR). However, despite the increasing support for the involvement of LDs in other cellular processes, mechanistic insight into the fundamental process of LD biogenesis and its direct physiological relevance to the cell remains rudimentary. The fat storage inducing transmembrane (FIT) family of proteins comprises of evolutionarily conserved endoplasmic reticulum (ER)-resident proteins that have been reported to induce LD formation. Using Saccharomyces cerevisiae as a model, this study aims to dissect the role of LDs in cellular lipid and protein homeostasis through the yeast FIT homologs (ScFITs), SCS3 and YFT2. While LD biogenesis and basal UPR activation remain unaltered in ScFIT mutants, SCS3 was found to be essential in the absence of the sole yeast UPR sensor IRE1. Devoid of a functional UPR, Δscs3 mutants exhibited increased microsomal triacylglycerol levels, indicative of impaired ER-LD lipid partitioning and suggesting a UPR-dependent compensatory mechanism for LD biogenesis. Surprisingly, the absence of ScFIT results in the downregulation of the closely-related HSR pathway. In line with this observation, the turnover of cytoplasmic misfolded proteins is impaired in ΔScFIT cells, while a screen for interacting partners of Scs3 identifies components of the proteostatic machinery as putative targets. Taken together, these suggest that ScFITs may modulate proteostasis and stress response pathways with LD biogenesis at the interface between the two cellular processes.

Adaptive unfolded protein response facilitates melanogenesis.

A. KRISHNAN1, J. TANWAR1, R.K. MOTIANI1, V.T. NATARAJAN1, R.S. GOKHALE1,2;
1CSIR-Institute of Genomics Integrative Biology, New Delhi, India, 2National Institute Of Immunology, New Delhi, India

The endoplasmic reticulum (ER) is a network of membranous tubules within the cytoplasm of a eukaryotic cell that is involved in protein and lipid synthesis. The ER possesses oxidizing environment, chaperones, protein-disulfide isomerases and glycosylating enzymes that facilitate protein folding. Any perturbation that disrupts protein folding capacity in the ER activates a signaling cascade called the unfolded protein response (UPR). UPR functions to bring back ER protein folding homeostasis, dysregulation of which can eventually result in apoptosis. The paradoxical role of UPR has been examined in variety of cellular models and is particularly critical to secretory cell types such as plasma cells, pancreatic β cells etc. Melanocytes are unique pigment secreting skin cells. These cells synthesize the pigment melanin within organelles called melanosomes, which are subsequently transferred to keratinocytes. Melanosomes are Lysosome-related organelles & several key melanosomal proteins are heavily glycosylated and dependent on glycosylating enzymes in the ER-Golgi channel for their folding. Biosynthesis of melanin and melanosomes is activated during tanning resulting in increased secretory load on melanocytes. We set out to decipher the role of ER UPR during the melanogenesis process. We employed previously developed B16 pigmentation oscillator model, wherein cells can be triggered to produce melanin pigment in a cell autonomous way in 6-8 days. This model is particularly useful to study temporal regulation of pathways during the transition from ‘white’ to ‘black’ cells. While following the changes in the ER UPR markers during melanogenesis, we observed a concomitant activation of the UPR pathways; particularly the X-box binding protein-1 (Xbp1) splicing was upregulated. We could also identify other downstream UPR genes to be upregulated along with melanogenesis. Other than the canonical UPR pathways, our unbiased analysis of the pigmentation oscillator model revealed molecular signature for the regulation of Cyclic-AMP Response Element Binding Protein 3-like protein 2 (Creb3l2). CREBs are known to be crucial to the regulation of Microphthalmia-Induced Transcription Factor (MITF), a Master regulator of melanocyte biology. Activation of Creb3l2 is marked by protease-mediated release

Monday-434
of its N-terminus, which acts as a transcription factor. Both Creb3l2 expression and activation was regulated during early time points of pigmentation. Thapsigargin, an ER stress-inducing agent, also caused a clear activation of Creb3l2 in B16 cells. Pharmacological induction of ER stress increased melanogenesis, while rescue with chemical chaperones caused depigmentation. Overall, our study reveals the essential function of ER adaptation via the UPR for melanogenesis.

Exploring and enhancing the metazoan disaggregate system to combat protein aggregation.
E. Chuang1,2, J. Shorter1,2;
1Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, 2Pharmacology, University of Pennsylvania, Philadelphia, PA

Proteins perform a myriad of essential and non-essential functions within the cell; however, proteins must be properly folded in order to function. During cellular stress, proteins may become misfolded and aggregate through aberrant intermolecular interactions. The 70 and 40 kDa heat shock proteins (Hsp70 and Hsp40) form one of the predominant molecular chaperone systems within the cell that unfolds and refolds misfolded proteins. However, aggregated proteins contain stable intermolecular interactions that are more difficult to break. Hsp110, a member of the Hsp70 super-family, collaborates with Hsp70 and Hsp40 to enable disassembly of protein aggregates and restoration of native protein function. Our lab has shown that the metazoan disaggregate system (MDS) comprising of Hsp70, Hsp40, and Hsp110 family members refolds disordered aggregates such as urea-denatured luciferase and heat-denatured GFP in vitro. The human genome contains 13 Hsp70 genes, over 50 Hsp40 genes, and 4 Hsp110 genes, giving rise to thousands of three-component combinations of the MDS. Select combinations more effectively disassemble α-synuclein amyloid than others, suggesting that different combinations of the MDS can have drastically different efficacy against the same substrate. This combinatorial phenomenon may be the key to understanding how a disaggregate system of under a hundred genes could chaperone a proteome of tens of thousands of proteins. We have purified a number of Hsp70, Hsp40, and Hsp110 proteins that are expressed in the cytosol of cells and systematically assessed the disaggregate activity of each combination against a variety of aggregated substrates. We are also screening a library of small molecules to identify enhancers and inhibitors of the MDS. Identified small-molecule enhancers are promising candidates for the treatment of neurodegenerative diseases. The results presented here further our understanding of the MDS and provide crucial therapeutic leads for a devastating class of diseases.

A guardian factor that protects folding polypeptides from promiscuous degradation.
S. Zhang1,2, C. Xu1,2, K.E. Larrimore2, D. Ng1,2;
1Department of Biological Sciences, National University of Singapore, Singapore, Singapore, 2Temasek Life Sciences Laboratory, Singapore, Singapore

Newly synthesized proteins engage molecular chaperones that assist folding. Their progress is monitored by quality control systems that target folding errors for degradation. Paradoxically, chaperones that promote folding also direct unfolded polypeptides for degradation. Hence, a mechanism was previously hypothesized that prevents the degradation of actively folding polypeptides. In this study, using genetic and biochemical approaches, we show that a conserved endoplasmic
reticulum (ER) membrane protein complex, comprised of Slp1 and Emp65 proteins, performs this function in the ER lumen. The complex binds unfolded proteins and protects them from degradation during folding. In its absence, the degradation of misfolded ER proteins is aberrantly accelerated, and, more importantly, approximately 20-30% of newly synthesized normal proteins that could otherwise fold are degraded. Our further analysis revealed that Slp1 specifically associates with premature ER proteins to protect them from ER-associated degradation (ERAD). Slp1-Emp65 complex hosts a broad range of clients and protects both glycosylated and non-glycosylated proteins. However, the substrates of this complex are restricted to soluble proteins. Taken together, these studies demonstrate the vulnerability of newly translated, actively folding polypeptides and the discovery of a new proteostasis functional class we term “guardian” that protects them from degradation.

Defining conserved and divergent functions of Hsp104.
Z.M. March¹, J. Shorter¹;
¹Department of Biochemistry and Biophysics, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Hsp104 is a hexameric AAA+ protein disaggregate from yeast that rapidly dissolves disordered aggregates, preamyloid oligomers, amyloids, and prions. These protein-remodeling activities facilitate resistance to and reversal of stress-triggered protein misfolding, and have allowed yeast to harness prions for adaptive purposes. Hsp104 homologues are found in all nonmetazoan eukaryotes and eubacteria, but the vast majority of these remain unexplored. Thus, Hsp104 sequence space, and the extent of protein-remodeling activities enabled by it, is unknown. Here, I present our efforts to functionally define diverse Hsp104 homologues from fungal, plant, algal, and protozoan lineages using a comparative biology approach. Hsp104 homologues perform various protein-remodeling activities performed by Hsp104 from *S. cerevisiae* (ScHsp104) via a conserved mechanism. However, we find that they are also able to antagonize unique and diverse proteotoxic misfolding events under conditions where ScHsp104 is inactive. I also present our work to understand the molecular mechanisms underpinning these activities. Our results establish that natural Hsp104 homologues can have therapeutic-disaggregate activity, and suggest that sequence variation among Hsp104 homologues may be a valuable resource for engineering therapeutic disaggregases to counter disease.

Recognition of transmembrane domains by HRD1 E3 ligase during the membrane protein quality control.
M. Mariappan¹, S. Sun¹;
¹Cell Biology, Yale University, New Haven, CT

A significant proportion of newly synthesized transmembrane proteins are misfolded and degraded by the endoplasmic associated quality degradation (ERAD) pathway. The mechanisms by which ERAD pathway selectively recognizes misfolded or non-native transmembrane domains (TMDs) of membrane proteins are unclear. To address this question, we identified a novel ERAD substrate, WRB, which has three TMDs and robustly degraded when it fails to assemble with its membrane subunit. We find that the conserved E3 ligase HRD1 recognizes a single lysine residue in the third TMD of WRB for ubiquitination and retrotranslocation into the cytosol. Replacing the lysine residue in the third TMD with
either a negative or hydrophilic residue can also be recognized by HRD1 for degradation. Unexpectedly, an efficient recognition of these aberrant TMDs by HRD1 is not occurring within the lipid bilayer, but rather requires the flipping of the TMD into the ER lumen. Unexpectedly, we find that the TMD flipping into the ER lumen is not only due to the low hydrophobicity but also due to its shorter cytoplasmic tail. Interestingly, HRD1 appears to recognize the overall hydrophobicity of the flipped TMD, but not specific charge or hydrophilic residues in the flipped TMD. Future studies are focusing on whether HRD1 directly recognizes the flipped TMD, which is still attached to the membrane through other two TMDs of WRB. We propose that flipping of TMDs may be a standard feature for discriminating between misfolded and folded multi-transmembrane proteins by E3 ligases in the ER.

Induction of Activator of G-Protein Signaling 3 Puncta: Role of Serine/Threonine Residues in the G-Protein Regulatory Domain and Lysosomal Inhibition.
A. VURAL1, S.S. Oner2, D. Ma3, S.M. Lanier1;
1Pharmacology, Wayne State University, Detroit, MI, 2Goztepe Research and Training Hospital, Istanbul Medeniyet University, Istanbul, Turkey, 3Molecular, Cellular and Developmental Biology, University of California, Santa Barbara, Santa Barbara, CA

Activator of G-protein Signaling 3 (AGS3), a receptor independent activator of G-protein signaling, contains 7 tetratricopeptide repeats (TPR) and 4 G-protein regulatory motifs (GPR) connected by a linker region. Disruption of TPR organization by point and deletion mutations induce the formation of punctate structures facilitating entrance into the aggresomal pathway. To further define regulatory factors affecting AGS3’s subcellular “positioning”, we addressed the role of potential sites of protein phosphorylation in the GPR domain. AGS3 is a phosphoprotein with putative phosphorylation sites in the GPR domain. We generated a series of AGS3 constructs with mutations of potential serine/threonine (S/T) phosphorylation sites in the GPR domain and transiently expressed the cDNA constructs in COS-7 and HEK-293 cells. Mutation of all 24 S/T residues in the GPR domain to alanine (AGS3-GFP-PM1) resulted in the distribution of AGS3 to cytosolic punctate structures in marked contrast to the distribution of WT AGS3 (cell cortex and diffuse cytosolic). Proteasome inhibition shifted AGS3-GFP-PM1 puncta to a perinuclear aggresome. The subcellular distribution of AGS3-GFP-PM1 to the pre-aggresomal punctate structures was also observed with mutation of a single residue (T602A) located between GPR-III and GPR-IV. Coexpression of G[alpha]i3 antagonist gallein (10 uM) or with pertussis toxin (200 ng/ml) had no effect. Interestingly, the preaggresomal punctate distribution observed with AGS3-GFP-T602A was also observed with WT AGS3 upon cell treatment with the lysosome inhibitor (ammonium chloride - 25 mM, 24 hrs) and a protease inhibitor cocktail (Sigma; 1:100 dilution), but not with pharmacological manipulation of autophagy. These data are consistent with the hypothesis that the movement of AGS3 into or within the aggresomal pathway, and its potential functional role in this pathway, is a regulated process influenced by cell signaling mechanisms.
Amyotrophic lateral sclerosis (ALS) is a devastating neurodegenerative disorder caused by the selective loss of the upper and lower motor neurons. Only 10% of all cases are caused by a mutation in one of the two dozen different identified genes, the most common of which are C9orf72, SOD1, and TDP-43, together responsible for at least 60% of familial ALS. The remaining 90% of cases are likely caused by a combination of as yet unidentified genetic and environmental factors. Remarkably, despite the large degree of heterogeneity, all cases of ALS have protein aggregates in the brain and spinal cord that are immunopositive for SOD1, TDP-43, OPTN, and/or p62. Protein inclusions are normally prevented and cleared by heat shock proteins (Hsps), suggesting that ALS motor neurons have an impaired ability to induce the heat shock response (HSR). Accordingly, there is evidence of decreased induction of Hsps in ALS mouse models and in human post-mortem samples compared to controls. However, the role of Hsps in protein accumulation in human motor neurons has not been fully elucidated. Here we generated motor neuron cultures from human induced pluripotent stem cell (iPSC) lines carrying mutations in SOD1, TDP-43, or C9orf72. We show that despite a lack of overt motor neuron loss, there is an accumulation of insoluble aggregation prone proteins in iPSC-derived motor neuron cultures but that content and levels vary with genetic background. Additionally, protein aggregation corresponds to an incomplete induction of the HSR and minimal stress granule formation. We therefore conclude that ALS iPSC-derived motor neurons recapitulate key early pathological features of the disease and fail to endogenously upregulate the HSR in response to increased protein burden. As such, we believe that iPSCs represent a valuable model to further study the role of the HSR in ALS.

The unfolded protein response (UPR) is an intracellular signaling network that adjusts the abundance and protein folding capacity of the endoplasmic reticulum (ER) according to need. The most converged branch of the UPR is mediated by the ER-resident transmembrane kinase/endoribonuclease IRE1. It senses unfolded protein accumulation within the ER and transduces the signal via a non-conventional mRNA splicing mechanism. In response to direct binding of unfolded proteins in the ER lumen, IRE1 activates by oligomerization and accumulates in dynamic foci. IRE1 foci are not autophagosomes as they did not colocalize with the autophagosomal marker LC3. Fluorescence recovery after photobleaching (FRAP) experiments indicate that IRE1 molecules in the foci remain in equilibrium with IRE1 molecules in the surrounding ER network. We determined the structure of IRE1 foci in cells by whole cell correlative light – electron tomography. Our results show that IRE1 oligomers induce
membrane deformations, leading to the protrusion of narrow 30 nm ribosome-free tubes that remain connected to the ER and are twisted into glomeruli of complex topology. The tubes contain two parallel filaments in their lumen, likely representing oligomerized IRE1 ER-lumenal domains. Taken together, our findings define a previously unrecognized subdomain of the ER membrane and shed new light on the structure and organization of active mammalian IRE1 inside the cell.

Autoregulatory transcriptional control of prions by G-Quadruplex motifs in prion promoter. P. Pradhan, V. Perumal, B. Kundu; 1Kusuma School of Biological Sciences, Indian Institute of Technology Delhi, New Delhi, India

Cellular prion protein (PrP\(^C\)) misfolds into an aggregated and infectious conformer, PrP\(^Sc\) (scrapie) that forms the hallmark of pernicious diseases commonly known as transmissible spongiform encephalopathies (TSEs). The association of prions with random quadruplex forming nucleic acid sequences has been recently identified but the exact physiological role of this interaction still remains obscure. Herein, we show that the promoter region of the human prion gene (PRNP) incorporates two G-rich sequences (Q1 and Q2) that could assume stable hybrid intra-molecular G-quadruplex structures (\(T_m\) >70 \(^\circ\)C). We found that both Q1 and Q2 specifically bind to native, \(\alpha\)-helical PrP\(^C\) with high affinity \((K_D \sim 70-100\ nM)\) but showed very weak or no association with \(\beta\) sheet rich-PrP oligomers (PrP\(^Sc\) like). To further probe the relevance of these interactions, a battery of kinetic and structural studies have been utilized that involved surface plasmon resonance (SPR), fluorescence, NMR, circular dichroism and molecular modeling. We demonstrated that the N-terminal unstructured tail of PrP (residues 23-88) is crucial for binding and unwinding of both the quadruplex sequences. Interestingly, cell-based luciferase assays showed that PrP\(^C\) auto-regulated its expression by binding to G-quadruplexes present in its own promoter sequence. Evidently, the autoregulatory function was lost on mutating one of the quadruplex sequences. Overall our data indicate the presence of feedback transcriptional regulation of PRNP gene by native PrP\(^C\) through the dynamic unwinding of quadruplex structures by native PrP\(^C\) that apparently gets affected by pathogenic PrP\(^Sc\) formation. The identification of feedback transcriptional regulation could be a crucial event in the pathogenic cycle of prions which may be targeted for developing newer therapeutic interventions.

Potential mechanisms of platelet-activating factor induced neutrophil NETosis. Y. Li, V.P. Werth, M. Liu; 1Department of Dermatology, Perelman School of Medicine at University of Pennsylvania, Philadelphia, PA, 2Department of Dermatology, Michael J. Crescenz V.A. Medical Center, Philadelphia, PA

Background/Purpose: Platelet-activating factor (PAF) is a proinflammatory lipid mediator, and plays a critical role in autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis, psoriasis, and lupus, by affecting different immune cells. Increasing evidence indicates the importance of neutrophils in development of autoimmune diseases. Neutrophil NETosis is a newly described form of cell death, and NETotic neutrophils release neutrophil extracellular traps (NETs) that are involved in various human diseases. Although the PAF signaling cascades have been widely investigated in other human
pathophysiological conditions, the cellular and molecular mechanisms of PAF in the new type of cell death, NETosis, are still less understood. Our study explores the cellular and molecular mechanisms of PAF mediated neutrophil NETosis.

Methods: Primary healthy human neutrophils were isolated with Dextran and Histopaque 1077. The human promyelocytic leukemia (HL-60) cell line was differentiated with 1.2% DMSO for 5-6 days to develop HL-60-derived neutrophil-like cells. Protein kinase C-alpha (PKCα) and Rho-associated protein kinase (ROCK) inhibitors were used to study the potential involvement of PKCα and ROCK. Cells were fixed with 2% PFA and stained by Sytox Green after treatment with PAF in the presence/absence of PKC/ROCK inhibitors. NETosis was detected at 504/523 nm in the microplate readers, and NET formation was confirmed by Fluorescent Microscopy.

Results: In the current study, we found that PAF induced the formation of neutrophil NET and NETosis in both human primary and HL-60 neutrophils in a dose-dependent fashion. Our immunoblot results show that PAF treatment caused activation and phosphorylation of PKCα in a time-dependent manner during PAF-induced neutrophil NETosis. Moreover, several PKC inhibitors, including specific inhibitor peptide, could significantly attenuate PAF-induced neutrophil NETosis, suggesting that PKCα is involved in PAF-induced neutrophil NETosis. Interestingly, ROCK inhibitors could also attenuate PAF-induced neutrophil NETosis.

Conclusion: Our findings indicate that PKCα and ROCK activation play vital roles in PAF-induced neutrophil NETosis. These results suggested that ROCK or PKCα signaling pathways might be therapeutic targets for PAF-mediated autoimmune diseases via regulating NETosis.

Antiapoptotic proteins’ expression profile upon FGF1 and FGF2 translocation.

A.M. Lampart¹, J. Sławski², M. Zakrzewska³;

¹Protein Engineering, University of Wrocław, Wrocław, Poland

Fibroblast growth factor 1 (FGF1) and 2 (FGF2), canonical members of the FGF family, act through specific tyrosine kinase receptors (FGFRs) and activate specific downstream signaling pathways. Unique feature of FGF1 and FGF2 among other fibroblast growth factors is their ability to translocate into cytosol and nucleus under stress conditions. Based on the function of novel FGF1 binding partners, we suggested that intracellular FGF1 plays a role in cell survival. This hypothesis is strongly supported by our observation that FGF1 and FGF2 are able to inhibit apoptosis induced by serum starvation or staurosporine treatment in the presence of specific FGFR inhibitor. To understand the mechanism of antia apoptotic activity of translocated FGF1 and FGF2, we studied the expression profile of 35 apoptosis-related proteins upon FGF1 treatment in serum starved U2OS cells stably transfected with inactive variant of FGFR1 K514R. We conducted protein level analysis using Proteome Profiler Human Apoptosis Array Kit (R&D Systems). We found that 16 h incubation with FGF1 led to upregulation of some antia apoptotic proteins including: clusterin, HSP60, HSP70, livin, survivin and XIAP, and downregulation of phospho-p53 and cleaved caspase-3. By the use of ApoLive-Glo Multiplex Assay (Promega) we confirmed that translocated FGF1 and FGF2 downregulate caspase-3 activity in serum starved U2OSR1K514R. Next, we conducted a more detailed analysis of selected proteins’ levels in serum starved or staurosporine treated U2OSR1K514R and NIH3T3 cells upon FGF1 and FGF2 translocation. Our data indicate that translocation of FGF1 and FGF2 evokes changes in expression profile of proteins mentioned above.

The role of nuclear localization of translocated FGF1 and FGF2 for their antiapoptotic activity.
A.M. Lampart1, J. Tomala1, J. Sławski1, M. Zakrzewska1;
1Protein Engineering Department, University of Wrocław, Wrocław, Poland

Fibroblast growth factors 1 and 2 belong to a large family of fibroblast growth factors. FGF1 and FGF2 act through binding to four specific cell-surface tyrosine kinase receptors (FGFRs, FGFR1-4) followed by FGFRs' dimerization and activation. In contrast to other growth factors FGF1 and FGF2 possess the unusual property to cross cellular membranes and translocate into cytosol and nucleus in a receptor-dependent manner. Our data showed that translocated FGF1 and FGF2 inhibit apoptosis induced by serum starvation or staurosporine treatment in the presence of specific FGFR inhibitor. We also observed that the protective effect is more profound in the case of FGF2 than of FGF1. We assumed that these differences may result from diverse nuclear retention time. In order to study the relationship between the time of FGF nuclear localization and cell survival, we tested selected FGF1 mutants with different duration within the nucleus. FGF variants were expressed in bacterial system and purified using heparin-affinity chromatography. To verify proper folding of obtained mutants, we applied fluorescence and circular dichroism measurements. Subcellular localization of translocated FGFs in NIH3T3 cells was determined via fractionation. Antiapoptotic activity of translocated FGF1 variants was measured by flow cytometry annexin V assay and caspase-3/7 activity in serum starved NIH3T3 cells incubated with FGF variants in the presence of FGFR kinase inhibitor. The results were verified using U2OS cells stably transfected with FGFR1 and inactive variant of FGFR1-K514R. Our preliminary data suggest that subcellular localization of FGF1 and FGF2 may be important for their antiapoptotic activity.

The cis-1 gene regulates physiological apoptosis in a CED-13 dependent manner within the germline of Caenorhabditis elegans.
S.D. King1, C.F. Gray1, L. Song1, R. Mittler1, P.A. Padilla1;
1Department of Biological Sciences, University of North Texas, Denton, TX

The mitochondrial localized, iron-sulfur binding, CISD proteins (mitoNEET/CISD1, NAF-1/CISD2, Miner2/CISD3) are involved with several human pathologies including diabetes, neurodegeneration, and Wolfram syndrome 2. Studies indicate that NAF-1/CISD2 binds to Bcl-2 and disruption of NAF-1 function leads to increased apoptosis, suggesting that NAF-1 has a role in apoptosis. We used C. elegans to examine the cisd genes role in apoptosis. The C. elegans genome contains three uncharacterized cisd genes that code for CISD-1 (homology to the vertebrate mitoNEET/CISD1 and NAF-1/CISD2), CISD-3.1 or CISD-3.2 (both have homology to vertebrate CISD3). Using CRISPR technology we determined that the cis-1p::GFP transcriptional reporter is expressed in the adult germline. In C. elegans, apoptosis occurs within the germline during the normal process of oogenesis. To test the hypothesis that the cisd genes have a role in physiological germline apoptosis we used DIC microscopy and programmed cell death markers (eg. CED-1::GFP, ACT-5::YFP, acridine orange staining) to quantify the number of cell corpses within the germline of the cis-1(tm4993) mutant and animals with RNA interference knock-down of the cisd-1, cisd-3.1 or cisd-3.2 genes. Disruption of cisd gene function results in a significant increase in the
number of cell corpses within the adult germline and additional germline defects (e.g. distal tip cell migration defects). To determine the function of cisd-1 in the context of the apoptotic pathway we examined the impact of altered core apoptotic machinery on the cisd-1(tm4993) mutant phenotype. In C. elegans the core apoptotic machinery involves the CED-9 (Bcl-2) protein which functions to prevent cells from dying by binding and regulating CED-4 (APAF); CED-9 and CED-4 interaction ultimately impacts CED-3 (Caspase) protein cleaving activity. We found that the cisd-1(tm4993);ced-3(RNAi) and cisd-1(tm4993);ced-9(n1950) animals have a reduced number of cell corpses in the germline relative to the cisd-1(tm4993) mutant. Note that the ced-9(n1950) is a gain-of-function mutant. In C. elegans, the egl-1 and ced-13 genes code for pro-apoptotic, BH3 (Bcl-2 homology region 3) containing, proteins that physically interact with the anti-apoptotic CED-9 protein. To test if cisd-1 functions upstream of ced-9, we examined the impact of egl-1 or ced-13 dysfunction on the cisd-1(tm4993) mutant phenotype. RNAi knockdown of ced-13, but not egl-1, significantly reduced the number of cell corpses observed in the cisd-1(tm4993) mutant. This work is significant because it demonstrates that the cisd genes function in the process of apoptosis and places the cisd-1 gene as a regulator of physiological germline programmed cell death acting through CED-13 function.

Two small GTPases function antagonistically in corpse removal of a developmental non-apoptotic dying cell.
L.M. Kutscher¹, W. Keil¹, S. Shaham¹;
¹Laboratory of Developmental Genetics, The Rockefeller University, New York, NY

Programmed cell death and subsequent cell clearance are necessary in the development and maintenance of organisms and tissues. Defects in cell clearance can result in inappropriate inflammatory responses and autoimmune disorders. Much is known about apoptotic corpse removal; however, our understanding of mechanisms driving the clearance of cells dying by non-apoptotic means is rudimentary. Linker cell death in C. elegans is an excellent model of non-apoptotic cell death. The linker cell is a male-specific cell that is born in the second larval stage, leads the elongation of the developing gonad, and then dies in a programmed manner independently of known apoptosis, autophagy, or necrosis genes. Importantly, linker cell corpses are robustly engulfed in mutants lacking the capacity to engulf apoptotic bodies, suggesting utilization of a novel engulfment program. To elucidate the mechanism of linker cell corpse removal, we carried out a forward genetic screen to identify mutants that are defective in this process. F2 mutant males were propagated by artificial insemination, as surviving linker cells or corpses may block spermatid exit and promote male sterility. From this screen, we isolated two loss-of-function mutants in the RAB-35 guanine nucleotide exchange factor (GEF), rme-4, and a gain-of-function mutant in the small GTPase, arf-6. Using a variety of genetic and cell biological methods, we have uncovered the relevant GEFs, and GTPase activating proteins (GAPs) for RAB-35 and ARF-6 in this process, and have determined that these two proteins and their regulators have antagonistic functions; RAB-35 promotes corpse clearance, and ARF-6 inhibits it. Using a microfluidic imaging-device we developed, we imaged the dynamics of these proteins over a 20h period, capturing linker cell migration, engulfment, and degradation. We found that YFP-RAB-35 is localized to the extending pseudopod membrane, and remains at the membrane for the duration of phagosome maturation. While ARF-6-YFP is also localized to the extending pseudopods, it changes localization from the plasma membrane to intracellular vesicles after engulfment is complete. These results, together with our genetic and protein interaction studies, suggest that ARF-6 and RAB-35 localize to the plasma membrane during corpse recognition and engulfment, but RAB-35 then inactivates ARF-6, likely through
its GAP CNT-1, to allow phagolysosome maturation to proceed. Rab35 and Arf6 have been previously implicated together in the recognition and removal of foreign particles in mammals, but not in the degradation of programmed cell death corpses. *rab-35* and *arf-6* may work together to preferentially degrade corpses that die by non-apoptotic mechanisms.

**Modifiers of proteotoxicity associated with multisystem proteinopathy.**

O.Y. Zhou¹, A.F. Ford¹,², J. Shorter¹;

¹Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, ²Neuroscience Graduate Group, Perelman School of Medicine at University of Pennsylvania, Philadelphia, PA

Multisystem proteinopathy (MSP) is a rare, genetic degenerative disorder that can affect bone, muscle, and the central nervous system. It is commonly referred to as inclusion body myopathy (IBM) associated with Paget’s disease of bone (PDB), frontotemporal dementia (FTD), and amyotrophic lateral sclerosis (ALS), or IBM/PD/ALS, because clinically, it can present with single or multiple phenotypes encompassing all these disorders. Mutations in the prion-like domain of heterogeneous nuclear ribonucleoproteins (hnRNPs) A1 and A2 are associated with MSP. These nuclear RNA-binding proteins normally function in RNA metabolism and processing, splicing, and nuclear-cytoplasmic shuttling. In disease, these proteins misbehave and form cytoplasmic aggregates which contribute to neuron death. However, the exact molecular mechanisms underpinning pathogenesis are not well understood. To better understand pathogenesis and possible ways to combat it, we used Saccharomyces cerevisiae to model disease. An unbiased gene deletion screen revealed forty modifiers of proteotoxicity. These modifiers implicate several classes of proteins in pathogenesis such as ribonucleoprotein-granule components, spliceosome proteins, and molecular chaperones. All suppressors of toxicity of hnRNP A1 also suppressed toxicity of hnRNP A2, suggesting mechanistic convergence. Interestingly, very few modifiers of hnRNP A1 and A2 overlapped with known modifiers of TDP-43 and FUS, RNA-binding proteins implicated in ALS, suggesting mechanistic divergence between these outwardly similar proteins and diseases. From these suppressors of toxicity, we generated a network of protein-protein interactions that advance our understanding of MSP. Importantly, these studies highlight pathways implicated in pathogenesis and suggest potential therapeutic targets.

**HMA induces changes in the nuclei and mitochondria of BHK21 cells in a caspase3-independent manner.**

E.A. Peterson¹, Z.C. Murphy², E.M. Konieczko¹, M.J. Judy¹;

¹Gannon University, Erie, PA, ²University of Rochester, Rochester, NY

Apoptosis, also known as programmed cell death, is common control mechanism required for regulating the number and function of cells. Apoptosis is characterized by morphological changes in the plasma membrane, mitochondria, and nuclei of cells. Previous studies examined the maturation of erythroblasts, a process similar to apoptosis (Malik et al., 2013). This research examined apoptosis in Baby Hamster Kidney (BHK21) cells, an adherent cell line (Macpherson, 1961). To induce apoptosis, BHK21 cells were incubated with hexamethylene amiloride (HMA) (Altairac S, et al. 2003.). Control cells were incubated with dimethyl sulfoxide (DMSO). HMA-treated cells exhibited fewer number of cells per ml than stock cells. Cells were stained with MitoTracker (MT), fixed with formalin, permeabilized, and

Monday-443
then stained again with an antibody directed against Caspase 3. Finally, cells were stained with 4,6'-diamidino2-phenylindole (DAPI). Additional controls consisted of cells stained with two of the three markers (Fluorescence Minus One [FMO] controls). All cells were analyzed by multispectral imaging flow cytometry and IDEAS software v6.2 (Amnis Corporation, Seattle, WA; Niswander et al., 2014). Compared to DMSO-treated cells, HMA-treated cells exhibited a higher mean fluorescence intensity (MFI) for DAPI and MT, indicating changes in the nuclei and mitochondria, respectively. There was no change in the MFI for Caspase 3 in HMA-treated cells, as compared to DMSO-treated cells, suggesting that Caspase 3 was not involved in HMA-induced changes in BHK21 cells. Brightfield images of HMA-treated cells revealed slightly more rounded cells, as compared to control cells. However, the majority of HMA-treated cells exhibited no significant plasma membrane changes. Taken together, these results suggest that the observed HMA-treated cells are not undergoing apoptosis in a caspase-dependent manner. Further studies will examine possible activation of other caspase enzymes in HMA-treated cells and inducement of apoptosis in BHK21 cells using staurosporine or etoposide, reagents used to cause apoptosis in other cell lines.

The importance of isoflavone metabolism to regulate lactating mammary epithelial cells.
Y. Tsugami¹, K. Matsunaga¹, T. Suzuki¹, T. Nishimura¹, K. Kobayashi¹;
¹Hokkaido University, Research Faculty of Agriculture, Sapporo, Japan

Isoflavones are a class of polyphenolic compounds present in legumes. After metabolic conversion by enteric bacteria, isoflavones and the metabolites are absorbed into the body. There are two primary isoflavone metabolic pathways. One is associated with formononetin, daidzein, equol and the other with biochanin A, genistein, and p-ethylphenol. These isoflavones show different influences in non-lactating mammary epithelial cells (MECs) and breast cancer cells. However, it remains unclear whether metabolic conversion of isoflavone is involved in milk production during lactation. In this study, we investigated that influence of isoflavones and their metabolite on behavior of lactating MECs by using a lactating MEC culture models. MECs isolated from the mammary glands of ICR mice (9-14 weeks) were cultured with prolactin and dexamethasone to induce milk production ability. Subsequently, lactating MECs were treated with each isoflavone. To evaluate the influence of isoflavones on milk production ability, we investigated the expression of β-casein and phosphorylated-signal transducer and activator of transcription 5 (pSTAT5) in MECs by western blot analysis. MECs treated with biochanin A or genistein at 25 µM for 2 days reduced β-casein production and pSTAT5, whereas biochanin A or genistein at 5 µM didn’t influence β-casein production and pSTAT5. However, MECs treated with biochanin A or genistein at 5 µM for 7 days reduced β-casein production and pSTAT5. To evaluate the influence of isoflavones on apoptosis, we investigated cellular viability by cell counting WST-8 kit and the expression of cleaved caspase-3 in MECs by western blot analysis. Treatment of biochanin A or genistein at 25 µM for 2 days decreased cellular viability. Treatment of biochanin A or genistein at 5 µM for 7 days also decreased cellular viability. Cleaved caspase-3 was detected in MECs treated with biochanin A or genistein at 25 µM for 2 days and at 5 µM for 7 days. However, p-ethylphenol didn’t influence β-casein production, pSTAT5, cellular viability and expression of cleaved caspase-3 any concentrations and treatment time. These results indicate that metabolic conversion of upstream isoflavones is detoxifying action to lactating MECs.

The intrinsic ability of the Bax family to activate caspase 8-mediated cell death.
A.T. Nelson, A. Mañas, S. Wang, J. Xiang;
1Biology, Illinois Institute of Technology, Chicago, IL, 2Human Genetics, Computation Institute, University of Chicago, Chicago, IL

The majority of pro-apoptotic members of the Bax protein family induce cell death through targeting mitochondria. Interestingly, certain subgroup members within the Bax family, such as BaxΔ2 and BaxΔ2ω, induce cell death through the formation of cytosolic protein aggregates, and activation of caspase 8. However, the functional domain(s) that are responsible for triggering this noncanonical pathway were previously unknown. Recently, our data showed that C-terminal removal in BaxΔ2 and BaxΔ2ω did not inhibit the formation of cytosolic aggregates, but did abolish their ability to recruit caspase 8. In addition to the critical role the C-terminus plays in the cytotoxic action of these proteins, the data also indicated that the helical conformation of the C-terminus, rather than the primary sequence, was crucial for recruitment of caspase 8. Furthermore, we report that impairing the ability of the parental Baxα protein to target mitochondria via point-mutation, resulted in Baxα mimicking the aggregation behavior of BaxΔ2. Notably, the functional domains responsible for aggregation are shared by almost all Bax family members. Together, these results imply an intrinsic potential for aggregate-mediated caspase 8-dependent cell death in the Bax family.

Development of assays to detect apoptosis and necrosis in real time using a plate reader.
1Promega Corporation, Madison, WI, 2Promega Biosciences, San Luis Obispo, CA, 3Olympus Corporation, Tokyo, Japan

We have developed a homogeneous assay for detecting apoptosis in real-time that is recorded using a standard plate-reader. The assay is based on binding of annexin V to phosphatidyl serine (PS) that is exposed on the outer leaflet of the cell membrane during apoptosis. We engineered two fusion proteins composed of annexin V linked to a small or large fragment of a luciferase. The annexin-luciferase fragment fusion proteins and a luciferase substrate are added as a reagent directly to cultured cells. The individual annexin V-luciferase fragment fusion proteins have very low background luminescence in the presence of non-apoptotic cells. When exposed to apoptotic cells, the annexin V-luciferase fragment fusion proteins bind to PS in close proximity on the cell surface, an active luciferase enzyme is reconstituted and a luminescent signal is generated. The reagent can be added to cells for extended periods of incubation enabling detection of the progress of apoptosis in the population of cells in real time. We have multiplexed the homogeneous luminescent assay with a vital fluorogenic DNA binding dye to simultaneously quantify the accumulation of apoptotic and necrotic cells from the same sample at progressing times. By recording data in a kinetic mode, we demonstrate the onset of annexin V binding precedes loss of membrane integrity and secondary necrosis in vitro. We further demonstrate detection of caspase-3/7 activity precedes annexin V binding by comparison to endpoint assays of caspase-3/7 activity as an orthogonal marker of apoptosis. We also demonstrate concordance of the real-time annexin V binding assay with traditional flow cytometric analysis of apoptosis and necrosis. The assay has been validated using a number of anchorage dependent and suspension cell lines and has been shown to correlate with activation of caspase-3/7 activity as an orthogonal marker of apoptosis.
Imaging the luminescent and fluorescent signals enables creation of time laps movies showing heterogeneity among individual cells in a population undergoing apoptosis. This new homogeneous apoptosis assay method represents a simplification and improvement over flow cytometry and endpoint assay methods by providing kinetic data from the same sample of live cells in real time using a multimode plate reader.

Co-receptors are dispensable for tethering receptor-mediated phagocytosis of apoptotic cells. J. Lee1,2, B. Park1,2, H. Moon1,2, D. Lee3, J. Cho4, D. Park1,2;
1School of Life Sciences and Bio Imaging Research Center, Gwangju Institute of Science and Technology, Gwangju, South Korea, 2Research Center for Cellular Homeostasis, Ewha Womans University, Seoul, South Korea, 3Department of Surgery and Pharmacology and Cell Biology, University of Pittsburgh, Pittsburgh, PA, 4Department of Biology Education, Chosun University, Gwangju, South Korea

During efferocytosis, phagocytic cells recognize dying cells by receptors binding to ligands specifically exposed on apoptotic cells. Multiple phagocytic receptors and some of their signaling pathways have been identified. However, the downstream pathways of tethering receptors that secure apoptotic cells remain elusive. It is generally assumed that tethering receptors induce signaling to mediate engulfment via interacting with co-receptors or other engulfment receptors located nearby. However, it is poorly understood whether co-receptors for tethering receptors exist during efferocytosis, and if they do, whether they are indispensable for this process. Here, we address this issue using glycophasphatidylinositol (GPI)-anchored annexin A5 (Anxa5-GPI), an artificial tethering receptor without a putative co-receptor. Phagocytes expressing Anxa5-GPI exhibited enhanced binding of apoptotic cells, resulting in promoted ingestion of apoptotic cells in a phosphatidylserine-dependent manner. Anxa5-GPI-induced phagocytosis of apoptotic cells relied on the known cytoskeletal engulfment machinery but partially depended on the Elmo-Dock-Rac module or the integrin pathway. In addition, Anxa5-GPI-mediated efferocytosis provoked anti-inflammatory responses. Taken together, our work suggests that co-receptors are dispensable for tethering receptor-induced efferocytosis and that tethering receptors mediate the engulfment of apoptotic cells through multiple engulfment signaling pathways.

Behavior of labile ferrous ions and reactive oxygen species during ferroptotic response of cells. M. Sato1, T. Hirayama2, T. Fujii1, H. Nagasawa2, I. Minoura1;
1Goryo Chemical Inc., Sapporo, Japan, 2Laboratory of Pharmaceutical and Medical Chemistry, Gifu Pharmaceutical Univ., Gifu, Japan

Ferroptosis is a recently identified iron-dependent regulated cell death (Dixon and Stockwell 2014). Understanding mechanisms and regulations of this oxidative cell injury may bring us new therapeutic methods for cancer and neurodegenerative diseases. The injury may be caused by reactive oxygen species (ROSs) which are generated by Fenton reaction between labile ferrous ions (Fe2+) and peroxides. Therefore, Fenton reaction should be a key for ferroptotic responses of cells. However, other indirect pathways to generate ROSs should be also considered. To further understand the mechanisms how ROSs are generated during the ferroptotic responses, we tried to visualize labile Fe2+ and ROSs by using cell permeable, activatable fluorescent probes. As previously described, >20 μM of erastin caused
ferroptosis of HT-1080 cells. To visualize the responses for an enough time-period (~9 hours), we chose the erastin concentration of 30 μM and observed the behavior of labile Fe²⁺ and ROSs by fluorescence microscopy. To detect labile Fe²⁺, both commercially-available chemical probe FeRhoNox-1 (RhoNox-1, Hirayama, et al., 2013) and newly-synthesized RhoNox-4 which possesses a higher sensitivity with high specificity to labile Fe²⁺ were used. To detect ROSs, aminophenyl fluorescein (APF, Setsukinai et al., 2003) which fluoresces by either hydroxyradical, peroxinitrite, or hypochlorous acid, and OxiORANGE (Koide et al., 2007) which does by either hydroxylradical or hypochlorous acid were used. The fluorescence signals indicating labile Fe²⁺ reached the maximum at 3 hours after erastin stimulation. On the other hand, fluorescence signals of APF and OxiORANGE became maximal at 6 hours after the stimulation. The results were consistent with the simple model that hydroxyradical is generated by the reaction between cytoplasmic labile Fe²⁺ and peroxides and thus causes the ferroptotic cell death.

Peroxidasin (PXDN) Promotes Prostate Cancer Progression.
J. Dougan 1,2, L.J. Burton1,2, O.A. Hawsawi1, K. Jones2, J. Zou1, P. Nagappan1, G. Wang 3, Q. Zhangb3, N.J. Bowen1, C. Hinton1, V. Odero-Marah1;
1Center for Cancer Research and Therapeutic Development, Biological science, Clark Atlanta University, Atlanta, GA, 2School of medicine, Emory University, Atlanta, GA, 3Chemistry, Xavier University, New Orleans, LA

Peroxidasin (PXDN), a human homolog of Drosophila PXDN, belongs to the family of heme peroxidases and has been found to promote oxidative stress in cardiovascular tissue. PXDN has been associated with melanoma, but its role in prostate cancer has not been previously elucidated. We hypothesized that PXDN promotes prostate cancer progression. Immunohistochemical staining showed that PXDN expression increased with prostate cancer progression as compared to normal tissue or cells. Stable knockdown of PXDN followed by proteomic analysis revealed that PXDN knockdown affected oxidative stress and gluconeogenesis pathways. PXDN knockdown also resulted in decreased cell viability and adhesion to collagen or fibronectin, along with an increase in reactive oxygen species (ROS) and apoptosis as shown by Annexin V assay. Finally, PXDN knockdown decreased colony formation on soft agar. Overall, we propose that PXDN plays a role in prostate cancer by modulating pathways involved in oxidative stress leading to decreased apoptosis possibly via scavenging ROS. Therefore, PXDN may be a biomarker associated with prostate cancer and a potential therapeutic target.

Assaying free radical scavenging abilities of herbal remedies and anti-apoptotic gene expression effects of *Ginkgo biloba* in an *in vitro* stroke model.
K.M. McIntyre¹, R. Koseki², A. Brown¹, A. Ross¹, T. Johnson¹, K.J. Karnas¹, A.J. Ettinger¹; ¹Biological Sciences, Cedar Crest College, Allentown, PA

Ischemic stroke is a leading cause of death and disability in the United States, and current treatment options are both limited and time-sensitive. In the brain, cellular apoptosis pathways are active for days following the initial ischemic insult, expanding the area of damage. Herbal remedies that possess antioxidative components may convey prophylactic protection against this secondary damage, and this study examined several commercially available herbals to assess their potential efficacy in blocking apoptotic injury. A particular focus of this study, *Ginkgo biloba* leaf extract, is an herbal remedy long used in traditional medicine, and previous work has demonstrated that it contains several components with antioxidant properties and that one particular purified extract (EGB761) has neuroprotective effects on cultured cells. This study used a spectrophotometric assay to directly test the free-radical scavenging ability of separate batches of an easily accessed, over-the-counter *Ginkgo* supplement; a dose-dependent effect was measured, and samples from different lots showed similar radical scavenging. This assay is currently in use to test additional herbal remedies for free-radical scavenging activity; while dietary supplements are not regulated as drugs by the FDA, these compounds may be clinically useful as neuroprotectants, and the assay provides a straightforward way to provide an initial screen of over-the-counter preparations. To further assess the *Ginkgo* supplement, primary brain and body *Gallus gallus* cell isolates served as a stroke model in which hydrogen peroxide was used to induce apoptosis, mirroring the cell death that occurs following the initial ischemic event. Prophylactic *Ginkgo* treatment of these cell isolates was assessed in cell viability assays using trypan blue exclusion at 0-24 hours post-treatment, and demonstrated that treated cells had improved survival compared to PBS-treated control cells. Gene expression differences were also noted in treated cells via two independent PCR arrays that indicated up-regulation of anti-apoptotic genes and down-regulation of pro-apoptotic genes such as caspases that are components of the Fas death-inducing signaling complex; Western blots will determine whether protein level changes are consistent with the observed gene expression changes. Together, these results suggest that a commercially available, crude *Ginkgo biloba* supplement may convey protection from cellular apoptosis following stroke, and initiates studies of other candidate herbals. Future work will include the direct inhibition or activation of the Fas death-inducing pathway to confirm its role in mediating the protective effects of *Ginkgo* extract, and cellular viability studies using the newly identified herbals.

Actin nucleation factors are important for caspase activation and cell death.
N.L. Leclair¹,², V.L. King¹,², K.G. Campellone¹,²; ¹Institute for Systems Genomics, University of Connecticut, Storrs, CT, ²Department of Molecular and Cell Biology, University of Connecticut, Storrs, CT

Actin nucleation factors control many vital cellular functions, including morphogenesis, motility, and division, yet they remain relatively uncharacterized in relation to programmed cell death pathways. JMY is a versatile nucleation factor that can both polymerize actin directly and activate the Arp2/3 complex to assemble actin filament networks in the cytoplasm. Upon DNA damage, JMY is translocated into the
nucleus, where it cooperates with the transcriptional regulators p53 and p300 to promote apoptosis. To gain a better understanding of the relationship between actin nucleation factors and programmed cell death, we generated JMY knockout (KO) human fibroblasts and monitored their responses to DNA damage. Compared to JMY-expressing parental cells, JMY KO cell lines exhibited significantly lower levels of Annexin-V staining and cell death, indicating that the loss of JMY results in less apoptosis. Consistent with these observations, caspase cleavage was inefficient in cells lacking JMY. Interestingly, JMY inactivation had a broad effect on the transcriptome and caused a dramatic upregulation of RhoD, a small G-protein known to interact with the JMY homolog WHAMM. Similar to JMY-deficient fibroblasts, WHAMM KO cell lines displayed lower levels of apoptosis. In contrast, RhoD KO cells exhibited increases in caspase cleavage and cell death. These findings suggest that both JMY and WHAMM are capable of performing pro-apoptotic functions, but that their actions may be inhibited by RhoD.

Charcot-Marie-Tooth (CMT) disease is the most common hereditary neuromuscular disease characterized by progressive loss of muscle tissue followed by sensory loss and skeletal deformities. Approximately 1 in 2500 individuals is affected by CMT, a condition that is still incurable. Mutations in Hsp27, a small heat shock protein, have been shown to lead to CMT in humans. However, despite over a decade of research, there is no consensus as to how mutations in Hsp27 affect protein oligomerization and chaperone activity. My project aims to understand the disease mechanism by pairing cutting-edge Cryo-EM technology and negative stain EM with biochemical assays to resolve the long standing problem. We investigated the structure-function relationship of the wild type Hsp27 compared to the five disease-causing mutations: S135F, R127W, R136W, T151I, and P182L. The proteins were expressed in bacteria and purified to ~99% homogeneity by chromatography techniques. The chaperone activity of the purified proteins was assayed by measuring rescue of DTT-induced aggregation of alpha-lactalbumin in-vitro. Our results suggest that wt. Hsp27 was able to maintain chaperone activity, however, the mutants had compromised activity (<50% of wt.) and were not able to completely prevent protein aggregation. Could the reduced chaperone activity be due to the differences in oligomerization status of the mutant proteins? Negative-stained EM images coupled with data from size exclusion columns suggest that the wild type forms a 24-mer in a spherical ‘ball’ conformation. On the other hand, the mutant proteins formed fewer oligomers as the mutations appear to inhibit oligomerization. Furthermore, only the large oligomeric complexes had chaperone activity. Our data, for the first time, correlates the oligomerization status (complex size) of Hsp27 and the mutant proteins with chaperone activity with the aid of high resolution negative-stained EM images. Mutations in Hsp27 modulate the size of the complexes by regulating the oligomeric status and thereby reduce the chaperone activity of the proteins. Future experiments aim to obtain high resolution 3D- reconstructions of the complexes to drive the process of drug design to find a pharmacological cure for CMT.
We investigate the emergence of contractile behaviors in disordered non-muscle actomyosin networks, whose non-equilibrium dynamics remain largely unexplored when containing reversibly-bound passive cross-linkers and active myosin II motor filaments. Current understanding of how contractility emerges in disordered actomyosin networks of non-muscle cells is still largely based on the intuition derived from earlier works on muscle contractility. In addition, in disordered networks, passive cross-linkers have been hypothesized to percolate force chains in the network, hence, establishing large-scale connectivity between local contractile clusters. Our work, based both on analytical theory and detailed molecular simulations, shows that cross-linker binding dynamics plays a crucial role even at the level of elementary force generating elements in contractile actin networks. In particular, our results shed light on the non-equilibrium effects of transiently binding proteins in biological active matter, as observed in the non-muscle actin cytoskeleton, showing that highly efficient contractile force dipoles result from synergy of passive cross-linker and active motor dynamics. These findings begin to elucidate the tools available to this biological active matter to dramatically alter their micro-structural morphologies and generate active cellular forces.

The collagen fibrils are the main building block of connective tissues in mammals where they fulfill both structural and mechanical roles. The structure of a fibril is based on collagen molecules that self-assemble into micro-fibrils and sub-fibrils stabilized by hydrogen bonds and covalent crosslinks. The non-integer staggering of collagen molecules results in a characteristic D-band pattern along the fibril with a periodicity of 67nm. Besides this natural variation, localized damaged sites have been observed along the length of mechanically overloaded fibrils [1], which suggests the inherent existence of structural inhomogeneity along collagen fibrils. Recently, Dittmore et al. reached the same conclusion by tracking the diffusion kinetics of single fluorescently labeled MMP-1 molecules along collagen fibrils [2]. To explore this further we are using an atomic force microscopy (AFM)-based manipulation technique that allows us to perform tensile tests on a single fibril in bowstring geometry [3]. In this work, we are investigating the potential impact of structural inhomogeneity on the viscoelastic properties of single fibrils. 40 fibrils were extracted from two different bovine extensor tendons, around 50 microns long segments were isolated, stretched to a target strain of 5, 10, 15 or 20%, held at that strain for 150 seconds and then released. We observed two characteristic stress relaxation times as previously reported [4] and the absence of plastic strain, assessed optically, after release implying full axial recovery. However, AFM imaging of the released fibrils demonstrated a two to three-fold increase in the height fluctuations along the fibril length with a characteristic length scale larger than the D-band spacing, in the micrometer range. We propose that the inherent structural heterogeneity along the length of the fibril becomes a prominent feature after stress relaxation providing a new viscoelastic

Supergrowth: Effect of osmotic oscillations on the rate of cell growth and the regulation of the proteome.
B. Knapp1, E.R. Rojas2, K.C. Huang2, F. Chang1;
1Cell and Tissue Biology, UCSF, San Francisco, CA, 2Bioengineering, Stanford, Stanford, CA

Cell growth is a complex process in which the expansion of cellular dimensions are globally coordinated with biosynthesis of cellular components. While much is known about how certain intracellular structures such as chromosomes are replicated, less is known about how the proteome itself is duplicated in the cell cycle. Most cell types, including the fission yeast S. pombe, exhibit exponential growth, in which the growth rate of individual cells scales with cell size, suggesting that the amount of some cellular component(s) dictates the rate of growth. As the majority of proteins are maintained at fixed concentrations during the cell cycle, protein synthesis rates may be coordinated with the rate of cellular expansion. The mechanisms responsible for exponential growth and the coordination of global protein synthesis with growth rate are not well understood. Here, we identify a condition in fission yeast in which the rate of protein synthesis is globally de-coupled from growth, causing cells to grow many times faster than normal (supergrowth). In studying the functions of turgor pressure, we subjected cells to osmotic oscillations and then released them back into normal media. Cells grew slowly under these oscillations, but upon release, grew 2-3-fold faster than control cells for a few generations; we term this unprecedented rapid growth “supergrowth.” Cells maintained normal cell morphology and size control, and these effects were independent of the osmotic response pathway. The concentrations of a large majority of representative proteins were found to increase 10-100% higher than normal during typical oscillations (depending on protein and condition), and then were depleted back to normal concentrations during the supergrowth period. Cell growth and protein synthesis were thus uncoupled in these cells, as during oscillations, proteins were synthesized at normal rates even though cell enlargement was stalled. We provide evidence that this abnormal accumulation of proteins may drive supergrowth, as blocking this accumulation with cycloheximide prevented subsequent supergrowth. Our current model is that growth rates are set by an effective amount of “growth materials,” which accumulate to abnormal levels during oscillations and thus provide extra fuel for growth. During oscillations, cells may lack a negative feedback mechanism for controlling protein homeostasis, as they may not be able to properly sense growth or size. These studies provide one of the first examples of decoupling protein synthesis from cell growth/size control, and begin to give insights into this coordination and the mechanisms that control growth rates and the global regulation of the proteome.

Temporal control of cellular phenotype.
G. Li1, B.K. Kesler1, A. Thiemicke1; D.C. Rogers1, G. Neuert1;
1Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN

A hallmark of cellular stress response pathways is to protect cells from different environmental insults. While much is known about how cells are protected against acute stresses of different types, the
mechanisms underpinning how cells are protected against gradually changing stresses are poorly understood. Here we demonstrate that a linear stress gradient but not a step, pulse or a quadratic gradient of the same stressor and intensity causes a severe cell growth phenotype. We determined that this phenotype is caused by the failure of cells to activate the stress-activated protein kinase signaling pathway due to a threshold in the rate of stress application. This lack of response occurs despite cells physically detecting the relatively slow changes in stress signal. These findings have fundamental implications for understanding mechanisms of how temporally changing environments impact biological phenotype.

Soft matrix facilitates the activation of mesenchymal stromal cells into antifibrotic phenotypes by tumor necrosis factor-α.
S. Wong¹, A. Elujoba¹, J. Shin¹;
¹Department of Pharmacology and Bioengineering, University of Illinois at Chicago College of Medicine, Chicago, IL

Mesenchymal stem or stromal cells (MSCs) have been shown to ameliorate scar formation in some animal models of fibrosis by secreting paracrine factors. However, mechanical rigidity of scars can activate MSCs into myofibroblasts, which promote fibrosis by collagen production. Culturing MSCs on soft substrates is known to prevent mechanical activation. However, it remains unknown whether soft substrates play an active role in priming MSCs into anti-fibrotic phenotypes when they are exposed to inflammatory signals emanating from injuries. We show that human bone marrow MSCs encapsulated in a normal parenchymal tissue-like, soft Arg-Gly-Asp (RGD)-alginate hydrogel produce more paracrine factors that have been implicated in ameliorating fibrosis than those in a scar-like, stiff hydrogel upon activation with tumor necrosis factor α (TNFα). The factors include metalloproteinase-1 (MMP-1) and TNF stimulated gene 6 (TSG-6), which have been previously shown to ameliorate fibrosis by degrading collagen and facilitating M2 macrophage polarization, respectively. A higher level of TNFα binding on the cell surface was observed with MSCs in the soft hydrogel compared to the stiff hydrogel, thereby suggesting that substrate stiffness may regulate TNFα receptor dynamics. Surprisingly, transient pharmacological inhibition of actin polymerization by latrunculin A, but not myosin-II activity by blebbistatin, increases the production of the TNFα-induced factors from MSCs in both soft and stiff matrices. Interestingly, inhibition of caveolin, but not clathrin, mimics the effect of inhibiting actin polymerization, and increases TNFα binding to the cell surface. The results thus suggest a novel pathway to regulate TNFα activation of MSCs by substrate stiffness, thereby modulating the induction of potential anti-fibrotic paracrine factors.

CRYPTOCHROMES: FROM LIGHT-DEPENDENT FLAVIN REDUCTION TO CIRCADIAN CLOCK REGULATION.
S. Foroutannejad¹, B. Crane², R.A. Maillard³;
¹Chemistry, Georgetown University, Washington, DC, ²Chemistry and Chemical Biology, Cornell University, Itacha, NY

The circadian clock regulates biological and behavioral adaptations in response to day-night cycles. Cryptochromes (CRYs) are members of a family of photolyases involved in DNA repair that are...
responsible for the oscillation of the circadian clock. The structure of the drosophila Cryptochrome (dCRY) has a complex, re-entrant topology made of two lobes, a photolayase homology (PH) domain and a FAD binding domain. FAD photoreduction causes the release of a C-terminal tail (CTT) from the core of the FAD binding domain. The CTT in the light-activated dCRY recruits other transcription factors important for the transition between night and day cycles. Here, we studied the underlying mechanisms responsible for the light-induced conformational changes of dCRY coupled to FAD reduction. We used optical tweezers to mechanically unfold dCRY in the presence and absence of FAD. We show that in the absence of FAD, dCRY remains unfolded most of the time, and occasionally only the PH domain transiently folds into a native-like structure. In contrast, when FAD is present the entire protein folds with high probability, indicating that the cofactor is essential for the protein to attain its native tertiary structure. The mechanical unfolding process of the protein reveals several intermediate states, reflecting the complex topology of the protein. Ongoing experiments include determining how FAD in the reduced and oxidized states affects the mechanism of folding and the stability of the protein.

Soft matrix enhances autocrine production of transforming growth factor-β1 to facilitate tumor necrosis factor-α activation of mesenchymal stromal cells.

S. Wong1, A. Elujoba1, J. Shin1;

1Department of Pharmacology and Bioengineering, University of Illinois at Chicago College of Medicine, Chicago, IL

Mesenchymal stem or stromal cells (MSCs) have been tested in many clinical trials due to their ability to modulate the immune system during inflammation. Some disease conditions that involve immune cells, including fibrosis, show profound physical changes where tissues become rigid due to collagen deposition and crosslinking. How physical cues impact immunomodulatory functions of MSCs remains generally unclear. Transforming growth factor-β1 (TGF-β1) is known to play an important role in MSC differentiation into chondrocytes on soft substrates and into fibrotic phenotypes on stiff substrates. However, it remains unclear how TGF-β1 plays a role in regulating immunomodulation by MSCs. Here, we show that human bone marrow MSCs secrete a substantial level (~15 ng/ml per 100,000 cells per day) of endogenous TGF-β1 when they are cultured in a soft Arg-Gly-Asp (RGD)-alginate hydrogel, while MSCs in a stiff hydrogel produce ~2.5-fold less TGF-β1. MSCs in both soft and stiff hydrogels show a linear, constitutive kinetics of TGF-β1 secretion. The treatment of MSCs in the soft hydrogel with an inhibitor of TGF-β kinase, SB-431542, decreases the induction of chemokines, including CCL2 and interleukin-6 (IL-6), as well as vascular endothelial growth factor (VEGF) by exogenous recombinant tumor necrosis factor-α (TNF-α). In contrast, SB-431542 does not affect the TNF-α-mediated induction of paracrine factors from MSCs in the stiff hydrogel. Interestingly, inhibition of myosin-V normalizes the difference in endogenous production of TGF-β1 in MSCs in soft and stiff hydrogels. The results thus demonstrate a novel mechanism to regulate constitutive secretion of TGF-β1 in MSCs, which may play an important role in maintaining their immunomodulatory functions in an autocrine manner.

Integration of single molecule binding events in T cell activation.
S. Low-Nam\textsuperscript{1}, J.J. Lin\textsuperscript{2}, D.B. McAffee\textsuperscript{2}, S. Alvarez\textsuperscript{1}, S.D. Hansen\textsuperscript{1}, J.T. Groves\textsuperscript{1};
\textsuperscript{1}Chemistry, University of California, Berkeley, CA

T cells are capable of responding to antigenic ligands presented on major histocompatibility complex (pMHC) molecules with single molecule precision. Discrimination between ligands ensures selective and robust immunological responses upon T cell receptor (TCR) triggering. It remains unclear how binding inputs are integrated into productive, activating signals during cell decision-making. pMHC:TCR complexes activate ZAP70 kinase, which phosphorylates linker for T cell activation (LAT) molecules that are crosslinked into extended assemblies. We developed an assay that maps the spatial and temporal features of every pMHC:TCR complex experienced by a primary T cell to signaling clusters and a binary readout of T cell activation. Antigen densities are precisely controlled to ensure physiological, single molecule densities. Activating cells experience an ensemble of discrete, stochastic binding events whose cumulative numbers and duration vary widely. By capturing activation of rare cells that respond to a low density of weak agonist pMHC, we demonstrate that activation may include spatially and temporally coupled binding inputs. We demonstrate that T cells can transform binding inputs to create events of longer duration. Thus, T cells cross a molecular threshold for activation whose mean dwell time duration requirement is an order of magnitude longer than the population, ensemble average dwell time. We also show that activating cells are marked by extensive LAT clustering, arguing that initial binding events and ZAP70 activation are the critical steps in distinguishing cellular outcomes. LAT clustering only occurs in response to receptor ligation, and, strikingly, LAT clusters outnumber binding events by several fold. Direct visualization of LAT assemblies shows that ZAP70 is localized in these clusters, without association of a pMHC:TCR complex. These findings are consistent with a model for dispersion of active ZAP70 from pMHC:TCR that phosphorylate LAT and amplify signaling through generation of multiple clusters. The biochemical and physical mechanisms of Zap dispersion are under investigation. A detailed, molecular understanding of T cell activation is expected to promote actionable insights into control of immunological responses such as those seen in the emergence of chimeric antigen receptor (CAR) T cells.

Inferring emergent evolutionary features from alignments of intrinsically disordered regions despite poor sequence conservation.
A.S. Holehouse\textsuperscript{1}, R.M. Kiersten\textsuperscript{1}, M.O. Richardson\textsuperscript{1}, R.V. Pappu\textsuperscript{1};
\textsuperscript{1}Center for Biological Systems Engineering, Washington University in St. Louis, St. Louis, MO

Intrinsically disordered proteins and regions (IDPs) represent around 30% of eukaryotic proteomes and have been shown to play crucial role in a variety of complex processes, from cell signaling to cellular organization. Despite their importance for cellular function, IDPs show poor sequence conservation. This leads to an apparent paradox: why should such functionally important protein regions show so little conservation, assuming of course that sequence conservation is the only way to glean evolutionary importance. In this work, we use ideas borrowed from statistical physics with extant biophysical analysis to argue that conservation in IDPs exists in a space orthogonal to conventional sequence conservation. We suggest that sequence features that lead to specific emergent properties are conserved, even when sequences themselves are poorly conserved. We use our framework to evaluate the conservation of
disorder across a range of well-studied proteins, and showcase important implications for assessing how mutations in disordered regions might influence phenotype.

Mobility of DNA-binding species in the nucleus: the transient anomalous subdiffusion model.
M.J. Saxton1;
1Biochemistry Molec Med, University of California, Davis, CA

Single-particle tracking experiments have measured the distribution of dwell times of DNA-binding species diffusing in living cells, including CRISPR-Cas9, TetR, and LacI. The observed distribution, a truncated power law, implies transient anomalous subdiffusion, in which diffusion is anomalous at short times (mean-square displacement proportional to t^α, α < 1) and normal at long times (MSD proportional to t). Monte Carlo simulations are used to characterize the time-dependent diffusion coefficient D(t) in terms of the exponent α, the crossover time, and the limits D(0), D(∞), and to relate these quantities to the dwell time distribution. We examine how the underlying dwell time distribution is broadened by the statistics of escape to give the ideal observed distribution of dwell times. The actual observed distribution may be further modified by experimental uncertainties. We examine sampling in relation to the truncated power-law distribution, to see how long a Monte Carlo simulation is required and how many experimental observations are required to characterize the distribution. The simplest interpretation of the model is that the dwell times are actual binding times to DNA. One alternative interpretation is that the dwell times are the periods of 1D diffusion on DNA in the standard model combining 1D and 3D search. The model has several implications for cell biophysics. (1) The initial anomalous regime represents the search of the DNA-binding species for its target DNA sequence, so this regime is of fundamental interest. (2) Non-target DNA sites have a significant effect on search kinetics. False positives in bioinformatic searches are potentially rate-determining in vivo. For simple binding, the search would be speeded if false-positive sequences were eliminated from the genome. (3) Both binding and obstruction affect diffusion. The proper controls for obstruction are GFP as a calibration standard among laboratories and cell types, and the DNA-binding species with the binding site inactivated. Given the lack of a consensus on a model of chromatin, obstruction effects ought to be characterized experimentally as well as by modeling. (4) Overexpression of the DNA binding species reduces anomalous subdiffusion because the deepest binding sites are occupied and unavailable. (5) The model provides a coarse-grained phenomenological description of diffusion of a DNA-binding species, useful in larger-scale modeling of kinetics and FRAP. (Supported in part by NIH grant GM038133)

Oscillatory heat dissipation by cell cycle signaling during early vertebrate embryogenesis.
J. Rodenfels1, J. Howard1; K.M. Neugebauer1;
1Molecular Biophysics Biochemistry, Yale University, New Haven, CT

During early embryogenesis, rapid cell proliferation poses an extra extraordinary challenge for metabolism to provide energy for DNA replication, chromosome segregation, and mitosis. Yet, we lack a global view of the energetics of embryogenesis. Here we have used isothermal calorimetry to measure the heat dissipation during the synchronous reductive cleavage divisions of zebrafish development. Embryos displayed cell cycle signaling dependent oscillatory heat dissipation atop a more strongly
Increasing component. Chemical perturbation and mathematical modeling supported the hypothesis that the phosphorylation and dephosphorylation events by cyclin-dependent kinase and its counteracting phosphatase generate the oscillatory heat dissipation. Thus, a signaling mechanism that coordinates cell growth and division contributes significantly to global energy metabolism during embryogenesis.

**Building the phase diagram of a cellular body in vivo.**

A. Ladouceur¹, S.G. Thope¹, S.C. Weber¹;  
¹Biology, McGill University, Montreal, QC

Intrinsically-Disordered Proteins (IDPs) tend to drive molecules to phase separate, i.e. form liquid drops within a liquid mixture. Recently, phase separation was found to be important for the assembly of membrane-less organelles (cytoplasmic or nucleoplasmic granules). I have chosen a simple and highly tractable model organism to study phase separation in vivo. Bacteria do not have membrane bound vesicles so we can suppose that phase separation drives cytoplasmic granule assembly. It is predicted that E. coli’s genome has a relatively low proportion of IDP compared to mammals but transcriptional proteins are surprisingly enriched in IDP. Interestingly, RNA polymerase (RNAP) localization changes according to changes in metabolism such as growth in different media; it goes from being diffuse in poor growth media to punctate in rich growth media (known as transcriptional foci, TF). I hypothesize that prokaryotic TF assembly is regulated by phase separation in response to changes in growth conditions. Physical models predict that phase separation occurs at a discrete boundary between a mixed and demixed (i.e. phase-separated) solution. The following will directly test my hypothesis and identify relevant 1) environmental and 2) molecular parameters that drive TF assembly. I have developed a quantitative assay to measure the formation of TF in living cells through imaging of a rpoC::mCherry E. coli strain (RNAP). This assay will be use to establish a phase diagram in relation to different testable parameters. First, we are establishing whether TF assemble as a function of environmental conditions such as growth medium. A sharp transition in fluorescence distribution (from diffuse to punctate) in relation to growth rate would indicate the presence of a phase boundary. Predictions from phase diagrams suggest that at the phase boundary, TFs would disassemble. Therefore, this boundary could signal between cellular growth and TF assembly/disassembly. Second, I am performing a targeted screen on a list of E. coli transcriptional protein we have predicted to be disordered (DP). I am generating DP mutants (deletion) in the rpoC::mCherry strain in order to analyze TF assembly. Mutations in a protein required for TF assembly would be predicted to modify the phase diagram of TF assembly. In addition to my microscopy assays, I have purified hits to assess their phase separation activity in vitro. Thus, I am using high-resolution microscopy of a simplified bacteria system, a reverse genetic screen and biochemistry assay to determine how growth condition affects TF assembly.

1Bioengineering, Stanford University, Stanford, CA, 2ISAE-SUPAERO, Toulouse, France

What sets the fundamental limits on speed of motility of a microscopic swimmer? Many freely swimming ciliates can exhibit an avoidance response in the form of a short, rapid backward swimming motion or a ‘jump’ which punctuates their normal swimming motion. This swimming behavior is exemplified in the common pond-water dwelling ciliate Halteria grandinella whose swimming motion is characterized by periods of forward swimming at a modest 10 body lengths/s alternating with extremely rapid backward ‘jumps’ reaching maximum speeds of more than 150 body lengths/s. ‘Jumps’ occur when the motile cilia transition to a high amplitude, high-frequency (~100Hz) beat-form with an associated reversal in the direction of thrust generation. Preliminary measurements and estimates show that these jumps are at the limits of metabolic rate of the cell. We also discovered that H. grandinella is capable of sensing hydomechanical signals in the ambient fluid and transitions to a jump when this signal exceeds a critical threshold value. Towards elucidating the energetics of this extreme swimming motion we use their sensitivity to hydomechanical signals to perturb the natural swimming behavior of the organisms by confining them to artificial micro-chambers of varying spatial periodicity (aka microfluidic pin-ball machine) which leads to a modified frequency of jumps. We combine such external perturbations with measurements of intracellular signaling molecules such as calcium to understand how jumps are triggered and how intracellular energy flows occur during a jump. Since we hypothesize that H. grandinella is operating at the limits of its metabolic rate, studying the underlying mechanism offers insights into the limiting factors governing energy storage and release. Concurrently their sensing apparatus allows an understanding of the physical limits of microscale hydrodynamical sensing.

Berkeley, Berkeley, CA, 5Howard Hughes Medical Institute, Chevy Chase, MD

Crowding within the cell is optimized to accelerate reactions, but not excessively impede diffusion. However, the mechanisms that regulate crowding are unknown. We developed genetically encoded multimeric (GEM) nanoparticles to study the physical properties of the cytoplasm. GEMs self-assemble into bright, stable fluorescent particles of defined size and shape. We used this system to discover signaling pathways that modulate crowding in yeast and mammalian cells. We found that the mTORC1 pathway tunes macromolecular crowding through regulation of ribosome concentration and thereby regulates the effective diffusion of macromolecules larger than 16 nm in diameter but has no effect on the diffusion of molecules at the 5 nm length-scale. Crowding tunes the degree of phase separation of model proteins in vitro and in vivo. Our results connect a central regulator of growth and metabolism to the biophysical properties of the cell.

**Impact of compressive stress on the C. albicans transdifferentiation.**

M. Delarue¹, N.M. Chabot¹, G. Brittingham¹, L. Holt¹;
¹Institute for Systems Genetics, NYU Langone Medical Center, New-York, NY

Tensile and compressive stresses are the two main types of mechanical stresses experienced by cells. While tensile stresses arise from mechanical adhesion between cells, compressive stresses naturally emerge when cells grow and divide in a confined environment. Although tensile stresses have been extensively studied, and our understanding of their integration and downstream effect is good, much less is known about compressive stresses, despite their paramount importance in all living kingdoms, from microbes to metazoans. We have recently shown that Msb2, a mucin-like transmembrane protein, is a mechanosensor for S. cerevisiae under a compressive stress. Interestingly, this protein is one of the most upstream sensors controlling the transdifferentiation event of the yeast-to-hyphal transition in multiple organisms, including the human pathogen Candida albicans. Candida is the fourth most common bloodstream infection in the United States. Its pathogenicity is complex, but the yeast-to-hyphal transition has been shown to be important for the pathogen’s virulence. We show that the yeast-to-hyphal transdifferentiation event can be mediated by a compressive mechanical stress in C. albicans, and that a deletion of Msb2 causes a huge decrease of this transition. Interestingly, the efficiency of the transition depends on both the compressive stress applied to cells, as well as the pH of the growth media, in a complex and non-linear way, suggesting an optimal pH-compressive value at which the transition occurs. To the best of our knowledge, it is the first time that a compressive stress has been reported to impact transdifferentiation. We postulate that C. albicans virulence could then be influenced by the biophysical changes occurring when the pathogen infects a tissue, as the preferred infected organs present a wide range of pH and elasticity, the latter parameter impacting the mechanical stress. Thus, pathogenicity may not only be dependent on changes in the chemical environment. RNA-seq now allows us to determine key genes transducing compressive stress and it is appealing to use them as new therapeutic determinants to treat C. albicans infection. This study may well lead to new understandings of this important pathogen, but also place compressive stresses at the center of a new biomechanical differentiation paradigm.

**Cytoplasmic density dynamics in fission yeast studied by quantitative phase imaging.**

P.D. Odermatt¹,², K.C. Huang², F. Chang³;
¹Cell and Tissue Biology, University of California San Francisco, San Francisco, CA, ²Bioengineering Department, Stanford University, Stanford, CA

The density of the cytoplasm may be a critical factor for many cellular reactions within the living cell. How cytoplasmic density is regulated and what happens to cellular processes when cytoplasmic density is altered are poorly understood. The rod-shaped fission yeast *S. pombe* is a powerful eukaryotic model for studying the cell cycle and growth because of its simple geometry and growth patterns. Recent evidence in the lab suggests that scaling of protein synthesis with cell growth is critical for maintaining cytoplasmic density and for determining the rate of cell elongation (B. Knapp et al, unpublished). We are developing the use of quantitative phase imaging (QPI) as a tool to estimate the density of individual yeast cells. Analysis of the intensity propagation of light along the z-direction based on brightfield image
stacks allows estimation of the refractive index of the living cell\(^1\), enabling quantification of the biomass of single cells\(^2\). We are currently validating this approach using a number of approaches. In preliminary findings, inhibition of the secretory pathway by brefeldin causes a inhibition of cell elongation accompanied by a steady increase in cytoplasmic density, consistent with previous findings with yeast secretory mutants\(^3\). Preliminary data also suggest that cytoplasmic density increases during mitosis/cytokinesis in the normal cell cycle. We are currently screening mutants for abnormalities in cytoplasmic density and hope to test the effects of altered density on cellular processes. The establishment of this simple quantitative microscopy-based assay will facilitate the study into the coordination of cytoplasmic density, cellular mechanics and cell growth.

A two-step mechanism to activate PARP-1 and stabilize it on a DNA break.

L. Zandarashvili\(^1\), M. Langelier\(^2\), P.M. Aguiar\(^3\), B.E. Black\(^1\), J.M. Pascal\(^2\);

\(^1\)Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, \(^2\)Department of Biochemistry and Molecular Medicine, University of Montreal, Montreal, QC, \(^3\)Department of Chemistry, University of Montreal, Montreal, QC

PARP-1 cleaves NAD\(^+\) and transfers the resulting ADP-ribose moiety onto target proteins and onto subsequent polymers of ADP-ribose. An allosteric network connects PARP-1 multidomain detection of DNA damage to catalytic domain structural changes that reverse autoinhibition of catalytic activity; however, the mechanism of PARP-1 autoinhibition remains poorly defined. In this work, we utilized the NAD\(^+\) analog benzamide adenine dinucleotide (BAD), and a combination of Hydrogen-Deuterium Exchange Mass-Spectrometry (HXMS), x-ray crystallography, binding studies and catalytic activity assays, to reveal that PARP-1 autoinhibition results from a selective block on access to the NAD\(^+\) binding site.

One of these approaches, HXMS, is a solution-based method that provides structural and dynamic information that complements conventional structural approaches. HXMS revealed that BAD only gains access to the catalytic center of PARP-1 in the first step of the mechanism after it engages a DNA break causing the unfolding of the autoinhibitory HD domain. Surprisingly, BAD binding, in turn, leads to allosteric changes visible as changes in HX, culminating in HX protection back at its DNA binding surface that is \(~35\) Å away from the catalytic center of PARP-1. Indeed, we found that in the second step of the mechanism the binding affinity of PARP-1 toward damaged DNA site is increased after BAD binds, providing the first evidence of a reverse allosteric mechanism. Overall, this work provides new insights into PARP-1 domain assembly on DNA damage and how a two-step PARP-1 allosteric activation network ultimately influences persistence on DNA damage.

Morphological Changes of Epithelia Cells Induced by Viscous Conditions.
J. Flourny¹, G. Sun¹, D. Maity², Y. Chen¹;
¹Mechanical Engineering, Johns Hopkins University, Baltimore, MD, ²Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Cells are highly sensitive to their microenvironments. While many chemical effects on the microenvironment are known, most biophysical effects are yet to be studied. One example is the effect of viscosity on cells. Understanding the effects of viscosity is pertinent to cancer research as increased viscosity is a prominent mechanical effect observed in the tumor microenvironment. In this study, we used media containing a 2% thickening agent to examine the effects of viscosity on a variety of cell lines, including EPH4, 67NR, 4T1, NIH-3T3, and MDA-MB231. Using reflectance imaging, we observed that cells exhibit a significant morphological change when viscous conditions are introduced by replacing regular medium with medium containing a thickening agent. Parameters such as the percentage of filopodia positive cells, number of filopodia per cell, the length of the filopodia, the basal area of the cell, and the length of the cell were quantified before and after the viscosity change. We found the under viscous conditions all cell lines became 100% filopodia positive. All cells exhibited an increase in the average number of filopodia per cell. The greatest increase in the average number of filopodia occurred in 4T1 and MDA-MB231, which were 8.28 fold and 13.66 fold respectively. The average length of filopodia per cell also increased in all cell lines. EPH4 had the largest increase in average filopodia length, which was 2.78 fold. The average cell area increased in all cell lines except MDA-MB231 which decreased by 30%. The average aspect ratio increased significantly in EPH4, 67NR and MDA-MB231. Despite the changes in the basal area and the length of the cells, the volume of the cells remained constant. Furthermore, the cell motility of NIH-3T3 cells was compared between control and viscous conditions and no significant differences were observed. These results suggest a potentially distinct mechanism for cells navigating at high viscosity as under viscous conditions all cells exhibited significantly denser and longer filopodia. It is especially interesting that metastatic breast cancer cell lines, MDA-MB231 and 4T1, had the greatest increase in filopodia per cell, indicating that this may aid in the ability to navigate the tumor microenvironment. Further investigation could lead to the mechanistic insight for how cancer cells adapt to the tumor microenvironment with higher success, as well as potentially novel treatment strategies for breast cancer.

Molecular mechanisms of perilipins targeting to lipid droplets.
A.R. Thiam¹;
¹Physique, Ecole Normale Supérieure, Paris, France

Lipid droplets (LDs) are organelles regulating cellular energy metabolism and homeostasis. While most organelles are bilayer-bounded, LDs have an oil core covered by a single phospholipid monolayer containing proteins, forming thereby intracellular oil-in-water emulsion droplets. Thus, because of their oil/water interface, LDs cannot bear proteins with transmembrane domains. Instead, most LD proteins use hairpins or amphipathic helices for targeting. How proteins specifically localize to LDs is among the main questions of LD biology. One of the first class of identified LD proteins is the Perilipin family (PLIN 1 to 5); they are the most abundant LD proteins, and regulate the accessibility of enzymes to LDs. PLINs do not all perform the same functions, as they are expressed at different levels in different tissues. Despite
their early identification and critical function in metabolism, how PLINs specifically target LDs is still not fully understood. PLINs bind with multiple domains containing amphipathic helix motifs. However, while they share similar structural binding motifs, they target different LDs within a same cell, which suggests their selectivity for LD surface. Such unique surface selectivity could be the driving force for the occurrence of distinct LD pools, with distinct fates, marked by PLINs. We capitalized on our knowledge of emulsion and membrane biophysics to address the molecular mechanisms of PLIN proteins binding to LDs. We deciphered in cells and in vitro how the binding of PLINs to LDs is regulated.

PEA-15 phosphorylation homeostasis and allosteric regulation of cell proliferation and apoptosis.
J. Marrero¹, S. Crespo¹, S. Hassan¹, Y. Wei¹
¹Chemistry, New Jersey City University, Jersey City, NJ

PEA-15 (phosphoprotein enriched in astrocytes, 15 kD) is a small, non-catalytic, death-effector domain (DED) containing protein, that is widely expressed in different tissues and highly conserved among mammals. Although the overall expression level of PEA-15 is mostly constant in most tissues, its phosphorylation states of the two serine residues on the C-terminal tail vary significantly depending on cell and tissue types and/or cellular environment and conditions. The phosphorylation states control the interactions of PEA-15 with other protein targets in various pathways, including Fas-associated death domain (FADD) and procaspase-8 (apoptosis), extracellular signal-regulated kinase (ERK) 1 and 2 (cell cycle entry), and phospholipase D (PLD) 1 and 2 (diabetes). We have previously reported a surprising conformational change of PEA-15 DED upon interaction with ERK2 using nuclear magnetic resonance (NMR) dynamics and residual dipolar coupling (RDC) data. We recently demonstrated again that the DED conformation is also modulated by the phosphorylation states of the C-terminal serine residues. Upon phosphorylation, mimicked by serine to aspartic acid mutations (PEA-15DD), the DED conformation is very distinct from the wild type protein, and its binding specificity switches from ERK1/2 to FADD. Additionally, the PEA-15DD structure is not significantly different from the FADD complex. Based on our most recent results, we propose that the DED conformation is allosterically controlled by the phosphorylation states of the C-terminal tail, which in turn determines the binding specificity of the protein. We further propose that the balance between phosphorylated and unphosphorylated PEA-15 is strictly regulated in different cell types and tissues to control the cellular outcomes, which we termed phosphorylation homeostasis, and any disruption of the delicate balance could lead to various diseases, such as cancers and neurodegenerative diseases.

Understanding the Role and Regulation of Cell Wall Hydrolases in Bacillus subtilis.
S.A. Wilson¹, E.C. Garner¹
¹Molecular and Cellular Biology, Harvard University, Cambridge, MA

The main goals of this project are to the determine the roles that different cell wall hydrolases play in bacterial growth, and to understand how they are regulated. Most bacteria are encased in a rigid meshwork called the cell wall. In order to grow, cells must break bonds in this meshwork. These breakages are mediated by critical enzymes called cell wall hydrolases, whose activity must be carefully regulated in space and time. If too many bonds are broken, or if bonds are broken in the wrong place,
the cells will lyse. If too few are broken, the cell cannot grow. We currently know little about the specific roles that cell wall hydrolases play during cell growth or how their activity is regulated. I have developed a microscopy-based assay to track the flow of cell wall material through the wall with high spatial and temporal resolution using fluorescent probes that are covalently incorporated into the cell wall. This assay allows me to measure 1) the rate of incorporation of new material, 2) the rate of cell growth, and 3) the rate of removal of old material. With this assay, I have shown that two hydrolases, LytC and LytD, are involved only in the removal of old material and do not contribute to cell growth, while two other hydrolases, CwIO and LytE, contribute only to the expansion of the meshwork required for growth. Additional work will extend these observations to understand the role and regulatory mechanisms of other highly expressed hydrolases.

Fluorescence spectroscopy reveals two types of binding sites for endogenous ligands in CISD proteins.

R.A. Skoilk1, R. Guan2, R. Napier1, M.E. Konkle2, M.A. Menze3;
1Biology, University of Louisville, Louisville, KY, 2Chemistry, Ball State University, Muncie, IN

The dimeric proteins CISD1 and CISD2 belong to a unique family of iron-sulfur cluster containing proteins and are implicated in a variety of disorders including type-2 diabetes, Wolfram syndrome 2, and neurodegeneration. Localized at the mitochondrion, endoplasmic reticulum, and mitochondria-associated ER membranes, CISD proteins are directly or indirectly involved in cellular energy homeostasis, but the specific mechanism(s) of regulation remain ill defined. Our lack of a mechanistic understanding how CISD proteins integrate into cellular bioenergetics is in part due to the fact that interacting proteins and ligands are still mostly uncharacterized. Recent studies have suggested that both proteins, CISD1 and CISD2, are involved in redox sensing via binding to NADPH, but a more comprehensive study of interaction with other cellular metabolites is missing. We demonstrate that the soluble portion of both proteins have one tyrosine and tryptophan residue per monomer which undergo fluorescent emission quenching upon ligand binding. This feature allows for the development of a simple fluorescence-based assay to characterize binding of physiologically relevant organic ligands to CISD1 and CISD2. Excitation at l = 280 nm results in fluorescent emission of both tyrosine and tryptophan, while excation at l = 295 nm generates only tryptophan emission. By monitoring the fluorescent emission of CISD1 and CISD2 excited at l = 280 nm or l = 295 nm, we could demonstrate that reduced nicotinamide adenine dinucleotide (NADH) binds with significant affinity to two different binding sites, while the oxidized form and adenine nucleotides such as ATP and ADP only interact with one type of site. The physiological concentration of NAD+ ranges between 0.3 - 0.4 mM, only approximately 2 – 3-fold lower than the apparent Kd = 1.1 mM and 0.7 mM, respectively). Furthermore, binding affinities of CISD1 to ATP and ADP are within the physiological range of the phosphorylated nucleotides (Kd = 3.4 ± 0.2 mM and 1.5 ± 0.1 mM). Our approach offers a versatile system to characterize physiological relevant binding partners and to rapidly screen for potential therapeutics that interact with CISD proteins. Importantly, we demonstrate that CISD1 and CISD2 could be governing or responding to the cellular redox state by binding with physiologically significant affinities to a variety of compounds that are directly or indirectly related to the cellular energy state (Supported by NSF CHE-160944).

Crystal structure of thioredoxin reductase from Cryptococcus neoformans in complex with FAD a potential target for antifungal drug.

C.P. Bravo Chaucanés¹, N. F Valadares², A.K. Abadio², M.S. Felipe¹, J.A. R. G. Barbosa¹;
¹Celular Biology, Biophysical laboratory, University of Brasilia, Brasilia, Brazil, ²UNEMAT, University of Mato Grosso State, Nova Xavantina, Mato Grosso, Brazil

In resource-limited regions, invasive fungal infections constitute a major public health problem, especially in immunocompromised patients. Cryptococcosis is an important opportunistic fungal infection caused by Cryptococcus neoformans, an encapsulated fungus that causes an initial asymptomatic pulmonary infection and can spread systemically especially in patients with AIDS. Cryptococcosis affects about one million people each year and kills about 625,000. Despite the tireless search to the development of new antifungal strategies, there are few drugs to treat systemic and superficial fungal infections available. Relatively the few drugs are toxic, present undesirable secondary effects and poor absorption and efficacy. Using comparative genomics strategy it was identified the potential of new drugs targets for human fungal pathogens. One of those is the thioredoxin reductase, a essential gene in C. neoformans. In this study, we present the heterologous expression, purification, enzymatic characterization and crystallographic structure of oxidized TrxR at 2.25 Å, the first human pathogenic fungi Cryptococcus neoformans structure. The expressed product was purified by affinity chromatography on nickel column. It was possible to identify a band of 39 kDa. The enzymatic activity of the recombinant protein was confirmed by assays of enzyme kinetics. CnTrxR was concentrated to 10 mg/mL, then it was incubated with FAD and finally concentrated to 35 mg/mL in 10 mM Tris-HCl, pH 8.5 and 300 mM NaCl. The purified recombinant protein CnTrxR was crystallized at 20°C. The CnTrxR crystals diffract to 2.25 Å resolution primitive orthorhombic space group P21 21 21, considering the asymmetric unit, two CnTrxR molecules were expected in the asymmetric unit. X-ray diffraction data were collected using the Brazilian synchrotron source and the structure was solved by molecular replacement and refined to a crystallographic R factor of 0.16 and a free R factor of 0.22. The overall structure of C. neoformans TrxR is very similar to that the S. cerevisiae TrxR1 as the research model. The root-mean square deviation of the 300 α atoms of the two structures superimposed was found to be 1.82 Å. Sequence alignment shows that CnTrxR shares a sequence identity of 71%, 64%, 48% and 24%, with TrxRs of S. cerevisiae, A. thaliana, E. coli and H. Sapiens (high-molecular-mass TrxR) respectively. In addition, small molecules that interact with a TrxR model were selected from the virtual screening library, among the best hits, 2 of them showed antifungal activity in vitro against C. neoformans. In summary, our findings described here represent advancement and may contribute to the development of new drugs with broad-spectrum activity for the treatment of fungal infections.

The notochord, a conserved axial structure required for embryonic axis elongation and spine development, consists of giant vacuolated cells surrounded by an epithelial sheath. During morphogenesis, vacuolated cells maintain their structural integrity despite being under constant mechanical stress. We hypothesized that the high density of caveolae present in vacuolated cells could buffer mechanical tension. Caveolae are 50- to 80-nm membrane invaginations lined by cage-like polygonal structures formed by caveolin 1 (Cav1) or Cav3 and one of the cavin proteins. Recent in vitro work has shown that plasma membrane caveolae constitute a membrane reservoir that can buffer mechanical stresses such as stretching or osmotic swelling. Moreover, mechanical integrity of vascular and muscle cells is partly dependent on caveolae. However, the in vivo mechano-protective roles of caveolae have only begun to be explored. Using zebrafish mutants for cav1, cav3, and cavin1b, we show that caveolae are essential for notochord integrity. Upon loss of caveola function, vacuolated cells collapse at discrete positions under the mechanical strain of locomotion. Then, sheath cells invade the inner notochord and differentiate into vacuolated cells, thereby restoring notochord function and allowing normal spine development. Our data further indicate that nucleotides released by dying vacuolated cells promote sheath cell vacuolization and trans-differentiation. This work reveals a novel structural role for caveolae in vertebrates and provides unique insights into the mechanisms that safeguard notochord and spine development.

Wnt5b regulates basal constriction during neuroepithelial tissue folding.
M.R. Visetsouk1, R.J. Garde1, E.J. Falat1, J.L. Wendlick1, C. Kwas1, J.H. Gutzman1;
1Biological Sciences, University of Wisconsin-Milwaukee, Milwaukee, WI

Epithelial cell shape changes are regulated by intracellular and extracellular signals that tightly control cytoskeletal dynamics, which together are needed for proper development of tissue and organ structure. We have utilized the zebrafish neuroepithelium as a model to identify and understand the mechanisms that control neuroepithelial cell shape. Using the highly conserved structure known as the midbrain-hindbrain boundary (MHB), we identified a novel cell shape change required to fold the neuroepithelium, basal constriction. While we have previously shown that basal constriction requires laminin, and is likely to depend on non-muscle myosin II function, the signaling cues that are required, and how they regulate the cytoskeleton to mediate basal constriction are not well understood. Here, we have identified an upstream regulator of basal constriction, Wnt5b. Wnt5b is an extracellular signaling molecule with known roles in planar cell polarity and cell migration and it is expressed specifically at the
MHB during morphogenesis. Using live confocal imaging and a digital sectioning morphometric technique that we developed, we have uncovered a role for Wnt5b in the regulation of basal constriction. During MHB morphogenesis in wild-type embryos, we observed that cells simultaneously become deeper in the dorsal-ventral direction and narrower in the anterior-posterior direction at the basal end of the cell. This polarization of cell shape basally is lost with knockdown of wnt5b. 2D-Gel based proteomic studies and Western blot analysis revealed changes in alpha-tubulin levels following wnt5b knockdown. Therefore, we investigated the role of the microtubule cytoskeleton in mediating Wnt5b-directed basal constriction. Live confocal imaging of microtubule dynamics using a plus-end binding protein, EB3-GFP, and cell shape analysis after drug-induced manipulation of microtubule polymerization, suggests that Wnt5b signaling may be required for modulating microtubule stability during basal constriction. Next, we investigated a potential role for JNK, a known regulator of microtubule dynamics and downstream mediator of Wnt5b signals, in this process. We observed a decrease in phosphorylated JNK with knockdown of wnt5b, and hypothesize that Wnt5b mediates microtubule cytoskeletal activity through JNK signaling. Together, we have identified Wnt5b as an upstream mediator of basal constriction that is required to fold the neuroepithelium. Our results further suggest that Wnt5b modulates basal constriction through regulation of the microtubule cytoskeleton and JNK activity during embryonic brain morphogenesis.

Apical cell-cell adhesions reconcile symmetry and asymmetry in zebrafish neurulation.
C. Guo¹, X. Wei¹;
¹Ophthalmology, University of Pittsburgh, Pittsburgh, PA

The symmetric tissues and body plans of animals are paradoxically constructed with asymmetric cells. To understand how the yin-yang duality of symmetry and asymmetry are reconciled, we asked whether or not apical polarity proteins orchestrate mirror-symmetric neural tube development in zebrafish by hierarchically modulating apical cell-cell adhesions. We found that apical polarity proteins localize by a pioneer-intermediate-terminal order. Pioneer proteins establish the mirror symmetry of the neural rod by initiating two distinct types of apical adhesions: The parallel apical adhesions (PAAs) cohere cells of parallel orientation, and the novel opposing apical adhesions (OAs) cohere cells of opposing orientation. Subsequently, intermediate proteins selectively enhance the PAAs when the OAs dissolve by endocytosis. Finally, terminal proteins inflate the neural tube by generating osmotic pressure. Our findings suggest a general mechanism to construct mirror symmetric tissues: Tissue symmetry can be automatically established by simply aligning cellular asymmetry opposingly via adhesions.

Rho signaling is fine-tuned by multiple feedback mechanisms during epithelial morphogenesis.
K.L. Ong¹, C. Collier¹, S. DiNardo³;
¹Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

While hexagonal packing represents a low energy arrangement of cells in an epithelium, such a simple geometry is rarely useful in vivo. Instead, anisotropic forces are deployed within and across cells to generate the complex geometries necessary for physiological function. Rho GTPase signaling is a conserved mechanism for generating forces through activation of contractile actomyosin. How this pathway is tuned to produce different morphogenetic outputs is poorly understood. To investigate this,
we study an event in the *Drosophila* embryonic epithelium (termed “alignment”) that generates rectilinear columns of cells where the cell-cell interfaces separating the columns align. We found that this cellular rearrangement is driven by contractility of supracellular actomyosin cables that elevate the local tension along aligning interfaces. Our data suggest that Rho signaling planar polarized to aligning interfaces promotes the formation of the actomyosin cables. Rho-GTP and two of its effectors, Rho Kinase (ROK) and Diaphanous (Dia), are enriched along aligning cell-cell contacts. Inhibition of any of these three factors caused loss of alignment. Depletion of ROK or Dia led to distinct defects in actin and Myosin-II (Myo-II) planar polarity. Expression of constitutively active forms of ROK or Dia produced ectopic furrows in the epithelium, suggesting that precise regulation of this pathway is necessary to achieve the aligned geometry. There is emerging evidence that feedback mechanisms can modulate Rho-GTPase signaling for morphogenesis. Therefore, we tested whether feedback between components in the pathway could play a role in controlling signaling outcomes during alignment. We found a mutual dependence for F-actin and Myo-II: cytochalasin D treatment resulted in a loss of Myo-II planar polarity and Myo-II knockdown led to depletion of cortical actin. Surprisingly, each of these conditions had different effects on Rho signaling. Consistent with findings in starfish and *Xenopus*, the disruption of F-actin led to upregulation of Rho-GTP and Dia, suggesting that negative feedback allows for fine tuning of Rho signaling during alignment. However, Myo-II knockdown had no impact on Rho activation or polarity. This contrasts with findings in the early embryo where actomyosin contractility positively feeds back to the Rho pathway. Yet, we did find that Dia is depleted from aligning interfaces with ROK inhibition, suggesting an interaction between these two effectors that is independent of contractility. This work suggests that multiple feedback mechanisms factor into maintaining polarized Rho signaling and driving coordinated cell shape changes.

Direct quantification of swelling pressures that drive chick neural tube morphogenesis.

W.G. Stewart¹, J.L. Pelesko¹, J.P. Gleghorn¹;
¹Biomedical Engineering, University of Delaware, Newark, DE

Fluid pressure has been shown to be an important contributor to the morphogenesis of several organs including lungs, vasculature, and kidney. A number of studies have also shown qualitatively that altering the pressure in the embryonic neural tube dysregulates morphogenesis. Increasing pressure increases the size and alters the shape of the neural tube whereas decreasing pressure leads to neural tube collapse and tissue death. However, few attempts have been made to quantify the pressures in the neural tube during development. By quantifying how neural tube pressures change over gestation, physical models can be created to understand how these mechanical forces direct morphogenesis and may identify downstream mechanotransduction pathways relevant in dysregulated neural tube development. In these studies we performed measurements of chicken neural tubes at a range of gestational ages and directly assessed the effect of beta-D-xyllose on neural tube pressure. *Gallus gallus* fertilized chicken eggs were incubated at 37° C under periodic rotation and staged chicken embryos were then extracted and cultured *ex ovo* for 24 hours on an agar/albumin hydrogel prior to pressure measurements at HH 18 and HH 22 gestational stages. To measure pressure, a pulled glass microneedle was wetted and connected to a differential pressure transducer. Continuous pressure measurements were captured by computer and data was recorded and analyzed with custom LabVIEW and MATLAB programs. To measure pressure, the embryo hindbrain was cannulated with the microneedle using a micromanipulator. Our pressure measurement method was extensively calibrated and validated with a measurement resolution of 5 Pa. Mean baseline pressures found in the neural tube at HH 18 gestational stage were approximately 20 Pa. Physical and pharmacological methods were used
to perturb neural tube pressures and alter morphogenesis. Pressures were recorded as neural tubes were physically “popped” by creating a hole with a glass microneedle. Pressure decreased and the wound healed with the neural tube reinflating. To increase pressure in the neural tube, embryos were treated with either beta-D-xyloside to dysregulate chondroitin sulfate synthesis or vehicle control at the start of ex ovo culture. Treatment with beta-D-xyloside increased neural tube pressure and led to corresponding increases in neural tube volumes. The methods we have developed to measure pressure in the developing chick neural tube provide quantitative data of luminal fluid forces to be used in the development of computational models of morphogenesis over gestation. Further, our techniques can be adapted to quantify the magnitude and role of fluid pressures in several other organs during embryonic development.

Interphase localization of Abnormal Spindle to the nucleus is important for proper brain size.
T. Schoborg¹, S. Smith¹, L. Smith¹, C.J. Fagerstrom¹, Y. Yu², T. Lee², N.M. Rusan¹;
¹Cell Biology Physiology Center, National Institutes of Health, Bethesda, MD, ²Janelia Research Campus, Ashburn, VA

Autosomal recessive primary microcephaly (MCPH) is a neurodevelopmental disorder characterized by reduced brain size and life span. While the clinical aspects of the disorder are well characterized, the molecular mechanism remains poorly understood. Previous models favored cell division defects induced by mitotic spindle errors as the cause of the disorder, leading to reduced neuron/glia numbers and a smaller brain. The most commonly mutated gene in human MCPH patients, *Abnormal Spindle-Like, Microcephaly Associated (ASPM)* is known to be important for proper centrosome and mitotic spindle function during mitosis. However, our recent analysis of the Drosophila melanogaster ortholog, *Abnormal Spindle (Asp)*, showed that mitotic spindle & cell division defects are not the primary cause of MCPH in Asp mutant animals, suggesting the current model needs to be revised. We now provide evidence that Asp contributes to proper brain size through a novel role in the interphase nucleus. Using a combination of transgenic rescue assays and high resolution microcomputed tomography (micro-CT) of intact animals, we have identified the minimal fragment of Asp’s N-terminus (AspNMF, 597 aa) required for proper brain size and morphology. Mutation of a highly conserved asparagine residue located within the ASH domain of the AspNMF fragment abolishes the rescue phenotype. Subcellular localization of AspNMF within the developing larval & adult brain revealed an unexpected localization to the interphase nucleus of distinct neural stem cell populations and mature neurons. Intriguingly, RNA-Seq analysis of Asp mutant brains revealed a significant downregulation of actin-related genes, including *myosin heavy chain (Mhc)* and the troponin complex member *wupA*, whose expression could be restored to wildtype levels in the AspNMF background. In accordance with Asp’s role as a nuclear protein, we identify and characterize a novel interaction between AspNMF & umbra (HP6), a heterochromatin binding protein located exclusively in the interphase nucleus. Together, our data highlights the first interphase role for Asp and suggests that other MCPH genes may contribute to the disorder through non-canonical pathways that funnel through the nucleus.

iPSC Derived Cerebral Organoids Reveal Early Developmental Malformations In Schizophrenia.
A. Dimitri1, L. Bayona Chuye1, S. Dhiman1, P. Sarder1, M.K. Stachowiak1, E.K. Stachowiak1;
1Pathology and Anatomical Sciences, State University of New York at Buffalo, Buffalo, NY

Improper migration and premature maturation of neuronal precursor cells into neurons have been suggested to alter brain structure and destabilize function in schizophrenia patients. Cerebral organoids are 3D organ structures that mimic human brain development during the first trimester and allow insight into early developmental processes and cortical organization. We generated cerebral organoids using Induced Pluripotent Stem Cells (iPSCs), which are derived from adult human fibroblasts. They were reprogrammed into a pluripotent state using specified transcription factors. Organoids are used to study brain structure and protein expression and can give insight into how neurological disorders that appear later in life manifest in fetal development, as proper neuronal migration, maturation, and organization during development plays a critical role in brain structure and function. Two week and 35 day old cerebral organoids derived from patients with Schizophrenia were analyzed for proliferative marker protein Ki-67, neuronal transcription factor TBR1 and regulatory protein Fibroblast Growth Factor Receptor 1 (FGFR1). Organoids embedded in gelatin were sliced into 30μm sections and stained and by fluorescent immunohistochemistry for each protein of interest. Schizophrenia derived organoids showed a marked increase in cells expressing Ki-67 as well as a disorganization of proliferative rosettes when compared to control samples. A computational minimum spanning tree analysis studying inter-cellular distance distances between neighboring cells demonstrated a significant increase in distance spread within proliferative neural progenitor. Moreover, the percentage counts of nuclear TBR1 and FGFR1 in the outer cortical plate were significantly lower in Schizophrenia organoids, indicating premature advancement of neuronal development when compared to control organoids. Supported by NYSTEM (C026415, C026714), National Science Foundation (CBET-1555720, CBET-1706050) and Patrick P. Lee Foundation.

Smc5/6 complex maintains genome stability in the stem and progenitor cells of developing mouse cerebral cortex.
A. Boyko1, M. Xu1, M. Pryzhkova1, P.W. Jordan1;
1Biochemistry and Molecular Biology, Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD

The Structural Maintenance of Chromosomes (SMC) 5/6 complex plays a central role in maintaining genome integrity (Gallego-Paez et al., 2014, Gómez et al., 2013, Wu and Yu, 2012). Previous reports showed that mutations in the Smc5/6 complex cause severe developmental defects, including microcephaly and primordial dwarfism in humans (Payne et al., 2014). However, it is not known exactly how the loss of Smc5/6 disrupts the molecular pathways in the developing brain. We have developed a novel mutant mouse model harboring a conditional knock-out (cKO) allele of Smc5. These mice exhibit microcephaly during embryonic development through adulthood, thus mimicking the defect seen in humans. We confirm our previous observation that cKO of Smc5 results in the destabilization of the entire Smc5/6 complex (Pryzhkova and Jordan, 2016). We compared brain morphology and neural stem cell status in Smc5 cKO and control mice during fetal development, neonatal development and adulthood. We found that Smc5 cKO mice had severely underdeveloped cerebral cortex and showed
reduced numbers of neural stem cells and progenitors within the ventricular zone (VZ) and lower cortical layers (VI-IV), respectively. In our current work, we are closely assessing development of the fetal brain to determine the direct consequences of destabilizing the Smc5/6 complex. We are also assessing the genetic causes of the apoptotic response that is responsible for the development of microcephaly. Ultimately, our research will contribute to understanding of the molecular functions of the Smc5/6 complex during brain development in humans.

1BIOLOGY, MIAMI UNIVERSITY, Oxford, OH

The larval nervous system of the fruit-fly Drosophila melanogaster is reorganized during the 4-day transition period of metamorphosis, which is crucial for establishing adult specific behaviors. A prominent anatomical restructuring is the fusion of five pairs of posterior abdominal nerves to form a terminal nerve trunk (TNT). Segmental nerves defasciculate from the TNT at regular intervals to innervate the body wall. Glial cells that ensheath individual nerves are likely to play a significant role in nerve fusion. Our recent studies using confocal and EM approaches have shown that layer specific remodeling occurs during the 4-day period of pupal development. Our current work focuses on the most external glial layer, the perineurial glia (PG), which undergoes four-fold increase in number during the first day of metamorphosis (25% of development). Coincident with this increase in PG numbers is the breakdown of the adjacent extracellular matrix-the neural lamella (NL). It is possible that disintegration of NL during day 1 of metamorphosis triggers signaling mechanisms to bring about PG proliferation. Our experiments will test the hypothesis that FGF signaling plays a role in PG proliferation. Preliminary experiments using the Gal80ts target system to temporally control transgene expression, have identified that disruption of the FGF receptor-heartless in PG cells leads to eclosion defects in animals. Additionally, a significant number of animals that emerge have defective TNT patterns. Our research on glial remodeling in Drosophila will lay the groundwork for future studies on the role of glia-glia and glia-neuron communication during TNT formation, and could lead to the establishment of a model system to study gliopathies.

Tissue macrophages are fundamental effectors in the modulation of several organs development, mainly in processes as branching morphogenesis and vasculature formation. Although these cells are present throughout lung developmental stages, their contribution to its formation is unknown. Accordingly, we
hypothesize that fetal tissue macrophages play critical roles in lung developmental events, such branching morphogenesis, differentiation and maturation. Using a macrophage-deficient mouse model (colony stimulating factor-1 receptor (Csf1r) knockout (KO) mice), we performed morphological analysis at different lung developmental stages, which evidenced a disruption of distal lung morphology in KO mice, with a significantly increase in lung non-epithelial-like volume and decrease in air space compartments at saccular stage. Since, lung saccular stage is largely characterized by differentiation of several cell lineages (e.g. alveolar epithelial, myofibroblasts) with the continuous vascular network formation, we evaluated distal epithelium, myofibroblasts/smooth muscle and vasculature differentiation. Transcripts expression levels of distal epithelial markers evidenced a clear impairment in macrophage-deficient mice in this compartment. Deregulation in relative transcripts expression of myofibroblasts/smooth muscle cell related molecules was also observed in the lung of these animals. Alveolar markers type I and II protein expression investigation showed a significant reduction in alveolar differentiation in KO mice. On the other hand, a substantial increase in mesenchymal cell marker and myofibroblast marker expression was observed, suggesting a disruption in this cellular lineage differentiation. Vascular mediators analysis showed an imbalance of transcript expression levels in the KO mice. However, protein expression evaluation of two specific vascular markers showed no evident impairments in vasculature formation in KO mice at this stage. Our data demonstrate the influence of fetal tissue macrophages in the modulation of lung sacculation and alveologenesis, namely shaping distal epithelial and myofibroblast lineage differentiation. These results strongly suggest that fetal tissue macrophages act as paracrine suppliers indispensable to the formation of a functional pulmonary system.

A Novel Role for Paxillin during Mammary Gland Morphogenesis.
W. Xu1, G.J. Goreczny1, E.C. Olson1, C.E. Turner1;
1Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Abstract:
Paxillin is a scaffold protein that localizes to focal adhesions and has previously been implicated in multiple cellular processes including integrin-mediated signaling, polarized trafficking, directional cell migration and maintaining Golgi integrity. Our study aims to understand the role of paxillin in vivo, during mammary gland development. Global paxillin knockout in mice causes embryonic lethality so we generated a conditional paxillin knockout mouse that drives cre expression under the Mouse Mammary Tumor Virus (MMTV) promoter to specifically ablate paxillin in the mammary epithelial cells. To assess the role of paxillin during mouse mammary gland development, we performed whole mount staining and immunohistochemistry (IHC), as well as ex-vivo organoid 3D culture. The whole mounts of 6-week-old mammary glands revealed that paxillin^fl/fl cre glands have significantly less branching and dilated ducts. Similarly, reduced branching was observed in the paxillin^fl/fl cre organoids. Furthermore, epithelial cell shape in both paxillin^fl/fl cre mammary glands and organoids were more elongated as compared to controls. IHC analysis of the paxillin^fl/fl cre ducts revealed that the Golgi apparatus is mislocalized and apical polarity proteins also have a dispersed distribution, indicative of disrupted apical-basal polarity in paxillin^fl/fl cre glands. Interestingly, our preliminary data also showed both mislocalization and reduction of acetylated-tubulin in the paxillin^fl/fl cre glands. Taken together these data suggest paxillin is required for mammary gland morphogenesis by regulating epithelial cell apical-basal polarity formation potentially via microtubule acetylation-associated trafficking.

Smooth muscle differentiation guides domain branching in the embryonic mouse lung.
K. Goodwin¹, C.M. Nelson¹²;
¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Molecular Biology, Princeton University, Princeton, NJ

During branching morphogenesis, a simple cluster or tube of cells proliferates and branches to generate an arborized network that facilitates the flow and exchange of gases or fluids. Branched organs are found throughout the animal kingdom, and while their function varies, their morphogenesis is driven by similar molecular programs. To achieve a specific final morphology, physical cues are required to guide branching of the epithelium into the surrounding mesenchyme. During murine lung branching morphogenesis, the airway epithelium develops concomitantly with a layer of smooth muscle, which is derived from the mesenchyme and wraps around the airways. Specific spatial patterns of smooth muscle differentiation are required for terminal bifurcation. Here, we examined the role of smooth muscle differentiation in shaping emerging domain branches (branches that bud laterally off the side of an existing branch) during early lung development. We found that the position and morphology of domain branches are highly stereotyped: branches begin as wide buds that thin at their base as they elongate. At the same time, there is an increase in the amount of smooth muscle wrapped around the parent branch at the base of the new domain branch. Perturbing the pattern of smooth muscle differentiation results in abnormal branch positioning and morphology. Loss of smooth muscle results in ectopic branching events and slows branch thinning, and enhanced smooth muscle differentiation suppresses branch formation and elongation. Our work uncovers a role for smooth muscle differentiation in sculpting emerging domain branches, and sheds light on the physical mechanisms of branching morphogenesis of the mouse lung.

¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Molecular Biology, Princeton University, Princeton, NJ

Cells integrate biochemical and biomechanical cues from the microenvironment to execute developmental programs during organogenesis, including airway branching morphogenesis in the lung. To understand how cells in the developing lung sense and respond to the local microenvironment, we carried out RNA-sequencing analysis of critical stages of branching of the embryonic chicken lung, which revealed changes in expression of genes associated integrin signaling and extracellular matrix (ECM) remodeling. Therefore, we sought to define the relationship between ECM synthesis, remodeling, and airway branching morphogenesis. We found that prior to branching, the basement membrane (BM) is a uniform sheath wrapping the airway epithelium with no observable BM turnover prior to branch initiation. However, the BM is significantly reduced at the tip of elongating airway branches after of branch induction. Cultures of embryonic lung explants reveal that BM thinning at branch tips is mediated by matrix metalloproteinases (MMPs). Inhibiting MMPs suppressed branch extension, but did not prevent the initiation of new branches. As epithelial branches extend, cells in the surrounding

Monday-471
mesenchyme become highly elongated in shape and activate focal adhesion kinase (FAK). This local activation of FAK is associated with the synthesis of tenascin-C (TNC) at branch tips. Moreover, disrupting FAK activity blocks initiation of new branches. Based on these data, we propose a model by which the airway epithelium initiates branches in a FAK-dependent manner. While matrix remodeling is not required for branch initiation, BM depletion at branch tips is required for branch extension. As branches extend, neighboring mesenchymal cells are deformed, which promotes a change in local ECM composition via FAK activation, ultimately shaping the growing branch.

A microfluidic ex vivo culture model of neonatal mouse lungs to investigate alveolar development.  
R.A. McKee¹, M.D. Athanasopoulos¹, J.P. Glehorn¹;  
¹Department of Biomedical Engineering, University of Delaware, Newark, DE

Preterm infants are born with an underdeveloped lung that is unable to meet their tissues’ oxygen demand. Standard care of these infants requires enrollment into neonatal intensive care units and the use of mechanical ventilation (MV) which is known to expose the developing lung to altered mechanical forces. Even with recent therapies, MV can result in alveolar injury and long-term pulmonary issues. The most common complication associated with MV is bronchopulmonary dysplasia (BPD). MV induced BPD is characterized by the presence of fewer, enlarged alveoli indicating a failure of the alveoli to undergo septation. A common co-morbidity occurring in one-third of BPD diagnoses is pulmonary hypertension (PH), which has a three-year mortality rate of 75%. Unfortunately, new therapies for BPD and PH are hindered, as current models are unable to study mechanical forces in an intact organ; therefore, the genetic pathways linking altered mechanical forces to cellular behaviors remain largely unknown in the developing lung. We have created a novel, microfluidic, ex vivo organ culture platform that enables long-term culture of neonatal mouse lung explants. In this device, the trachea of the explant is intubated and the organ vasculature cannulated with custom fabricated microneedles. Each compartment is connected to separate pump systems allowing for independent control of cyclic airway ventilation and vascular perfusion during culture. The culture model was validated by quantification of explant ventilation and serial perfusion of dye throughout the vasculature. Histological analysis of lungs cultured in our device over 48 hours show increased alveolar septation compared to bath cultured samples. Additionally, the septation of lungs culture in our ex vivo device more closely resemble that of age-matched, in vivo, sibling controls. Similarly, EdU staining demonstrates uniform cellular proliferation throughout a lung lobe in device cultured explants compared to an absence of proliferation in the central one-half lobe volume in explants cultured using traditional methods. This microfluidic culture platform enables future studies to directly quantify the dynamics of alveolar morphogenesis. Additionally, combining this model with pharmacological interventions and established genetic methods can elucidate the role of mechanotransduction pathways in BPD and PH and allow for the development of adjuvant therapies for infants undergoing mechanical ventilation.

Epithelial deformation during lung development as a driver of localized growth signaling.
R.M. Gilbert1, Z.A. Sexton1, J.P. Gleghorn1;
1Biomedical Engineering, University of Delaware, Newark, DE

During development, the lung is unique in its ability to form a stereotyped branched architecture. It is well accepted that during the pseudoglandular stage of development, when the main conducting airways are being formed, reciprocal signaling between the epithelium and mesenchyme at the distal tips is a major contributor to the normal branching architecture. However, it is not well understood how the signaling events are initiated at specific locations within the developing epithelial tree. Our work and the work of others have documented airway smooth muscle contractions that push luminal fluid to the distal airway tips causing significant cyclic stretch at these sites. Importantly, these distal tips are also regions that have been identified as active sites for several key reciprocal molecular signaling pathways responsible for regulation of airway branching morphogenesis. Whereas it has long been believed that cyclic stretch of the distal epithelium may be responsible for regulation of molecular signaling events in the developing lung, no one has directly demonstrated this is true, nor which signaling molecules can be induced by this stretch. To investigate these questions, we have developed a technique to manually dissociate embryonic mouse lung explants (E12-14) into its three main functional tissue compartments: epithelium, mesenchyme, and mesothelium. Using qPCR, we demonstrate that the tissue compartments were properly separated, and we developed in vitro culture methods to stably maintain isolated cells. To specifically investigate the role of stretch, we adapted a custom microfluidic flex cell that allows dynamically controlled stretch of a thin polydimethylsiloxane (PDMS) membrane between 0 and 15% strain. Isolated embryonic primary cells were seeded onto this PDMS membrane and allowed to form a confluent layer. Cells were stretched statically and dynamically for 12-24 hours and collected for downstream processing by IF and qPCR to determine the change in growth signaling molecules. Our results indicate that the key signaling molecules, HIF1a and VEGF, are increased when epithelial cells are exposed to physiological levels of stretch. These molecules have long been investigated for their role in branching morphogenesis, but have not been directly connected to stretch in the tissue. We can use this device and tissue separation technique to directly stretch isolated tissues in an effort to uncouple the reciprocal signaling pathways between tissue layers found in the embryonic lung and assess the tissue specific molecular signaling changes due to stretch.

Precision abscission for cell surface integrity and plant fitness.
Y. Lee1, T. Yoon2, J. Lee4, M. Lee1, J. Lee1, S. Oh1, H. Chen1, S. Jeon1, H. Cho1, H. Mang1, J. Kwak1-2;
1Center for Plant Aging Research, IBS, Deagu, South Korea, 2Department of New Biology, DGIST, Deagu, South Korea

Organ separation, or abscission, in plants is critical for discarding leaves, flowers, and to conserve resources, and as a form of defense. Little is known about the mechanism guiding the spatiotemporal precision of abscission, nor how protection of the newly formed surface is maintained. Here, we identify two neighboring cell types in Arabidopsis that coordinate their activities to ensure precise organ abscission. One cell type produces a honeycomb structure of lignin, which acts as a mechanical brace to localize cell wall breakdown and spatially restrict abscising cells. The second cell type forms a layer of new epidermis with a protective cutin coat, defects in which lead to an imperfect surface barrier.
susceptible to infection. This transdifferentiation event demonstrates de novo specification of epidermal cell identity, which was thought to be restricted to embryogenesis.

Alterations in indices of internal anatomical structure of Brachypodium distachyon and Kazakhstani varieties of soft wheat under the action of Puccinia recondita pathogen.

N. Omirbekova¹, A. Akhmetova², Z. Zhunusbayeva¹, A. Zhussupova¹, S. Kenzhebayeva¹, A. Sailauova¹,², S. Zhangisina²;

¹Institute of Ecology, al-Farabi Kazakh National University, Almaty, Kazakhstan, ²al-Farabi Kazakh National University, Almaty, Kazakhstan

According to the Food and Agriculture Organization of the United Nations Kazakhstan is one of the world leading producers of high-quality wheat grain. Puccinia (P.) recondita pathogen can lead up to 40-60% in yield loss. The objective of study is the assessment of influence of P. recondita infection on the quantitative indices of internal anatomical structure of leaves, stalks and roots of a wild cereal model plant Brachypodium distachyon (standard line Bd21) and soft wheat varieties. Kazakhstanskaya 19 (K19), Kazakhstanskaya early (KE) with varying resistance to a brown rust (15 and 60%) and Bd21 were used as study materials. For anatomic studies above and underground vegetative parts of soft wheat and Bd21 collected on experimental and twice infected fields were used. Anatomic specimens (over 70) were prepared using a microtome with freezing unit; thickness of anatomic cuts was 10-15 microns (µ). Measurement of morphometric indexes was taken by eyepiece micrometer (ocular 10x22); microphotographs (lens 4x0.10) of anatomic cuts were produced on a trinocular microscope with the digital video camera. Statistically significant decrease by 13% in diameter of conductive bundles of leaf blades, increase by 24% in diameter of xyalary fibers are observed in Bd21 under the pathogen action, while the primary cortex is nearly reduced. Infected wheat plants show similar changes towards increase in the sizes of all tissues of leaf blade and dissimilar for stem (reduction in K19 and prevailation at KE, susceptible to brown rust). Increase in thickness of primary cortex (537.99 µ) and diameter of xyalary fibers (69.86 µ) are observed in internal structure of roots and the flag leaves of K19 causing increase in diameter of the central cylinder (770.41 µ). KE plants, on the contrary, display reduction of the sizes of primary cortex (269.34 µ) and the central cylinder (345.35 µ). Formation of anatomical structure of plants – growth process, sympathetic on the action of external conditions, especially during the early period of plant development, plays an important role in the course of plant adaptation to biotic factors.

Epithelial Cell Reintegration: Stray Cells Find Their Way Home.

N.S. Dawney¹, D. Na², D.T. Bergstralh¹;

¹Department of Biology, University of Rochester, Rochester, NY

Mitotic epithelial cells exhibit changes in cell position as well as cell shape. Although interkinetic nuclear migration is primarily studied in vertebrate pseudostratified neuroepithelium, apical-directed mitotic movement is also observed in cuboidal and columnar tissues. In some conditions, one of the two mitotic products will not inherit a connection to the basement membrane. That cell must therefore rebuild neighbour cell contacts de novo as it reintegrates into the layer. In Drosophila, reintegration is driven by the lateral cell adhesion molecule Neuroglian. L1-Cam, the vertebrate homolog of Neuroglian, is also expressed in vertebrate epithelial tissues in which reintegration behaviours have been observed. We are
currently investigating whether the reintegration mechanism is conserved, and whether it is impacted by the cell cycle.

MafA transcription factor as a marker of differentiated β-cells of islets of Langerhans in rats. M. Kaligin1, A. Plushkina2, M. Titova1, A. Titova1, A. Gumerova1, A. Kiyasov1;
1Morphology and general pathology, Kazan Federal University, Kazan, Russia

One of the markers of progenitor cells (PC) of β-cells is stem cell factor receptor- C-kit (CD117). MafA transcription factor is also indicated as the marker of PC of β-cells. It is assumed that it activates the expression of insulin gene in the PC of β-cells. According to other data, MafA is a marker of differentiated β-cells, because it is required exclusively for regulation of insulin secretion by adult β-cells. The aim of the work was to study the role of MafA during experimental diabetes in rats by analyzing the expression of MafA, C-kit, glucagon and insulin. The study was made on 33 rats, which were injected intraperitoneally with alloxan at dose of 180 mg / kg. Paraffin sections of pancreas stained immunohistochemically with antibodies against MafA, C-kit, glucagon and insulin. Statistical analysis was made with the help of Statistika program. In normal rats pancreas we observed the maximum amount of MafA+ and insulin+ cells in islets. After alloxan injection, the number of both cells populations decreased on early stages (1, 2, 3 days) of experiment. At the late stages (14, 21, 28 days) the number of MafA+ cells continued to decrease, while the amount of insulin + cells began to increase, but did not reach the norm. This increase in the number of insulin+ cells may be associated with the onset of regeneration of insulin-producing cells from progenitor cells after 14 days of diabetes. The continued decrease of MafA+ cells during the increase of insulin+ cells casts doubt on the involvement of MafA in activating the expression of insulin gene in the progenitor β-cell. In this case we would have to observe an increase in the number of MafA+ cells, earlier than the number of insulin + cells increased. There were no C-kit+ cells in normal pancreas. During experimental diabetes their number began to grow within 1 day, the amount of C-kit+ cells decreased at the 2 day, then increased again at7 day. At 14 day they almost disappeared and reappeared at the end of the experiment (21 day). It is interesting that the dynamics of changes in the population of glucagon + cells on the first days (1-5) completely corresponds to that for C-kit+ cells. Then the number of glucagon+ cells decreases (7 days), followed by an increase (14 days) and a gradual decrease in the last 24 hours. Fluctuations in the number of populations of insulin+, glucagon+ and C-kit+ cells we associate with the process of differentiation of C-kit+ cells into insulin-producing cells through the stage of glucagon+ cells. We can make the conclusion that MafA is not a marker of progenitor β-cells, because from 1 day of diabetes dur

Cxcl12a induces Snail1b expression to initiate collective migration and sequential FGF-dependent neuromast formation in the zebrafish Lateral Line primordium. U.M. NEELATHI1, D. Dalle Nogare1, A.B. Chitnis1;
1NICHHD, National Institutes of Health, Bethesda, MD

The zebrafish posterior Lateral Line (pLL) primordium migrates under the skin along the horizontal myoseptum following a path defined by the chemokine Cxcl12a, periodically depositing neuromasts, to pioneer formation of the lateral line system. We show that snail1b, previously known for its role in promoting Epithelial Mesenchymal Transition and cell migration, is expressed in leading cells of the
primordium and in underlying cells of the horizontal myoseptum. Expression in leading cells is promoted by Cxcl12a and inhibited in trailing primordium cells by FGF signaling. Knockdown of snail1b delays initiation of collective migration of the primordium. This delay is associated with aberrant expansion of epidermal cell adhesion molecule (epcam) into the leading zone and a simultaneous loss of cadherin2 expression in leading cells. Co-injection of morpholinos with a relatively low dose of snail1b mRNA prevents the initial delay in migration and restores normal expression of epcam and cadherin2. Cell transplantation experiments show that function of snail1b in the leading cells of the primordium, not underlying horizontal myoseptum cells, is critical for initiating collective migration. The delay in initiating collective migration of the primordium in snail1b morphants is accompanied by a delay in sequential formation of trailing FGF signaling centers and associated proto-neuromasts that normally form within the migrating primordium. Intriguingly, the delay in sequential formation of proto-neuromasts and associated FGF signaling centers is not specifically related to knockdown of snail1b function but also associated with other manipulations that delay migration of the primordium without affecting snail1b expression. These observations reveal an unexpected link between migratory behavior and sequential formation of proto-neuromasts in the primordium

A Strain Map of Zebrafish Gastrulation Describes the Mechanics of Convergence and Extension and Emergence of Left-Right Chirality during Epiboly.

J. Zhong1, 2, D. Bhattacharya2, 3, A.J. Kabla4, S. Tavakoli5, P.T. Matsudaira1, 2, 3;
1Mechanobiology Institute, National University of Singapore, Singapore, Singapore, 2Center for Bioimaging Sciences, National University of Singapore, Singapore, Singapore, 3Singapore-MIT Alliance for Research and Technology, National University of Singapore, Singapore, Singapore, 4Engineering, University of Cambridge, Cambridge, United Kingdom, 5Faculty of Arts and Sciences, Harvard University, Cambridge, MA

During the development of the zebrafish embryo, the major embryonic axis and tissue patterns are organized by different morphogen gradients, such as Nodal (Xu et al. 2014) and BMP (Hardt et al. 2007), and biomechanical coupling through cell-cell and cell-matrix adhesions (Tada and Heisenberg 2012). How collective migration and local mechanical stress are coordinated globally over the entire embryo remains unknown. We have adapted the high spatial-temporal resolution of light sheet microscope system (Keller et al. 2008; Bhattacharya et al. 2012) for in toto imaging and a 2D tissue tectonics algorithm (Blanchard et al. 2009) to generate a 3D strain map of zebrafish gastrulation. The resulting strain maps reveal the time-course and location of areas undergoing deformation in 3 perpendicular directions during well-known morphogenetic movements, including convergence and extension, and somite formation. In addition, we detect rotational or curl strain, a new type of coordinated motion, as early as mid-epiboly. Rotational strain arises concurrently with axial and equatorial strain and contributes unique mechanical signatures of convergence and extension during gastrulation. Curl strain suggests that left-right asymmetry has been established and is mechanically coupled across the entire developing embryo.

Histone methyltransferase G9a is essential for osteoblastic differentiation and skull bone formation during development.
H. Ideno1, K. Komatsu1, A. Shimada1, Y. Arai2, K. Nakashima1, M. Tachibana3, H. Kimura4, A. Nifujii1; 1Department of Pharmacology, Tsurumi University School of Dental Medicine, Yokohama, Japan, 2Graduate School of Dentistry, Nihon University, Chiyoda, Japan, 3Institute for Enzyme Research, The University of Tokushima, Tokushima, Japan, 4Department of Biological Sciences, Tokyo Institute of Technology, Yokohama, Japan

The expression of cell lineage specific genes during cell differentiation and tissue development is subjected to epigenetic as well as genetic regulations. Posttranslational modifications of histone tails are critical epigenetic marks. Among them, methylation at histone 3 lysine 9 (H3K9) is a crucial modification that indeed affects gene expression and cell differentiation. The methylation of H3K9 is catalyzed by several H3K9 methyltransferases, such as G9a. Previously, we showed specific localization of G9a in the epiphyseal cartilages of long bones (Ideno et al. 2013). Therefore, we hypothesized G9a plays a role in bone formation. In this study, we used G9a-floxed mice to elucidate the function of G9a in bone formation, since G9a-null mice showed early embryonic lethality. We employed Sox9-Cre mice which expresses Cre in the cranial neural crest-derived tissues in vivo. At 3weeks after birth, G9a-fl/fl:Sox9-Cre mice showed reduced body size. The micro-CT analysis revealed mineralization defects and significant reduction of size in calvarial bone in G9a-fl/fl:Sox9-Cre mice. The skeletal preparation of G9a-fl/fl:Sox9-Cre mice at embryonic days (E)16.5, E18.5 and postnatal day1 also had the ossification defects of calvarial bones. The decreased expression of Osteocalcin (OC) was observed by in situ hybridization. However, the expression of Runx2, a transcription factor essential for osteoblastic differentiation, was not affected, suggesting G9a is required for Runx2 activities. We also generated G9a-knockout osteoblasts (G9a-KO OB) using Cre-recombinase expressing adenovirus in vitro. Proliferation assay showed the inhibition of proliferation in G9a-KO OB. OC promoter-Luc assays showed that G9a enhanced transcriptional activity of Runx2. G9a-KO inhibited accumulation of Runx2 on endogenous binding sites within the promoters of osteogenic marker genes in chromatin immunoprecipitation assay using a Runx2 antibody. These results suggest that the H3K9 methyltransferase G9a regulates osteoblastic differentiation and skull bone formation.

Effect of Sugar Cane Extract (SCE) Supplementation on Corticosterone Secretion in induced by ACTH injection Male Rats.
M. Zheng1,2, M. Mizu3, T. Furuta3, G. Watanabe1,2, K. Nagaoka1,2; 1Department of Basic Veterinary Science, Gifu University, Tokyo, Japan, 2Department of Veterinary Medicine, Tokyo University of Agriculture and Technology, Tokyo, Japan, 3Product Development Division, Mitsui Sugar Co., Ltd, Tokyo, Japan

Sugarcane extract(SCE) is the residue after removing glucose, fructose and sucrose from molasses. It is known that sugarcane extracts have various beneficial physiological function, such as anti-oxidative and anti-stress effects. Corticosterone is a main glucocorticoid produced in rodent, involved in regulating energy metabolism, immune reaction, and stress responses. This study investigated the effect of SCE on corticosterone production in male rats. Different time period (0, 30, 60, 120, 180minutes) of ACTH agonist injection was used to stimulate the production of corticosterone in the in vivo and in vitro
experiments. Three weeks male Wistar-Imamichi rats were fed with SCE-free diet or 2.16% SCE diet for 7 weeks. Blood samples were drawn for corticosterone, testosterone, LH and FSH measurement; mRNA of adrenal glands were analyzed for steroidogenic enzymes (P450scC, 3β-HSD, P450c21, P450c11) and ACTH receptor MC2-R gene expression. Plasma concentrations of corticosterone were significantly higher after 30 minutes of ACTH agonist injection in SCE group than control group (P<0.05). The basal mRNA level of the steroidogenic enzymes and ACTH receptor MC2-R showed higher expression in SCE group than control group. Results suggested that SCE supplementation increased adrenal response capacity of corticosterone secretion by enhancing the expression level of steroidogenic enzymes in male rats.

Systematically modulating cell-cell adhesion reveals cellular mechanisms of epithelial remodeling in Drosophila.
X. Wang1, K.E. Kasza1;
1Department of Mechanical Engineering, Columbia University, New York, NY

During development, simple epithelia reorganize and remodel into functional tissues with complex form and structure. Adhesion at cell-cell contacts and contractile tension generated by actomyosin contractility are thought to be key parameters that control tissue mechanics and remodeling during epithelial morphogenesis. How the balance between tension and adhesion determines the structure, mechanics, and remodeling of epithelial tissues, however, remains unclear. In the Drosophila embryo, oriented cell rearrangements in the embryonic epithelium rapidly elongate the body axis from head to tail. To gain insight into how the balance between adhesion and contractility influence tissue structure, mechanics, and remodeling, we are systematically modulating levels of E-Cadherin expression using multiple approaches, including transgenic overexpression. We are using live confocal imaging and quantitative image analysis to study the effects of modulating E-Cadherin expression on cell rearrangements, cell shapes, and tissue elongation. In embryos expressing increased levels of E-Cadherin, we find that cell rearrangements within the tissue are decreased compared to in wild-type control embryos. However, macroscopic tissue elongation is not significantly reduced in the embryos with decreased cell rearrangement. This appears to be due in part to differences both in the effectiveness of cell rearrangement and in cell shape changes, which can also contribute to macroscopic tissue elongation, as E-Cadherin expression is increased. These systematic, quantitative experimental studies reveal how cell-cell adhesion influences the cell behaviors that contribute to tissue remodeling during epithelial morphogenesis, and will be essential for building and testing theoretical models of epithelial mechanics.

Microtubule Dynamics in Developing Mammary Epithelium.
A.K. Fraser1, A.J. Ewald1;
1Cell Biology and Biomedical Engineering, Johns Hopkins University School of Medicine, Baltimore, MD

Branching morphogenesis closely coordinates cell proliferation and collective cell migration to expand tubular epithelial structures. In the mammary gland, early branching relies on cell proliferation to establish a stratified Terminal End Bud (TEB). Once this unit forms, coordinated migration of TEB cells acutely drives elongation and branching. Continued large scale expansion of the ductal network requires
complementary migration and proliferation. The involvement of microtubules in both mitosis and migration implies their critical role in directing this developmental process.

To investigate the dynamic contributions of microtubules to branching morphogenesis, we use three-dimensional culture of mammary organoids--epithelial cell clusters embedded within extracellular matrix. This culture system recapitulates the events of branching morphogenesis in a controlled and observable environment. When microtubule targeting drugs are added to murine mammary organoids at culture day 0 when proliferation is acutely required, they blocked branching (Nocodazole IC50 = 40nM, Paclitaxel IC50 = 5nM). However, nocodazole treatment at the branching IC50 does not affect the overall growth of the organoid suggesting that microtubule disruption alters organ morphology without affecting cell proliferation. We continue to investigate these results using several imaging modalities. Immunofluorescence demonstrates the relative alignment of the microtubule cytoskeleton, nuclei, golgi, and microtubule organizing center as well as the distribution of microtubule posttranslational modifications in three-dimensional epithelium. In addition, vital dyes and molecular biosensors in three-dimensional confocal time-lapse microscopy reveal microtubule dynamics in cell mitosis and migration within TEBs. These results offer novel insights into multicellular microtubule organization and dynamics in developing epithelial tissue.

**Emergence of tissue mechanics from cellular processes: shaping a fly wing.**

M. Merkel¹², R. Etournay³⁴, M. Popovic¹, G. Salbreux¹⁵, S. Eaton³, F. Julicher¹; ¹Max Planck Institute for the Physics of Complex Systems, Dresden, Germany, ²Department of Physics, Syracuse University, Syracuse, NY, ³Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, ⁴Institut Pasteur, Paris, France, ⁵Crick Institute, London, United Kingdom

Nowadays, biologists are able to image biological tissues with up to many thousand cells in vivo where the behavior of each individual cell can be followed in detail. However, how precisely large-scale tissue deformation and stresses emerge from cellular behavior remains elusive. Here, we study this question in the developing Drosophila wing. To this end, we first establish a geometrical framework that exactly decomposes tissue deformation into contributions by different kinds of cellular processes. These processes comprise cell shape changes, cell neighbor exchanges, cell divisions, and cell extrusions. As the key idea, we introduce a tiling of the cellular network into triangles. Our approach also reveals that tissue deformation can additionally be created by correlated cellular motion. Based on quantifications using these concepts, we developed a novel continuum mechanical model for the Drosophila wing. In particular, our model includes active anisotropic stresses and a delay in the response of cell rearrangements to material stresses. Taken together, our work helps to elucidate how tissue mechanical properties and thus organ shape emerge from the interplay of large numbers of cells.

Role of dynamics on the formation of zebrafish organ of asymmetry.
G. Erdemci-Tandogan¹, J.D. Amack², L. Manning¹;
¹Department of Physics, Syracuse University, Syracuse, NY, ²Department of Cell and Developmental Biology, State University of New York, Upstate Medical University, Syracuse, NY

In an embryo, epithelial cells actively change their shapes to generate emergent macroscopic patterns. How these programmed cell shape changes are regulated via a combination of mechanical forces and biochemical signaling pathways remains an open question in biology. The left-right organizer in the zebrafish embryo, Kupffer’s vesicle (KV), provides a simple system not only to investigate asymmetric organ formation but also to understand the origin of left-right asymmetries of vertebrates. During KV morphogenesis, monociliated epithelial cells in the KV undergo asymmetric cell shape changes along the anterior-posterior (AP) axis. These cell shape changes position more cilia in the anterior region of the KV, which is crucial for generating left-right asymmetries in the embryo. The developing KV and neighboring tissues, including the extending notochord and migrating mesodermal cells, are highly dynamic. While previous studies of the KV have successfully contributed to our understanding of how epithelial cells are regulated by differential interfacial tensions that are generated via localization and activation of cytoskeletal and ECM molecules, the role that dynamic cell motion plays in asymmetric cell shape changes has not been investigated. In the present work, using a self-propelled Voronoi model which unify tissue mechanics and cell motility, we explore the motion of the KV through the neighboring cells. Our model shows that in the presence of posteriorly-directed KV motion, with no other asymmetries, the KV becomes asymmetric along the AP axis with more ciliated cells packed into the anterior region. Our results suggest that these dynamical processes could help regulate KV cell shape changes and consequently play a role in establishing left-right asymmetries in the embryo.

Coordinated cell area fluctuations drive junction extension in epithelial cell quadruplets.
J. Großhans¹, D. Kong¹, S. Eule¹, F. Wolf²;
¹Institute for Developmental Biochemistry, University of Göttingen, göttingen, Germany, ²Dynamics and Self organisation, Max Planck Institute, Göttingen, Germany

Epithelial cell rearrangement underlies the complex choreography of large-scale morphogenetic tissue movements during development and regeneration. The minimal functional unit consists of a cell quadruplet with two old and two new neighbors. The stereotypic neighbor exchanges are driven by autonomous contractile activities in the old neighbors but presumably also depend on the surrounding cells. We analyzed the role of coordination between the four cells for neighbor exchange. We found that area fluctuations between old and new neighbors are antagonistically coupled especially during neighbor exchanges. xit and E-Cadherin RNAi mutant embryos have lost this coordination and are impaired in cell intercalation. Experimental interference to coordinated behaviour by optically induced cell contraction in new but not old neighbors prevented neighbor exchange. Our analysis reveals the essential function of coordinated cell behavior within the quadruplets and suggest a potential mechanotransduction mechanism by E-cadherin for concerted cell activities driving visible changes in morphology.

Ultra-fast contractions and emergent pattern dynamics: Primitive epithelium in Trichoplax adherence as a “living active solid”.
S. Armon¹, M. Bull², B. Marty³, M. Prakash¹;
¹Bio Engineering, Stanford University, Stanford, CA, ²Applied Physics, Stanford University, Stanford, CA, ³Computer Science, Ecole Polytechnique, Paris, France

Epithelium contractions are often associated with embryogenesis. Conventionally, these cellular contractions are slow and precisely controlled in space and time, patterning the shape and form of a developing embryo. In this work we report the discovery of ultra-fast epithelial contractions (50% cell area in 2 seconds, at least an order of magnitude faster) in a “simple” primitive marine invertebrate, Trichoplax adherence lacking neurons or muscles. Using a theoretical framework, we demonstrate that this speed can be explained by existing biophysical models of acto-myosin contractility, in a regime of low contractile load. We show that load reduction is possible due to the unique epithelial architecture of “T-shaped" cells and their dynamic stiffness variability. Furthermore, live in-toto imaging of the whole animal in vivo reveals emerging patterns including propagating radial and axial waves. Our work establishes a framework of studying primitive epithelium in early animals as “active solids”. We hypothesize that these contractile patterns are part of an ‘active cohesion’ mechanism, providing robustness. We further study the non-linear response of this ‘material’ to external stress using rheometry and simulation.

Identifying the molecular and mechanical requirements for coordinated tissue invagination.
M.A. Fuentes¹, B. He¹;
¹Biological Sciences, Dartmouth College, Hanover, NH

Epithelial folding mediated by apical constriction provides a fundamental mechanism that converts flat epithelial sheets into multilayered tissues. It remains elusive how forces generated near the apical surface mechanically drive tissue folding. We address this question by studying Drosophila ventral furrow (VF) formation, a well characterized model for epithelial folding. During VF formation, the prospective mesoderm cells constrict apically and subsequently invaginate into the interior of the embryo. Previous studies have demonstrated that apical constriction and invagination occur at temporally distinct phases, suggesting that apical constriction by itself cannot fully account for invagination. To elucidate the additional requirements for tissue invagination, we performed an RNAi-based candidate screen to identify genes that specifically regulate the invagination phase of VF formation. To measure the dynamics of tissue invagination, we developed a quantitative live-imaging approach to measure velocities of tissue movement on the surface of the embryo induced by apical constriction and invagination. Using this assay, we identified a unique class of mutants that exhibit relatively normal rate of apical constriction but greatly reduced rate of invagination. Interestingly, in the mutant embryos, the lateral, non-constricting cells flanking the constricting domain become hyper-stretched during apical constriction, as if they lose their rigidity and can no longer resist deformations imposed by the constricting cells. Consistent with this view, we found that the spatial distribution of cortical actin is misregulated in the mutant flanking cells. Further analysis has revealed an anti-correlation between the rate of invagination and the extent of stretching of the flanking cells. Together, our findings demonstrate that apical constriction alone is not sufficient to account for invagination;
instead, this process may depend on the mechanical integrity of the flanking, non-constricting cells. Further studies will be focused on understanding how cell rigidity is regulated and how such regulation may contribute to coordinated tissue invagination.

A collective solid-fluid transition in confluent 3D tissues.
M. Merkel1, L. Manning1;
1Department of Physics, Syracuse University, Syracuse, NY

Understanding how the mechanical properties of tissues emerge from cellular behavior is vital to elucidate mechanisms that guide development, cancer growth, and wound healing. A very basic question is whether a tissue is fluid-like, where cells change neighbors and migrate, or solid-like, where neighbor relationships are maintained. For confluent monolayers, it has recently been shown that a simple model correctly predicts a fluid-solid transition governed by cell shape; though the mechanism for solidification has remained unclear. Also, we’d like to understand whether a similar transition is predicted in fully 3D tissues. Therefore, we develop and study a 3D self-propelled Voronoi (SPV) model that takes into account cell shape, cortical elasticity, cell volume constraints, and motile forces generated by individual cells. In the limit that motile forces are small, we find a fluid-solid transition that is controlled by a cellular parameter describing the preferred cell shape. In particular, we show that solidity can be predicted from a purely geometrical observable, which characterizes the actual cell shape, and can thus be extracted from imaging data. Moreover, we demonstrate that the onset of solidity in this model is a collective cellular effect, and that the mechanism creating solidity is fundamentally different from other disordered materials. When active motile forces are significant they help fluidize the tissue, although the observed cell shapes still robustly predict solidity. Thus, our model suggests that image data can be sufficient to quantify whether a 3D tissue is solid or fluid.

Epithelial cells spatiotemporally coordinate molecular activities and mechanical forces to drive radial intercalation during ductal elongation.
N.M. Neumann1, M.C. Perrone2,3, J.H. Veldhuis2,3, R.J. Huebner1, H. Zhan1, P.N. Devreotes1, G.W. Brodland2,3, A.J. Ewald1;
1Cell Biology and Center for Cell Dynamics, Johns Hopkins University School of Medicine, Baltimore, MD, 2Civil and Environmental Engineering, University of Waterloo, Waterloo, ON, 3Centre for Bioengineering and Biotechnology, University of Waterloo, Waterloo, ON

During pubertal development, the mammary epithelium undergoes extensive elongation and bifurcation to form a ductal network. Elongation is led by a stratified, low-polarity structure known as the terminal end bud, which transitions to a polarized duct at the end of puberty. This process is regulated, in part, by receptor tyrosine kinases (RTKs). We sought to determine how cells coordinate the molecular activities in single cells with mechanical forces during elongation. Using organotypic culture and real-time confocal imaging, we first used fluorescent molecular biosensors to test whether the molecular logic of cell migration is conserved in cells within a tissue by visualizing the downstream signaling events of the RTK pathway. We observed individual cells asymmetrically enriching Ras activity, PIP3, and F-actin in protrusions, consistent with a migratory molecular polarity. In the protrusions, both Ras activity and PIP3 enriched concurrently at the site of F-
actin enrichment. Inhibiting actin dynamics prevented protrusion formation and morphogenesis, but did not prevent PIP3 enrichment.

For a duct to elongate, the basal surface must expand, which solely internal migration cannot accomplish. We therefore sought to examine the dynamics of migration as a cell approached the basal surface. We observed ductal elongation driven by radial intercalation in which migratory internal cells insert into the most superficial cell layer. We observed enrichments of Ras activity, PIP3, and F-actin in protrusions during intercalation. These dynamics are consistent with a transition from migratory front-rear polarity back to a stationary apico-basal polarity.

Next, we used the Cellular Force Inference Toolkit in 3D to analyze force balance equations at each cellular junction within an organoid. We found that migration through a tissue requires specific ratios of protrusion tension and posterior interfacial tension gradients. For intercalation, the duct requires high basal tension and a time-varying, increasing posterior interfacial tension gradient as protrusions are initiated. Finally, using finite element modeling, we generated in silico organoids with cells undergoing migration and radial intercalation to elongate a duct, solely based on mechanical alterations.

We conclude that ductal elongation results from an epithelial motility program that uses directed enrichments of Ras activity, PIP3, and F-actin in protrusions to drive migration and radial intercalation. These molecular dynamics create a spatial gradient of tensions across cells and time-dependent changes within the tissues that together accomplish morphogenesis. We now seek to understand how cancer cells re-access these developmental epithelial motility programs during metastasis.

Exploring the cell mechanics behind the T1 transition.

K. Cavanaugh¹, M.L. Gardel¹²;
¹Cell and Molecular Biology, University of Chicago, Chicago, IL, ²Physics, University of Chicago, Chicago, IL

Embryonic tissues elongate through cell-cell junction rearrangements within stereotypical T1 topological transitions. T1 transitions are characterized by dorsal-ventral junction contraction into a four-cell vertex, from which a new junction is synthesized in the anterior-posterior axis. Junction deformation in response to contractile forces is determined by junctions’ viscoelastic properties. And yet, a detailed understanding of how cells modulate such material properties during T1 transitions is lacking. We hypothesize that the molecular mechanisms mediating actin cytoskeletal reorganization differentially affect force transmission at cell-cell junctions, effectively modulating mechanical behaviors to drive vertex formation. To test this hypothesis, we use the TULIP optogenetic system to recruit RhoA-specific GEF Larg to cell-cell junctions within 2D confluent monolayers for local activation of actomyosin contractility. Live imaging shows rapid light-mediated recruitment of Larg followed by junction contraction. Surprisingly, constant junctional Rho activation was not sufficient for vertex formation. Rather, contraction stalled and reached a steady state length. Junction relaxation following activation was either elastic or contractile, while multiple activation periods showed only contractile behavior. The mechanical behaviors described here point to the regulation of actin dynamics and the coupling of cell-cell and cell-ECM interactions as an exciting mechanism for effective cell shape change. These data will directly test our current models of cell mechanics in a model tissue, allowing us to construct dynamic 3D models of multicellular force transmission that underlie T1 transitions.

A role for desmosomal cadherins in creating complex tissues.
J.A. Broussard¹, O. Nekrasova¹, J.L. Koetsier², K.J. Green¹;
¹Pathology and Dermatology, Northwestern University, Chicago, IL, ²Pathology, Northwestern University, Chicago, IL

The evolution of multicellularity was facilitated by the emergence of cell-cell adhesion molecules in the cadherin family, which couple cell-cell adhesion sites to the actin cytoskeleton to regulate tissue integrity, polarity, and morphogenesis. As metazoans evolved, tissue morphologies with increasingly specialized functions appeared in concert with desmosomal (DSM) cadherins. One of the best examples is the epidermis, in which multiple DSM cadherins give rise to specific types of intercellular connections and cytoskeletal attachments throughout the cell layers. We hypothesized that the functional overlay of these patterned DSM cadherins onto classic cadherins facilitated new mechanisms to increase tissue structural and functional complexity during evolution.

We addressed this question for the DSM cadherin desmoglein 1 (Dsg1), which is first expressed as keratinocytes initiate a program of epidermal differentiation and exit the basal layer, and is later concentrated in the superficial layers. Using a genetically manipulable epidermal reconstitution model, we show that Dsg1 promotes delamination of basal cells, inducing stratification. We identified two Dsg1-associated modules required for Dsg1 function: a dynein motor complex and an Arp2/3/cortactin actin remodeling complex. Using genetic, pharmacologic, FRET, and laser ablation approaches, we show that dynein-dependent positioning of Dsg1/cortactin/Arp2/3 drives actin remodeling to reduce cortical tension and promote delamination of basal cells. Importantly, ectopic expression of Dsg1, normally absent in simple epithelia, is sufficient to induce stratification and formation of a second adherent cell layer in simple epithelial MDCK cells. Based on its role in regulating cortical tension during stratification, we tested whether Dsg1 coupling to the actomyosin system also contributes to suprabasal functions.

Molecular indicators of tension and microablation experiments revealed the existence of a mechanical gradient in stratified control epidermis, with highest tension in the superficial layers. Loss of Dsg1 shifts the mechanical gradient towards the basal layers of the epidermis. Dsg1 silencing altered indicators of the force-sensitive adherens junction component vinculin and tight junction (TJ) component ZO1, the latter which contributes to formation of the superficially restricted TJ barrier. Moreover, our data suggest that Dsg1 regulates TJs through the ErbB family member ErbB2, which in human skin is localized to cell-cell contacts in the TJ-forming layer. Together, our data suggest a model in which Dsg1 regulates the formation and function of the epidermis by controlling the distribution of mechanical inputs to drive morphogenesis and the development of the life-essential epidermal barrier.

Apical myosin activation induces Rab11 puncta accumulation near the apical cortex.
W. Chen¹, B. He¹;
¹Biological Sciences, Dartmouth College, Hanover, NH

During tissue morphogenesis, cell shape changes driven by mechanical forces usually involve changes in cell surface area, which often require active regulation of intracellular membrane traffic. It is not fully understood how membrane traffic is modulated by mechanical stimuli. To address this question, we investigated the behavior of Rabs, the master regulators of membrane traffic, during apical constriction-mediated Drosophila mesoderm invagination. We found that Rab11, previously known to regulate
exocytosis and membrane recycling, undergoes dynamic reorganization during this process. Prior to apical constriction, Rab11 is enriched at the perinuclear region. As the cells apically constrict and elongate apical-basally, Rab11 becomes enriched near the apical membrane as small, dynamic puncta. The puncta formation is not dependent on dynamin-mediated endocytosis, but requires intact microtubules. Genetic or pharmacological inhibition of myosin, the major force generating protein underlying apical constriction, abolishes puncta accumulation. Conversely, enhanced myosin activation results in more puncta. The accumulation of apical Rab11 puncta also occurs in the endodermal cells as they undergo apical constriction during posterior midgut invagination, suggesting that the process is not mesoderm-specific. In wild-type embryos, Rab11 puncta are broadly dispersed near the constricting apical surface, with a substantial fraction of them adjacent to the cell-cell boundaries. However, in mutant embryos where apical myosin is disconnected from the adherens junctions, Rab11 puncta become clustered at the center of the apical domain where myosin coalesces. In contrast to wild-type Rab11, constitutively active Rab11 locked in the GTP-bound form is enriched along the cell-cell boundaries, and this enrichment becomes more prominent as the cells undergo apical constriction. We speculate that wild-type Rab11 is also recruited to the cell-cell boundaries in its GTP-bound form, but only transiently. Indeed, we were able to detect Rab11 along the cell-cell boundaries in fixed embryos.

In summary, our work demonstrates that apical myosin activation triggers accumulation of Rab11 puncta at the vicinity where myosin is enriched. We hypothesize that the accumulation of Rab11 puncta facilitates vesicle delivery to the cell-cell boundaries to support cell membrane expansion, allowing the cells to elongate as they constrict apically.

Differential Regulation of Actin Dynamics during Collective Cell Migration.
H. Olson¹, H. McGraw¹,², A. Nechiporuk¹;
¹Cell, Developmental Cancer Biology, Oregon Health Science Univeristiy, Portland, OR, ²School of Biological Sciences, Division of Cell Biology Biophysics, University of Missouri-Kansas City, Kansas City, MO

Collective cell migration is a specialized form of coordinated cellular migration, where cells maintain cell-cell contacts, group polarization and coordinated behavior. Collective cell migration is important in numerous processes during development, including neural tube closure, blood vessel branching and neural crest cell migration, as well as during adulthood in wound healing. As cells migrate, they must extend protrusions to interact with the extracellular environment, sense chemotactic cues, act as points of attachments, and signaling centers. The regulators of protrusive behavior have been widely studied in populations of cells that migrate individually; however, how protrusive behavior is coordinated throughout collectives is not well understood. Specifically, it has been difficult to define protrusive behavior of cells inside the collective, as cells are tightly packed due to cell-cell contacts. We are using advantages of the zebrafish model system, including amenity to live imaging and genetic approaches, to define protrusive behavior in collectively migrating cells. Towards this goal, we sparsely labeled filamentous actin in a small numbers of cells in the collective. Surprisingly, we discovered an abundance of brush-like, actin-based protrusions in multiple cells across the migrating cluster. Live imaging revealed that these structures were highly dynamic, oriented towards the direction of migration, and prevalent in the leading third of the collective. To identify factors that modulate this protrusive behavior, we have examined expression of genes that are regulated by the canonical Wnt signaling. We and others have previously showed that the canonical Wnt signaling is required for collective cell migration. We have found that an unusually high number of Wnt target genes regulates actin dynamics; these genes are expressed in distinct regions of the collective and their expression pattern is perturbed under Wnt-
deficient conditions. We are currently testing functional significance of these factors using CRISPR-Cas9 loss-of-function approach. We will present analysis of these mutant strains and how they regulate cellular movement and protrusive activity during collective cell migration.

A Rho GAP with a curved membrane-binding domain regulates morphogenesis via CDC-42.
H. Raduwan1, M. Soto2; 1Pathology and Lab. Med., Rutgers - RWJMS, Piscataway, NJ

Rho GTPases are important in regulating cytoskeletal dynamics. Members of this protein family had been implicated in cell migration, polarization, nutrient intake, and epithelial morphogenesis. In C. elegans, loss of different Rho GTPases causes the embryo to die during different stages of development. While the processes regulated by Rho GTPases are subject to intense research, the regulators upstream of these Rho GTPases are still poorly characterized. For example, C. elegans has 23 Rho GAPs but the roles of most of these are still not understood. In this study, we found genetic evidence that the Rho GAP Y34B4A.8, which on its own has a mild embryonic morphogenesis phenotype, regulates Cdc-42 Rho GTPase, but not CED-10/Rac1. Besides the Rho GAP motif, Y34B4A.8 also has a BAR motif, which binds to curved membranes. A vertebrate homolog, SH3BP1, has been implicated in cell migration and adhesion. We used CRISPR to generate a full deletion of Y34B4A.8, and found a similar phenotype as depletion via RNAi. We also used CRISPR to tag Y34B4A.8 and found a complex localization pattern. While most cells of the embryo and adult express low levels of this GAP, it is strongly enriched in a few tissues that may give us a clue as to how it regulates development. For example, some of the strongest signal is at the apical pharynx and intestine, during the beginning stage of gut polarization. Y34B4A.8 appears to localize basal to ERM-1, but apical to DLG-1/AJM-1 complex (DAC) in the lumen, yet we have not detected an effect in apical lumen polarization. Y34B4A.8 has slight enrichment at the front of migrating epidermal cells, similar to CDC-42, ARP-2 and epidermal F-actin. This suggests Y34B4A.8 may regulate processes mediated by cytoskeletal dynamics. Further experiments are underway to identify the processes affected by CDC-42 in Y34B4A.8-dependent manner.

Dynamic imaging of actin cytoskeleton in cardiac progenitors reveal the importance of intercellular tension during organogenesis.
E.S. Koo1,2, S.E. Fraser1,2,3, L.A. Trinh1,3; 1Biomedical Engineering, University of Southern California, Los Angeles, CA, 2Translational Imaging Center, University of Southern California, Los Angeles, CA, 3Molecular and Computational Biology, University of Southern California, Los Angeles, CA

The embryonic heart tube arises from the coherent migration and fusion of bilaterally symmetric populations of cells in the anterior lateral plate mesoderm (LPM). These bilateral progenitors undergo a myriad of structural alterations as they organize into the asymmetric linear heart tube. Traditionally, the specification and migration of cells and tissues during the formation of functional structures has been singularly considered from a biochemical signaling perspective. However, recent studies have established that mechanical forces play significant roles in the processes of tissue morphogenesis and organogenesis. Here, we explore the crucial contributions of biomechanical signals and intercellular forces to the morphogenesis of the LPM during embryonic heart tube formation in zebrafish. Using the
dynamics of the actin cytoskeleton as a readout of intercellular forces, we have acquired cellular resolution, three-dimensional, time-lapses of the actin fluorescent reporter, LifeAct-GFP in the developing LPM. Our 4-dimensional \((x,y,z, t)\) data has revealed a number of dynamic cellular interactions which is suggestive of differential force exertion from the cells as they undergo morphogenesis. These actin dynamics are asymmetrically distributed and are dependent on both biochemical signaling and biomechanical interactions. The asymmetries can be uncoupled genetically and are required for leftward placement of the heart tube. Taken together, these data suggest that multiple cellular traction forces provide key positional cues in the LPM as it undergoes migration and morphogenesis to form a leftward positioned linear heart tube.

**Tissue architecture of the *C. elegans* syncytial germline is maintained by actomyosin contractility of an extra-cellular inner tube.**

P. Agarwal\(^1\), R. Zaidel-Bar\(^1,2\);

\(^1\)Mechanobiology Institute, National University of Singapore, Singapore, Singapore, \(^2\)Cell and Developmental Biology, Sackler Faculty of Medicine, Tel-Aviv University, Tel-Aviv, Israel

Syncytial architecture is an evolutionary-conserved feature of the germline of many species and it plays a crucial role in their fertility. In *Caenorhabditis elegans*, multiple germ cell nuclei line the periphery of the gonad arm and remain connected to a common cytoplasm through stable openings (“bridges”) to a cell-free shaft called rachis. Actomyosin has been shown to be enriched at these bridges, and recent studies implicated actomyosin regulators in the stabilization of germ cell rachis bridges. However, the function of contractility in the maintenance of germline architecture remains poorly understood. Here, we combine genetic manipulations, laser ablations and 3D imaging to investigate the mechanobiology of the *C. elegans* syncytial germline. Importantly, 3D imaging revealed that the actomyosin network is not only enriched at bridges but is also present between bridges, outside the germ cells, forming an extra-cellular actomyosin-rich tube, akin to an inner corset. Laser ablation experiments demonstrated that the rachis tube has high contractility, which is dependent on myosin activity. We identified several key actomyosin regulators that control rachis tube contraction, and go on to show that there is a balance of mechanical forces between rachis tube contractility and germ cell membrane extension. Increasing contractility, by depleting the myosin phosphatase *mel-11*, leads to longer germ cell membranes and a reduced rachis core. Conversely, reducing contractility, by depleting the formin *cyk-1* or non-muscle myosin II (*nmy-2*), leads to shrinkage of germ cell membranes and a vastly increased rachis tube diameter. A mutant lacking the actin cross linker plastin (*pist-1*) displays non-homogenous distribution of myosin II along the rachis tube and clearly demonstrates the correlation between myosin levels and tube diameter. Taken together, our findings identify a novel multi-cellular actomyosin structure within the syncytial germline, map the balance of forces in the germline, and establish the critical role of rachis tube contractility in the preservation of a functional germline structure.

Cell-nonautonomously tunable actomyosin flows orient distinct cell division axes.
K. Sugioka1, B. Bowerman1;
1Institute of Molecular Biology, University of Oregon, Eugene, OR

Extrinsic controls of cell division orientation—whereby one cell instructs another to divide in a spatially organized manner—is a key mechanism for multicellular assembly. Indeed, cell divisions are oriented in diverse angles during stem cell division, organogenesis and embryogenesis, and anomalies in this process are associated with important human diseases including microcephaly, deafness, and cancers. Thus far, dynein-dependent pulling forces acting on astral microtubules are the only known extrinsically tunable force generation mechanism that drives oriented cell division. However, fruit flies or mice without centrosomes and astral microtubules still have relatively normal body plans; thus there might be unidentified additional force generation mechanisms underlying the division axis diversity observed in vivo. By focusing on oriented divisions that are independent of microtubule/dynein pathways, we have found that the non-muscle myosin II motor is an extrinsically tunable force generator that orients cell division axes through cortical actomyosin flows. Using a novel experimental approach to reconstitute multicellular environments with adhesive beads and isolated individual Caenorhabditis elegans cells, we identified three extracellular cues that generate different actomyosin flows. First, a single contact site locally inhibited myosin regulatory light chain (RLC) phosphorylation and myosin activity in a mechanosensitive manner, to generate asymmetric equatorial myosin flow specifically in the region proximal to the contact site. The actomyosin flow generates forces to trigger cell surface movements, thereby orienting AB cell division in parallel to the contact site at 2-cell stage. Second, size asymmetry of two contact sites polarized myosin activity and flow, thereby regulating left-right oriented ABA cell division at 6-cell stage. Third, an evolutionary conserved Wnt signaling also polarized myosin activity and flow, but in a manner overriding mechanosensitive effects, to specify the anterior-posterior oriented EMS cell division at the 7-cell stage. Notably, the contact-induced mechanosensitive myosin pathway also oriented cell division in mouse 2-cell embryos. To summarize, our results indicate that actomyosin flows constitute a new extrinsically tunable force generation mechanism that orients distinct cell division axes in response to different cues. Furthermore, we have documented an evolutionary conserved physical basis underlying the 4-cell stage architecture formation in C. elegans and mouse embryos. Tunable actomyosin flows acting in concert with microtubule/dynein pathways may specify diverse division axes during development to establish multicellular architectures. Cell Type-Specific Response to Spindle Misorientation and Effects on Tissue Growth.
A.S. Parra1, C.A. Johnston1;
1Biology, University of New Mexico, Albuquerque, NM

Coordination of cell polarity and spindle orientation with cell growth and proliferation ensures mitotic fidelity and thus proper animal development. Mitotic errors have been associated with aberrant tissue growth in both epithelial cells and stem cells. Mutations in cell cycle-promoting genes in neural stem cells cause a mild increase in the Drosophila central nervous system (CNS). Conversely, identical
mutations in Drosophila imaginal wing discs (IWD), terminally differentiated cells, lead to massive tissue overgrowth. The mechanisms underlying the differential responses of these cells to errors in cell division, however, are unknown. Here we seek to build a stem cell model and a differentiated cell model to elucidate the varied tissue-specific responses. We found that mutated growth-promoting genes cause substantial overgrowth in epithelial cells, while no significant change in the CNS was observed when expressed in neural stem cells. Additionally, loss of Mud, a gene essential for proper mitotic spindle orientation, results in apoptosis-mediated inhibition of IWD growth in response to mutated growth-promoting genes. Our results further highlight the differential response of epithelial cells and stem cells to mutated growth-promoting genes. Taken together, these results point to an overgrowth-inhibitory mechanism in epithelial cells stemming from errors in spindle orientation caused by these mutations. Further analysis will provide a better understanding of the cell signaling pathways that govern tissue level responses to defective cell division, which will be important to improving our understanding of the underlying molecular bases for numerous human diseases.

Phosphatidylinositol transfer proteins control Apical Golgi Distribution, Polarity and division of Neural Stem Cells During Neurogenesis.
S.K. Hur; Z. Xie; V.A. Bankaitis;
1MolecularCellular medicine Department, College of medicine, Texas AM University, College station, TX

Phosphatidylinositol (PtdIns) transfer proteins (PITPs) stimulate PtdIns-4-P synthesis and signaling in eukaryotic cells, but to what biological outcomes such signaling circuits are coupled remains unclear. Herein, we show that two highly related StART-like PITPs, PITPNA and PITPNB, act in a redundant fashion to support development of the embryonic mammalian neocortex. PITPNA/PITPNB cooperate in maintaining radial polarity of neural stem cells (NSCs) via a PtdIns-4-P and GOLPH3-dependent mechanism that promotes asymmetric distribution of the Golgi system into the apical processes of NSCs. We exploit an in utero electroporation approach to investigate the role of PITP-dependent inositol lipid signaling in the embryonic neural stem cell (NSC) pool. We found that the combination of a PITPNA null mouse line and PITPNB silencing evokes a dramatic depletion of NSC pools in embryonic brain. And, in an experiment using Emx1-Cre driver, which is forebrain specific driver, eviction of both PITPNA and PITPNB in forebrain leads to a mouse that is born but has an amazing microcephaly that is due to virtual loss of the forebrain. Neither PITPNA nor PITPNB eviction alone has any such effect. This experiment result is consistent with in utero electroporation data. Thus, we demonstrate that PITPNA and PITPNB redundantly control NSC homeostasis in mouse brain development. Moreover, while a plasmid which is isogenic to the wild-type PITPNA or PITPNB rescue eviction of both PITPs induced NSC depletion, PITPNA mutant clones which defeat phosphatidylinositol or phosphatidylcholine binding failed to rescue the NSC depletion in utero electroporation experiment. And saccharomyces cerevisiae SEC14 gene which stimulate PtdIns-4-P synthesis failed to rescue NSC depletion. We observed carefully daughter cell fate during NSC division and confirmed PITPs deficiency defeats NSC division program to accelerate differentiating cell divisions. We propose a mechanism where PITPNA/PITPNB drive PtdIns-4-P-dependent recruitment of GOLPH3 to Golgi membranes so as to promote asymmetric MYO18A- and F-actin directed loading of the Golgi network to apical processes of NSCs. And both PITPNA and PITPNB redundantly regulates daughter cell fate during NSC division.

Regulation of cell division by the intrinsic and extrinsic activities of small ovaries is required for germline development.

L. Benner$^{1,2}$, E.A. Castro$^3$, C. Whitworth$^4$, K.R. Cook$^4$, B. Oliver$^5$, D.A. Lerit$^3$;  
$^1$Department of Biology, Johns Hopkins University, Baltimore, MD, $^2$National Institute of Diabetes and Digestive and Kidney Diseases, NIH, Bethesda, MD, $^3$Department of Cell Biology, Emory University, Atlanta, GA, $^4$Department of Biology, Indiana University, Bloomington, IN

A balance between stem cell self-renewal versus differentiation is required for tissue homeostasis, the disruption of which is associated with tumorigenic or degenerate phenotypes. Both cell autonomous and extrinsic signals cooperate to maintain stem cell homeostasis. The *Drosophila* ovary is a valuable model to study stem cell division and differentiation. The ovary comprises multiple ovarioles, assembly lines of progressively maturing egg chambers, with a germarium residing at the anterior of each ovariole. Within the germarium, somatically derived niche cells physically contact and support the 2-3 germline stem cells required for oogenesis. Using clonal knockdown approaches, we show small ovaries (sov), a predicted Zn-finger protein, is differentially required both within the soma and germline to permit germline development. Sov is an essential niche factor required to support germline differentiation. Loss of sov within the niche results in ovarian tumors, tissue degeneration, and failure to produce functional oocytes. In contrast, germline depletion of sov permits oogenesis, yet results in inviable embryos. Our data suggest ovarian tumorigenesis and embryonic lethality are products of centrosome dysfunction, as well as disrupted spindle orientation and morphology. Further, gene expression profiling shows Sov functions to repress mobile genetic elements, or transposons. Excessive transposable element activity disrupts germline genome stability resulting in cell death. Mutant and expression analyses are consistent with a role for Sov in the piRNA/PIWI small RNA defense pathway. Through examination of sov, we aim to clarify the longstanding relationship between the piRNA pathway, cell division control, and centrosomes to determine how small RNAs contribute to the regulation of stem cell proliferation and differentiation.

Activity of the Arp2/3 complex is necessary for embryonic stem cell differentiation.

F.M. Aloisi$^1$, D.L. Barber$^1$;  
$^1$Department of Cell Tissue Biology, University of California San Francisco, San Francisco, CA

Despite abundant knowledge of the developmental cues and transcription factors controlling stem cell differentiation, how actin cytoskeleton dynamics drive the substantial morphological changes that occur with early differentiation remains poorly understood. New actin cytoskeleton filaments are predominantly generated by two distinct molecular machines, the Arp2/3 complex and formins, but neither has been reported as a regulator of stem cell differentiation. We found that substantial changes in actin filament architectures occur with differentiation of naïve mouse embryonic stem cells (mESCs) to primed epiblast cells (epiSCs), which require activity of the Arp2/3 complex but not of formins. Real-time imaging over 72 h of the differentiation process showed that naïve mESCs have a static circular colony morphology, large nuclear-to-cytoplasmic volume ratio, compact polygonal cell shape with a contiguous cortical ring of actin filaments and lack of plasma membrane protrusions. We found substantial changes in these properties with differentiation to epiSCs, which have a dynamic colony morphology, decreased nuclear-to-cytoplasmic volume ratio, elongated cell shapes and a dense ribbed

Monday-490
actin filament network in abundant highly dynamic plasma membrane protrusions. All of these changes are blocked by the Arp2/3 complex inhibitor CK666 but not the formin inhibitor SMIFH2. Additionally, CK666 but not SMIFH2 attenuates the transition from naïve to primed epiSCs as indicated by decreased expression of epiSC microRNAs, differentiation markers Fgf5 and Brachyury, and nuclear translocation of MRTF. We used a dual reporter mESC cell line expressing developmentally regulated miRNA clusters tagged with distinct fluorophores for fluorescence-activated cell sorting of differentiation stages. Neither CK666 or SMIFH2 affects the percentage of self-renewing mESCs. However, after 72h of differentiation in the presence of CK666 but not with SMIFH2 there is a significantly higher percentage of naïve cells compared with controls. We used qRT-PCR to show that CK666 attenuates changes in the expression of differentiation markers after 72h in differentiation medium but not naïve pluripotency markers. To our knowledge, these data are the first to show that Arp2/3 complex activity is necessary for the differentiation of naïve stem cells. Our findings open new directions for determining how the Arp2/3 complex and actin filament remodeling contribute to stem cell differentiation, with insights relevant to embryonic development, induced pluripotency and regenerative medicine.

The Expression of Sarcomeric Proteins During Myogenesis in C2C12 Myogenic Stem Cells.
G.R. Walker¹, J.E. Budde¹, R. Nyaboke², V. Silivis¹, N.T. Osborne¹, A.M. Mosser¹;
¹Biological Sciences, Youngstown State University, Youngstown, OH, ²Department of Curriculum and Instruction, University of Toledo, Toledo, OH

Myogenesis is a tightly regulated process resulting in the sequential change in gene expression leading to the expression of muscle cell specific proteins. During the process of myogenesis the basic units of contraction, sarcomeres, are assembled into to the extremely precise structures that provides for the slide filament mechanism of muscle contraction. This study examined the timing of expression of a number of muscle specific proteins that are relevant to myogenesis/sarcomerogenesis over the course of myotube development, using C2C12 mouse myogenic stems cell in culture. Using quantitative PCR, titin expression and specifically expression of the cardiac specific isoform, N2-B, was studied. The expression of several myosin isoforms were also examined. In addition to these sarcomeric components we also looked at the expression of myogenic transcription factors and the cell cycle regulator of the G2/M phase transition (cdk1). At the onset of myogenesis (confluency and lowered growth factors) the expression of cdk1 as well as a transitory increase in the myogenic transcription factor MyoD. In this study we have taken two approach to assessing gene expression in myogenesis and sarcomere genesis, normalize to the expression of GAPDH (expression relative to the cell) or actin (expression relative to the sarcomere assembly). Gene expression after re-exposure of myotubes to high serum was examined.

Glutamine sustains Cripto expression and function, enabling MyosinII/RAB11A-dependent endosomal/exosomal trafficking in stem cells to promote tissue regeneration.
E. Duell¹, M. Hoover¹, E. Booker¹, B. Williams¹, C. Arellano-Garcia¹, W. Fischer², P. Gray², J.A. Kelber¹;
¹Biology, California State University Northridge, Northridge, CA, ²Salk Institute for Biological Studies, La Jolla, CA

Stem cells are necessary for proper development, tissue homeostasis and regeneration while dysregulation of their activity leads to diseases such as diabetes and cancer. We hypothesized that the
stem cell marker, Cripto (or TDGF1), is a regulator of tissue regeneration. Using the zebrafish model of caudal fin wound healing, we show that expression of the zebrafish Cripto homolog, one-eyed pinhead (or oep), is increased in blastemal stem cell tissue at 96 hours post amputation. We further demonstrate that Cripto is necessary and sufficient for stem cell-mediated regeneration in this in vivo model. We identified non-muscle Myosin IIIs (MYH9/10) as novel Cripto-binding proteins using proteomics and confirmed these interactions by co-IP/Western blot and immunofluorescence (IF) in mesenchymal stem cells. Notably, dual pharmacological inhibition of Cripto and Myosin IIIs did not reduce caudal fin regeneration beyond that of either inhibitor alone, suggesting that these proteins function in the same pathway during this process. Consistent with these findings, we further report that Myosin II inhibition reduces cell surface localization and production of soluble (GPI anchor-cleaved) Cripto. Our group and others have previously demonstrated that soluble Cripto promotes tissue-specific stem cell functions via cell-surface binding to GRP78 (glucose-regulated protein 78). Since GRP78 primarily functions as an ER chaperone that responds to cellular stresses, we tested whether nutrient deprivation affects Cripto expression, sub-cellular localization or binding to Myosin IIIs in mesenchymal stem cells. Interestingly, we found that glutamine is necessary, but not sufficient, to sustain normal Cripto expression and its Myosin II-associated functions. Using the BioGrid database, we discovered Rab11A as a co-binder of GRP78 and Myosin IIIs. Given the endosomal/exosomal trafficking functions of Rab11A, we hypothesized that Cripto may in turn help traffic GRP78 or other cell surface proteins in a Myosin II-dependent manner. Inhibition of Myosin IIIs in mesenchymal stem cells transfected with wild-type, constitutively active or dominant negative GFP-tagged Rab11A revealed that Myosin IIIs act upstream of and in concert with Rab11A to regulate Cripto localization to Myosin II-rich membrane protrusions. Based upon these data, we propose a new model of glutamine-dependent Cripto function whereby Myosin II/Rab11A activities promote membrane localization of Cripto to facilitate a unique endosomal/exosomal transport processes and autocrine/paracrine signaling during stem cell-mediated tissue regeneration.

Quantification of Nuclear Morphology Changes During Induced Pluripotent Stem Cell Differentiation.
C. Wesley¹, D.L. Levy¹;
¹Molecular Biology, University of Wyoming, Laramie, WY

Understanding stem cell differentiation offers insight into organismal development with potential medical applications. Although cellular differentiation is known to involve a variety of activities, such as interactions with growth factors and the use of various transcription factors, questions remain about the underlying mechanisms. While nuclear size and shape have been noted to change during differentiation, it is unknown if and how these nuclear morphology changes contribute to the process. As a starting point, we used fluorescence microscopy and two- and three-dimensional quantification techniques to measure nuclear morphology and the nuclear-to-cytoplasmic ratio in human iPSC cells and stem cells differentiated into the three germ layers. Using these methods, we find that iPSC cells and the cells of these germ layers show statistically significant differences in their nuclear morphology in terms of overall area, shape factor, perimeter, and length to breadth ratio. More specifically, we observed that, compared to iPSC cells, ectoderm nuclei tend to be larger as evidenced by a 17.9% increased nuclear area and a 9.5% increase in nuclear perimeter whereas mesoderm nuclei tend to be smaller and more irregularly shaped as is shown by their 13.0% smaller nuclear area and 15.8% decrease in shape factor. We also observed that endoderm cells exhibit a longer, thinner morphology compared to iPSC cells, having a 22.5% larger nuclear length to breadth ratio and 12.3% smaller shape factor.

Monday-492
Having carefully quantified changes in nuclear size and shape during cellular differentiation, our future work will focus on understanding what controls these nuclear morphology changes and whether these changes contribute to differentiation. Toward the latter goal, we will use previously identified nuclear scaling factors to determine if manipulating nuclear size affects the ability of iPS cells to differentiate into cells of the three germ layers. Factors of particular interest are the nuclear lamins that are subject to a variety of post-translational modifications. Our group previously demonstrated that PKC-mediated phosphorylation of human lamin A at S268 influences nuclear size. We are currently using genome editing in human iPS cells to EGFP tag lamin A and introduce phosphorylation site mutations at S268. With these tools, we will quantify nuclear size and lamina dynamics, assess how PKC activity impacts these parameters, and investigate the differentiation potential of mutant cells with altered nuclear size.

Nuclear transport protein, Transportin Serine-Arginine rich, is required for germline stem cell proliferation and self-renewal in Drosophila.

T.D. Hinnant¹, E.T. Ables¹;
¹Biology, East Carolina University, Greenville, NC

Steroid hormones are critical for stem cell self-renewal and progenitor cell proliferation in diverse tissue systems. The mechanism by which they regulate tissue-specific stem cells, however, remains unclear. The Drosophila ovary harbors a population of tissue-specific stem cells known as germline stem cells (GSCs), which are a well-studied model for tissue-resident stem cell function. GSCs self-renew to maintain an undifferentiated cell population and give rise to differentiated germ cells. These actions are, in part, regulated by the steroid hormone ecdysone. Ecdysone binds to its receptor, ecdysone receptor (EcR), which transcriptionally regulates expression of many target genes. EcR is necessary for GSC self-renewal and proliferation, but the exact mechanism by which it regulates these processes is largely unknown. Multiple studies have identified a nuclear transport protein encoded by Transportin Serine-Arginine Rich (Trn-SR), as responsive to ecdysone signaling. Trn-SR is a highly conserved transporter that has been implicated in the targeting of proteins containing nuclear localization signals for transport into the nucleus. In vitro studies have identified some Trn-SR interacting proteins, but its cell biological role is not well understood. In this study, we show that like EcR, Trn-SR is necessary for GSC self-renewal. Trn-SR mutant GSCs also exhibit decreased proliferation rates and increased cell size as compared to wildtype GSCs. Further, Trn-SR mutant GSCs phenocopy loss of CycE and CDK2, which are also necessary for GSC self-renewal and proliferation. Indeed preliminary data indicate a strong genetic interaction between Trn-SR and CycE, suggesting a model wherein Trn-SR modulates key cell cycle controls to promote GSC self-renewal. Future studies will also address whether Trn-SR’s function is restricted to stem cells, or if its biological functions are imperative for differentiated cell populations as well. Together, these data will provide insight into the intrinsic cues that regulate cell function, as well as the actions remote cues take to control stem cell self-renewal and proliferation.

Placenta derived mesenchymal stem cells increases invasion ability of trophoblast via alteration of mitochondrial function.
J. Seok¹, J. Choi², J.J. Kim⁴, S. Lim³, H. Jeong¹, S. Park³, G. Kim¹;
¹Biomedical Science, CHA University, Seongnam, South Korea, ²Dermatology, Northwestern University, Chicago, IL, ³Pathology, University of Ulsan College of Medicine, Seoul, South Korea

Trophoblast plays an important role in early embryo fertilization and placental development. Especially, trophoblast functions such as invasion, proliferation and differentiation was important factor to successful implantation in the early development. Mitochondria are highly dynamic organelles which continually fuse and divide in response to diverse stimuli. Alterative mitochondrial function has been reported to be a key for the multi-functions of trophoblast. We previously reported that placenta derived mesenchymal stem cells (PD-MSCs) have several potentials for differentiation, immunomodulation, and affects the invasion ability of trophoblast. However, invasion mechanisms of trophoblast via mitochondrial functions are still unclear. Therefore, the objectives of this study are to analyze the functions of trophoblast with co-cultured PD-MSCs on proliferation, death and invasion ability, mitochondrial mechanism and compare their correlation between trophoblast functions and mitochondrial changes according to PD-MSCs co-cultivation. Finally, we investigated their ability of trophoblast by mitochondrial dynamics. Several markers related to proliferation, death and mitochondrial function include ATP production, ROS levels, membrane potential, mass and metabolism in static condition of trophoblast with PD-MSCs co-cultivation were analyzed by quantitative RT-PCR (qRT-PCR), western blot, immunofluorescence and Elisa. Mitochondrial DNA (mt DNA) was analyzed by qRT-PCR. In addition, invasion ability of trophoblast with PD-MSCs co-cultivation was analyzed by invasion assay. PTEN-induced putative kinase 1 (PINK1) and PARKIN, which are markers for mitochondrial autophagy (mitophagy), were analyzed in trophoblast by qRT-PCR and IF. Although, there are no difference for the survival and death of trophoblast, but PD-MSCs induce to change static condition of trophoblast. The mt DNA copy number was significantly increased in trophoblast with PD-MSCs co-cultivation (p<0.05). Also, PD-MSCs co-cultivation was significantly increased the invasion ability of trophoblast by increasing MMP-2/-9 activities and upregulated Rho family gene expression (p<0.05). Interestingly, mitophagy of trophoblast was increased in invaded trophoblast with PD-MSCs co-cultivation. Taken together, PD-MSCs can regulate trophoblast invasion by dynamic mitochondrial functions via autophagic mechanism. Theses results support the fundamental mechanisms of mitochondria function contribute to trophoblast invasion and suggest new therapeutic strategy in infertility.

BCP1 is a positive regulator of Notch signaling pathway in the regulation of mammalian neural stem cells.
J. Kim³, D. Han¹, S. Byun¹, M. Kwon¹, K. Yoon¹;
¹Genetic Engineering, Sungkyunkwan University, Suwon, South Korea

In the developing central nervous system, it has been widely known that Notch signaling preserves progenitor pools, inhibits neurogenesis, and drives astrocyte differentiation. BCP1 is known as an ion transporter protein containing membrane spanning regions. In this study, we assessed the role of BCP1 in the mammalian brain development. We first found that Notch intracellular domain increased
transcription of BCP1. Interestingly, BCP1 also synergistically increased transactivational ability of Notch. We used a retroviral vector system to investigate the effects of BCP1 expression on the properties of neural stem cells in vivo as well as in vitro. BCP1 induced efficient neurosphere formation, a high level of neural stem cell proliferation, and localization of neural progenitor population in the VZ and SVZ of developing mouse brain. Taken together, our data indicate that BCP1 is a novel Notch target gene and also a regulator in the canonical Notch signaling pathway.

A Hoxc dependent skin zip code controls regional adult stem cell regeneration.

Z. Yu$^{1,2}$, Z. Xu$^1$, H. Huang$^1$, D. Chen$^1$, K. Jiang$^1$, Z. Du$^2$, W. Xie$^2$, T. Kunieda$^3$, F. Wang$^1$, T. Chen$^1$;

$^1$National Institute of Biological Sciences, Beijing, Beijing, China, $^2$Tsinghua University, Beijing, China, $^3$Okayama University, Okayama, Japan

Stem cell regeneration ability is different in distinct body regions. Here, using an unbiased multi-step screening approach, we identified a single gene cluster, Hoxc, with expression associated with the regional activation of hair follicle stem cells (HFSC). Hoxc genes are only highly expressed in regions where HFSCs exhibit long-term regenerative ability. Lentivirus mediated in vivo over-expression in epithelial cells excludes the intrinsic ability of Hoxc gene in promoting HFSC activation. A chromosome 15 inversion results in ectopic expression of multiple Hoxc genes in dermis and results in regional activation of otherwise dormant HFSCs. Using CRISPER/Cas9 mediated gene knockouts and lentivirus mediated gene over expression in functional studies, we conclude niche expressed Hoxc genes function redundantly to determine the regenerative capacity of HFSCs. The region-specific expression pattern of Hoxc genes is controlled by antagonistic switch between PcG-dependent repression and enhancer activation epigenetic modifications. Circularized Chromosome Conformation Capture (4C) results reveal the chromosome 15 inversion leads to ectopic interaction of Hoxc cluster with an active regulatory chromatin domain and increased Hoxc genes expression. Dermis expressed Hoxc genes switch on the epithelial HFSCs regeneration through activating Wnt signaling. Together, these data delineate an altered epigenetic landscape in dermis from different skin regions that controls the differential expression pattern of Hoxc genes, which encode the positional identity of adult HFSCs and regulate their regenerative ability.

Tousled-like Kinase 1-Regulated Differentiation in Murine Embryonic Stem Cells.

J. Lee$^{1,2}$, M. Kim$^{1,2}$, S. Park$^{1,2,3}$, Y. Jang$^{1,2}$;

$^1$Department of Systems Biology, Yonsei university, Seoul, Korea, South, $^2$Initiative for Biological Function and Systems, Yonsei university, Seoul, Korea, South, $^3$Center for Genomic Integrity, Institute for Basic Science, Ulsan National Institute of Science and Technology, Ulsan, Korea, South

Embryonic stem cells (ESCs), derived from inner cell mass of blastocyst, are defined by their abilities of pluripotency and self-renewal. Core transcription factors, Oct4, Nanog and Sox2, play a crucial role in maintaining stemness in ESCs and these factors should be properly inhibited as cells differentiate. A serine/threonine kinase Tlk1 is evolutionarily conserved and plays an essential role in cell cycle progression, DNA damage response and chromatin assembly. In C.elegans and Drosophila, TLK is required for development but the role of Tlk1 during early lineage commitment in murine ESCs (mESCs) remains undefined. In this study, we knocked down Tlk1 using a specific short hairpin RNA and overexpressed Tlk1 using Tet-On inducible expression system in E14 mESCs to determine its function.
Tk1 downregulation resulted in delayed repression of core pluripotency factors and formed irregular shape of embryoid body during differentiation. Conversely, elevated expression of Tk1 causes downregulation of core pluripotency factors and correlated with decreased self-renewal activity with low AP activity and flattened morphology even in the presence of LIF. Moreover, Tk1 overexpression impairs cell growth with accumulation of G2/M phase population. Thus, our gain and loss-of-function studies in E14 mESCs revealed a novel function of Tk1 in modulating ESC stemness.

Drug induced arrhythmia is one of the most common causes of drug development failure. Human induced pluripotent stem cell-derived cardiomyocytes (iPSCMs) show great promise for cardiovascular research and predictive in-vitro cardiac safety screening. In the light of the new Comprehensive in Vitro Proarrhythmia Assay (CiPA), a FDA directed initiative to improve guidelines and standardize assays and protocols, the use of hiPSC-CMs may become critical in determining the proarrhythmic risk of potential drug candidates. Human stem cell-derived cardiomyocytes (hiPSC-CMs) have recently proven to recapitulate key features of human cardiac electrophysiology in vitro. Patch clamp assays, the gold standard of ion channel research, are distinguished by high complexity. Conventional patch clamp is technically demanding and is unsuitable for high-throughput screening (HTS) experiments. Chip-based approaches allow parallel patch clamp recordings without compromising data quality or technical sophistication. We present high-throughput voltage and current clamp recordings of CiPA reference compounds. Since drug efficacies may vary with temperature, we present recordings at room and at physiological temperatures. In addition to patch-clamping experiments, we present hybrid impedance (cell contractility) with MEA-like extracellular field potential (EFP) recordings. Pharmacological effects of a number of CiPA reference compounds including those designated high risk (e.g. Dofetilide), intermediate risk (e.g. Cisapride) or low risk (e.g. Verapamil) were evaluated and will be presented. Experiments were complemented with optical stimulation of monolayers of hiPSC-CMs expressing the light-gated cation channel Channelrhodopsin2. This approach allows frequency-dependent drug screening and detection of potential side effects on Na+, Ca2+ and repolarizing K+ channels. Furthermore, investigations of potential breaks in excitation-contraction coupling can accompany the ion channel screening with the final aim to enable a reliable automatized cardiac toxicity screening platform.

Toxic effect of titanium dioxide nanoparticles (TiO2) on Wharton Jelly mesenchymal stem cells.
A.B. Peralta-Vega1, J.R. Cáceres-Cortés1, A. Parra-Barrera1, M. Ramos-Godínez1, R. López-Marure1, G. Gutiérrez-Iglesias1;
1Posgrado, Instituto Politecnico Nacional. Escuela Superior de Medicina, Mexico, Mexico, 2Microscopia, Instituto Nacional de Cancerología, Mexico, Mexico, 3Fisiología, Instituto Nacional de Cardiología INCICH., México, Mexico

Titanium dioxide is one of the most used mineral pigments in the world in the last decades, its applications stand out in the field of paints, cosmetics, sun blockers, plastics, paper, food, etc. It has been reported that TiO2 at different nanometric scales is considered toxic, depending on the concentration and type of cell being exposed. TiO2 nanoparticles (TiO2-NPs) have the ability to cross biological barriers. In vivo models, it cross the blood-brain barrier and also it could to cross the fetoplacental barrier. On the other hand, human mesenchymal stem cells (hMSCs) are referred to as highly relevant cells because they have an immunomodulatory profile, preventing their rejection as well as the ability to regenerate various tissues. In most organs and tissues, hMSCs are forming niches where they can remain quiescent, self-renewing, or differentiated to the needs of the tissue that houses them. The effect of TiO2 in the capability for differentiation of hMSC remain unknown. In this work it was investigated if the TiO2-NPs exert toxic effects on Wharton’s jelly hMSC. We evaluated the morphology by cell staining and electronic microscopy, cell viability was measure by alamar blue and possible changes in cell differentiation was evaluated by specific staining oil red or alizarine-S red (adipogenic or osteogenic differentiation respectively). The results showed that cell viability of hMSC significantly decreased with the TiO2 treatment in a concentration and time dependent way. When treated cells were observed by microscopy, it was observed that hMSC had morphological changes, and more specific, that distribution of the TiO2-NPs inside the cell had a characteristic pattern of perinuclear TiO2-NPs accumulated, forming a characteristic halo. Finally, treatment of hMSC with TiO2-NPs interfered the osteogenic and adipogenic differentiation when hMSC were induced with the specific culture media. This results showed that TiO2-NPs has a significant impact on the viability and capability in cell differentiation of the hMSC. The use of nanotechnology in different products that contains TiO2 have to be regulated so that is does not affect the public health.

Is a microtubule-dependent mechano-transduction involved in early human Hematopoietic Stem Cells differentiation?
S. Biedzinski1,2, B. Vianay1,2, J. Larghero3, S. Brunet1,2,3, M. Théry1,2;
1IUH Hoptial St Louis, INSERM U 1160, PARIS, France, 2LPCV CEA CNRS INRA, CytomorphoLab, GRENOBLE, France, 3IUH Hopital St Louis; U Paris Diderot, Cell Therapy Unit, PARIS, France

Hematopoietic Stem Cells (HSCs), through their ability to differentiate into hematopoietic lineage cells and self-renew, are essential to maintain hematopoiesis throughout life and have major potentials for treatment of haematological diseases. Yet, how HSCs integrate cues from their environment to control self-renewal and differentiation is still poorly understood. It has been recently shown that actin cytoskeleton of adherent stem cells is central to this process. Actin can transmit external forces and modulate nucleus architecture, chromatin organization and gene expression controlling cell fate. HSCs are poorly adherent cells and it is not known whether similar or alternative mechano-transduction
mechanisms play a role in their differentiation.
To investigate this question, we have quantitatively analysed cell architecture during the early
differentiation of human HSCs into committed progenitors. We show that HSCs differentiation is marked
by nucleus reshaping. Initially ovoid, the nucleus exhibits large invaginations in progenitors. This
reshaping associates with chromatin reorganization, as shown by the spatial redistribution of
heterochromatin marker H3K9mE3. It also correlates with changes in gene expression program. In
parallel, HSC differentiation associates with a dramatic microtubule network reorganization, while actin
cytoskeleton remains unchanged. Microtubules, initially radiating in the cytoplasm, form bundles that
tightly clamp and deform the nucleus of committed progenitors. Using living imaging approaches, we
could show that the shape of HSC nucleus is fluctuating and that these fluctuations are microtubule-
dependent. Finally, pharmacologically perturbing microtubule dynamics during long tem in vitro HSC
differentiation significantly reduced nucleus deformations that normally take place during this process.
Taken together, our observations indicate that microtubules exert mechanical constraints on the
nucleus of HSCs and can deform it, and suggest that HSC early differentiation involves an original
microtubule-dependent mechano-transduction mechanism.

Molecular and cellular phenotyping of mouse embryonic stem cells from diverse inbred
laboratory mouse strains reveals strain-specific differences in cellular traits.
A. Czechanski¹, N. Raghupathy¹, C. Olivier¹, C. Byers¹, L.G. Reinholdt¹;
¹The Jackson Laboratory, Bar Harbor, ME

The naturally occurring genetic variation that distinguishes the genomes of inbred laboratory mouse
strains provides a powerful platform to elucidate the role of genetic variation in mammalian
development and disease. To determine if systems genetics approaches can be applied to cellular traits
that can be assayed in vitro, we created embryonic stem cell (mESCs) lines from a diverse panel of
inbred laboratory mouse strains, including the founders of the Collaborative Cross and Diversity Outbred
mapping populations. These include a strain background in which the naïve, ground pluripotent mESC
state is known to be unstable (NOD/ShiLtJ). Here we report our initial efforts to characterize the
phenome and transcriptome of these cell lines under pluripotent culture conditions (LIF, 2i) and for a
subset of lines, after removal of LIF and 2i. We found strain-specific differences in basic cellular and
molecular traits including gene expression, morphology, growth rate, self-renewal capacity, homology
directed repair of CRISPR-cas9 induced double strand breaks, and potentially early differentiation. These
data demonstrate that strain-specific molecular and cellular phenotypes are distinguishable in mESCs
from different inbred mouse strains and provide an initial set of resources for exploring in vitro systems
genetics approaches to cell biology, pluripotency and early lineage commitment. These data also
provide technical insight into the optimization of genome engineering across a variety of inbred strain
backgrounds.

Silencing Spermine Synthase in Mesenchymal Stem Cells mimics Snyder-Robinson Syndrome by showing impaired osteogenesis.
A.L. Ramsay1, A.M. McEnerney1, F.A. Fierro1; 1Institute for Regenerative Cures, University of California Davis, Sacramento, CA

Snyder-Robinson Syndrome (SRS) is a rare disease where patients harbor mutations in the spermine synthase (SMS) gene, resulting in multiple defects, including inadequate bone development. This defect has been suggested to be due to impaired osteogenic differentiation of bone marrow-derived mesenchymal stem cells (MSCs). In order to elucidate how defective SMS leads to impaired osteogenesis, we generated a lentivirus to deliver shRNA to silence SMS expression. Effective silencing of SMS expression was confirmed by RT-PCR. Interestingly, we found that silencing SMS strongly inhibits cell proliferation. To determine how silencing SMS affects osteogenesis, MSCs were cultured in osteogenic media and assessed for commitment, maturation and mineralization. Commitment is marked by an increase of Runx2 at day 1 of differentiation. However, silencing SMS had no significant effect on Runx2 expression. In contrast, while studying maturation at day 14, we observed a significant inhibition of bone sialoprotein (BSP) expression in MSCs transduced with the shRNA against SMS, as compared to controls. BSP is a major component of the bone extracellular matrix. Consequently, mineralization in MSCs with shRNA targeting SMS, showed lower calcium precipitation, as assessed at day 28 using Alazarin Red S staining. To elucidate the underlying mechanisms, mass spectrometry of primary metabolites was performed in MSC transduced with either control or SMS shRNA. RNAseq studies to determine altered gene expression are currently in progress. In anticipation to improve bone formation in SRS patients, our study aims to more clearly understand the role of SMS, especially in the context of inefficient osteogenic differentiation of MSCs.

Isolation and Expansion of Human Skeletal Stem Cells.
A.M. McEnerney1, C. Schumacher1, F.A. Fierro1; 1Institute for Regenerative Cures, University of California Davis, Sacramento, CA

Bone remodeling and repair requires the activity of osteoblasts, which orchestrate bone formation. During remodeling or after fracture, osteoblasts need to be replenished, because osteoblasts mature into post-mitotic osteocytes, which are embedded in bone salts. The existence of a resident stem cell in the bone marrow responsible for bone homeostasis and repair has been largely acknowledged, but to date these cells have not been isolated from human bone marrow, due to the lack of surface markers to isolate them. Based on recent work in mice, we have now found that the combination of markers CD45-CD51+ CD146+ CD200+ strongly enriches for cells capable of initiating colony forming units-fibroblast (CFU-F), a hallmark property of SSC. Here we show the results from isolating SSC from 7 different donors (varying from 24 to 52 years old). We determined the frequency of SSC, their ability to form CFU-F, and compared them to the frequency of total CFU-F, obtained by plating unsorted bone marrow mononuclear cells. Since SSC are present in very limited numbers in bone marrow, we also plated SSC and expanded them as CFU-F. In culture, SSC acquire all properties of regular Mesenchymal Stem Cells (MSC), including morphology, immune phenotype and differentiation potential into osteoblasts and adipocytes. However, we also found that sorted SSC after 14 days in culture expressed consistently lower levels of Gremlin1 and Mx1 as compared to the unsorted cells. These results suggest that even
after cell expansion, SSC retain differences from MSC. Human SSC are likely to lead to novel diagnostic and therapeutic tools in orthopedic medicine.

Successful enrichment of cardiac progenitors following differentiation of EGFP-expressing transgenic mouse ES cells.
D. Sridharan¹, P.B. Seshagiri²;
¹Department of Molecular Reproduction, Development and Genetics, Indian Institute of Science, Bangalore, India

Cardiovascular diseases are among the leading causes of deaths worldwide. In recent years, stem cell-based approaches to treat, for example, ischemic heart disease are being explored. Among the various cell types studied, cardiac progenitors (CPs) are the most promising ones. This is because CPs are multipotent, and they are capable of differentiating into cardiac cell types such as cardiomyocytes, endothelial cells and vascular smooth muscle cells. However, the major limitation has been the lack of optimized experimental system to enrich and expand CPs that are compatible for cell transplantation. In this study, we adopted a two-pronged approach to enrich and expand CPs, differentiated from our in-house-derived and well-established transgenic mouse embryonic stem cell line i.e., GS-2 ESCs (Singh et al, A. J. S. C.s, Vol 1(2) : pp 163-73 ; 2012). We developed experimental systems for enrichment of ESC-derived CPs by exploiting Sca-1 cell surface marker. We exploited this strategy because Sca-1 is identified as one of the key molecular markers associated with CPs’ plasma membrane. First, we assessed the use of extended cultures of ESC-derived embryoid bodies (EBs) in order to achieve better differentiation of GS-2 ESCs to CPs. We performed suspension cultures of EBs from the standard day 3 (D3) to D5 or D7 prior to plating EBs onto 0.1% gelatin coated-dishes. By flow-cytometry, we assessed the percentage of Sca-1⁺ cells obtained from EB outgrowths. Second, we enriched the CPs, derived from EB outgrowths (D7) by adopting the MACS approach exploiting Sca-1⁺ cell selection, following the depletion of CD31⁺ cells from the total cultured cells. The enriched Sca-1⁻/CD31⁻ cells were then assessed for their expandability and differentiation potential. Molecular phenotyping was performed for the differentiation associated markers by RT-PCR, immunofluorescence and FACS analyses. Our results show that the extended suspension cultures of EBs (D7 & D9) produced about a 2-fold increase in the percentage of Sca-1⁺ cells vis-à-vis standard attachment cultures. Moreover, MACS-based enrichment strategy showed a 2-4 fold enrichment of CPs (81.5 % ± 3.5; n = 4). Interestingly, the enriched CPs exhibited spontaneous differentiation to functional cardiomyocytes, evidenced by their rhythmic beating behaviour and expression of cardiac contractile protein markers such as αMHC and MLC-2v. Overall, we successfully developed an experimental strategy for efficient enrichment and expansion of CPs which could be exploited for engraftment studies in ischemic heart diseases and they have immense clinical significance in the context of regenerative medicine (Support: Dept. of Biotechnology, GoI, New Delhi).

Genome-wide CRISPR-Cas9 Screens Reveal Genes Promoting Entry into a G0-like State in Human Neural Progenitors.
H.M. Feldman¹, P.J. Paddison¹;
¹Human Biology Division, Fred Hutchinson Cancer Research Center, Seattle, WA

Mammalian tissue homeostasis is maintained by balancing cell division with cell quiescence during stem and progenitor cell lineage commitment. Recent data further suggests that even continuously dividing cells enter a transient G0-like state each cell cycle and that the duration of G0 determines the proliferation rate for any given cell type. Here, we performed genome-wide CRISPR-Cas9 screens in human neural progenitors to identify genes rate-limiting for their in vitro expansion. The screen revealed ~90 candidate growth-limiting genes, which were highly enriched in single nucleotide variant analysis across 7330 cancers, representing 29 distinct cancer types. Characterization of top scoring overlapping screen hits, including, for example, CREBBP, NF2, PTPN14, TAOK1, and TP53, revealed that knock out (KO) of the target genes invariably caused neural progenitors to grow faster by blocking entry into a G0-like state, regardless of cell density. Hallmarks of G0, including variable length G0/G1 transit times, low CDK2 activity, and high p27 levels were lost in KO cells, causing dramatically shortened G1-phases and cell cycles. Single-cell- and population-based gene expression profiling of KO cells revealed the impact of these genes on G1 subpopulations and also on development potential of the cells in differentiation assays. Taken together, our results demonstrate that a portion of the top pan-cancer mutated genes may act to limit cell growth by allowing entry into a G0-like state, possibly by permitting overall CDK2 activity to drop as cells exit mitosis.

Analysis of marker gene transcripts and 35 cytokines in adipose tissue mesenchymal stem cells spanning 15 consecutive passages.
H. Xia¹, J.L. Myers², T. Hua¹, M.Y. Caballero¹, S. Valtier³, G.J. Chaudry¹;
¹Center for Advanced Molecular Detection, 59 Medical Wing, San Antonio, TX, ²Medicine, University of Texas Health Science Center, San Antonio, TX, ³Science and Technology, 59 Medical Wing, San Antonio, TX

Mesenchymal stem cells (MSC) are multipotent stem cells, typically isolated from bone marrow, adipose tissue, and umbilical cord. But they have also been isolated from other fetal and adult tissues. MSC can differentiate into many different cell types, among them adipocytes, chondrocytes, and osteoblasts. The therapeutic potential of MSC has been assessed for a number of conditions, including conditions characterized by inflammation. MSC have been found to promote tissue regeneration and modulate immune responses involving inflammation. Thus, the cytokine secretion profile of MSC is important in these cells’ ability to modulate inflammation. However, with increasing in vitro passages, MSC progressively lose their potency. To ascertain the changes in their cytokine secretion profile during in vitro propagation, we grew adipose tissue MSC for 17 successive passages, and for each passage quantified 35 secreted cytokines by the Luminex microbeads multiplex assays. The results show that the cytokine concentrations in the culture media increased, with various cytokines peaking around passages 8-11. Then the levels decreased, in some cases precipitously. The variations in cytokine levels from passage to passage ranged from relatively small to dramatic. For example, eotaxin concentration at passage 10 was nearly 30-fold greater than that at passage 6, and it was below detection limit at
passage 17. The hepatocyte growth factor (HGF) and interleukin 1 receptor antagonist (IL-1RA) exhibited a different profile; both had early passage peak levels and then gradual drop. EGF, MIG, IL-3, and IL-15 could not be detected at any passage.

We also assessed the expression profile of the main MSC marker genes and several negative marker genes. The expression of the positive markers CD29, CD44, and CD73 expressions did not have appreciable changes across the span of passages, CD 90 expression generally increased with passage number, and CD166 had significantly higher levels at passages 4 and 5, but much lower at other passages. The most remarkable of the negative markers was CD34; its level at passage 15 was nearly 100-fold greater than its lowest levels at some earlier passages.

**Cell surface vimentin is involved in matrix stiffness dependent infection of endothelial cells by Listeria monocytogenes.**

E.E. Bastounis¹, J.A. Theriot¹,²,³, Y. Yeh⁴;

¹Biochemistry, Stanford University School of Medicine, Stanford, CA, ²Department of Microbiology and Immunology, Stanford University School of Medicine, Stanford, CA, ³Howard Hughes Medical Institute, Stanford University School of Medicine, Stanford, CA, ⁴Department of Bioengineering, University of California San Diego, La Jolla, CA

Vascular endothelial cells line the inner lumen of vessels forming a protective barrier against spread of bacterial infection. Endothelial cells display remarkable phenotypic heterogeneity in part due to the different mechanical stimuli transmitted from their extracellular environment. Although endothelial cell response to mechanical signals has been studied extensively, how bacterial uptake occurs in endothelial cells residing on varying stiffness environments was hitherto largely unknown. We exploit Listeria monocytogenes (Lm), a facultative intracellular bacterial pathogen, to determine the biophysical relationships between endothelial cells, the stiffness of their matrix and bacterial infection. We find that adhesion of Lm on human microvascular endothelial cells (HMEC-1) increases with increasing matrix stiffness in a focal adhesion kinase (FAK) dependent manner. We find that HMEC-1 residing on stiffer as compared to softer environments show higher FAK activity and that FAK activity is critical for uptake of Lm by HMEC-1. Through isolation of the surface receptors of HMEC-1 treated with a FAK inhibitor and mass spectrometry analysis, we find that the amount of cell surface vimentin is reduced when FAK activity is inhibited, which leads to reduced Lm uptake by HMEC-1. Our results identify a novel pathway wherein increased extracellular matrix stiffness sensed by endothelial cells leads to enhanced FAK activity that augments the amount of vimentin exposed at the surface of endothelial cells that in turn increases uptake of Lm.
Identification of polyubiquitinated species at sites of Listeria monocytogenes cell-to-cell spreading.
A.S. Dhand a 1, K.T. Lulic 1, J.A. Guttman 1;
1 Biological Sciences, Simon Fraser University, Burnaby, BC

The cell-to-cell dissemination of the pathogenic bacteria Listeria monocytogenes (L. monocytogenes) relies on their ability to hijack the host cell actin polymerization machinery. The spreading process of the bacteria begins inside the host cell where they simultaneously hijack and activate, to their surface, the Arp2/3 complex. Consequently, the bacteria cloak themselves in a branched filamentous actin (F-actin) cloud. Asymmetrical polymerization of this actin cloud causes the formation of long and slender actin-rich structures called comet tails that propel the bacteria throughout the host cell. Propulsion of these bacteria towards the host cell plasma membrane ultimately causes them to protrude out from it into neighboring cells via filopodia-like structures called listeriopods. Importantly, the molecular mechanisms governing listeriopod engulfment by neighboring cells remains largely unexplored. Since bacterial pathogens often exploit post-translational modification of proteins during their disease process, we investigated whether L. monocytogenes would also co-opt these modifications during their cell-to-cell spread. To test this, we infected human cervical epithelial (HeLa) cells with wild type L. monocytogenes and then stained fixed cells with an antibody which recognizes solely polyubiquitinated proteins. Interestingly, we saw no evidence of an enrichment of polyubiquitinated species at actin clouds surrounding stationary bacteria or at comet tails of motile bacteria. We also saw similar results when observing fully extended listeriopods that had yet to reach any nearby cells. Most importantly, when we examined listeriopods that had clearly invaginated into neighboring cells, we saw that the membrane region surrounding the protrusions was highly enriched with polyubiquitinated proteins. In summary, we provide evidence for a potential role of cellular post-translational modifications, specifically the polyubiquitination of proteins, during the dissemination process of the pathogenic bacteria L. monocytogenes.

Spatial organization of the human tongue dorsum microbiome at the micron scale.
S.A. Wilbert 1, J.L. Mark Welch 1, F.E. Dewhirst 1,3, G.G. Boris y 1,3;
1 The Forsyth Institute, Cambridge, MA, 2 Marine Biological Laboratory, Woods Hole, MA, 3 Harvard School of Dental Medicine, Boston, MA

Humans have co-evolved with the microbes comprising our microbiome but the significance of this symbiotic relationship for human health is only beginning to be appreciated. The individual microbiomes of the body may be considered the physiological equivalents of multi-cellular organs. As with other body organs, an understanding of their anatomy is essential for understanding their physiology. In previous work using multiplexed, spectral imaging and fluorescence in situ hybridization, we discovered a distinctive, multi-genus consortium in human supragingival plaque consisting of a radially arranged nine-taxon structure (Mark Welch et al 2016. PNAS 113 E791-E800). The distinctive structure permitted us to generate specific hypotheses for how the consortium develops, functions and is maintained. We now apply the multiplexed, spectral imaging approach to the microbiome of the human tongue. We designed oligonucleotide probes for taxa both abundant and prevalent on the human tongue dorsum as determined by oligotyping re-analysis of data from the Human Microbiome Project. Multiplexed imaging
revealed a highly structured spatial organization ranging in linear dimension from fifty to hundreds of microns. However, the organization differed from supragingival plaque in both structural detail and taxonomic composition. Featured on the tongue were consortia whose members were primarily cocci and bacilli drawn from the genera Streptococcus, Rothia, Neisseria, Actinomyces and Veillonella. Fifteen additional genera were detected at lower abundance and prevalence. The consortia radiated outward from a core of epithelial cells, with individual taxa clustering in domains suggestive of clonal expansion. The range expansion/contraction of these domains permits inferences regarding the selective advantage of the taxa during consortium development. Variations in taxon abundance from sample to sample and person to person were used to calculate correlations in relation to cell-cell and cell-host interactions. Finally, species-level analysis revealed distinctive tropisms in the oral microbiome. For example, the Rothia genus member on the tongue was determined to be almost exclusively R. mucilaginosa. Species level identification in combination with genomic information revealed that several of the tongue taxa possess nitrate reductase, a metabolic capacity not encoded by the human genome. This suggests that the tongue microbiome plays an important symbiotic role in nitric oxide homeostasis which is of significance for systemic control of vasodilation and blood pressure. Our work illustrates how high resolution analysis of micron-scale organization can provide insights into physiological functions and microbiome-host interactions. Supported by NIDCR Grant DE 022586.

Proteins in soy resistant to the digestive protease enzymes interact with intestinal epithelial cells and modulate metabolite absorption and microbiome profile in gut.  
J. Lim¹, J. Ma¹;  
¹Food Biomaterials, Kyungpook University, Daegu, Korea, South

Proteins are important nutrient for our body. Most of the food proteins are digested after they are consumed and processed along the digestive tract. Some food proteins, however, are resistant to the digestive proteolytic enzymes. For example, glycinin, a major protein in soy, is resistant to the proteolytic enzymes. Regarding this fact we hypothesized that the proteolytic enzyme resistant food proteins (PRFP) can interact with the intestinal tract, metabolites and/or with gut microbes. The interaction can change the physiological function of the intestinal epithelial cells, changes the profiles of the gut microbiome, and the absorption of metabolites in the digestive tract. The interaction of the FITC-labeled PRFPs with intestinal cells showed specific bound to the intestinal epithelial cell line, CaCo2, but not to the hepatoma cell line, HepG2. Interacting proteins on the membrane of CaCo2 cell and murine intestinal mucosa to PRFP were isolated by nearest-neighbor photo-affinity cross-linking and affinity purification, and identified by LC/MSMS. The list of interactor proteins includes membrane bound proteins involved in cholesterol uptake. The fact that PRFPs interfere the interaction of bacteria to intestinal cells can modulate the growth of the bacteria and change the profiles of the microbes in the gut.

Chlamydia uses ARF GTPases as a switch to control microtubule stabilization and actin polymerization.
F. Paumet1, J.T. Wesolowski1, C. Xander1;
1Microbiology and Immunology, Sidney Kimmel Medical College of Thomas Jefferson University, Philadelphia, PA

Both actin and microtubules are major cytoskeletal elements in eukaryotic cells that contribute to many cellular functions, including vesicle and organelle movement. During infection with the intracellular bacterium Chlamydia trachomatis, both of these cytoskeletal elements are drastically reorganized. For example, once inside the cell, Chlamydia develops into a parasitic compartment called an inclusion, which surrounds itself with actin and microtubule cages. Here, we address how one particular Chlamydial protein expressed on the surface of the inclusion, called CT813/InaC, controls both actin polymerization and the stabilization of microtubules around the inclusion in order to promote Chlamydia replication. To accomplish this task, CT813 binds the small GTPases ARF1 and ARF4, and uses ARF as a switch to coordinate both actin and microtubules. Finally, we establish that both actin polymerization and microtubule stabilization are necessary for Chlamydia 1) to build a physical scaffold around its inclusion, which re-enforces the inclusion membrane, and 2) to co-opt host organelles that are required for inclusion growth, respectively. Altogether, these results show for the first time that a single protein coordinates two major cytoskeletal elements using ARF GTPases as a switch.

A Chlamydia trachomatis protein mediates the remodeling of epithelial cytoskeleton and cell-cell junctions.
L. Dolat1, V.K. Carpenter1, Y.S. Chen1, R.H. Valdivia1;
1Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC

Chlamydia trachomatis is an obligate intracellular bacterial pathogen and a leading cause of sexually transmitted infections. Chlamydia delivers proteins to target epithelial cells to promote invasion and the formation of its replication vacuole, termed an “inclusion.” Infection of epithelial cells leads to the activation of multiple tyrosine kinases. We identified a bacterial protein TepP (translocated early phosphoprotein) that is translocated to the host epithelial cell and tyrosine-phosphorylated by Src kinases during early infection. TepP acts as a scaffold to recruit Crk adaptor proteins, which regulate the organization of the actin cytoskeleton, and the PI3-kinase complex to modify the early inclusion membrane and innate immune signaling. Significantly, Chlamydia lacking TepP (∆tepP) show decreased levels of tyrosine phosphorylation of multiple unknown proteins. Here, we performed a global phosphoproteomic analysis of host and bacterial proteins to identify proteins that are tyrosine phosphorylated in A2EN endocervical epithelia infected with wild type or TepP-deficient Chlamydia. We identified that Eps8, a filamentous actin-binding protein that localizes to epithelial tight junctions and apical microvilli, as a prominent TepP-dependent target of tyrosine phosphorylation. High-resolution microscopy shows that Eps8 is recruited to punctate F-actin structures associated with early inclusions in a TepP-dependent manner. Eps8 recruitment is dependent on its C-terminal actin-binding domain and coincides with altered F-actin organization, epithelial cell morphology and cell-cell junction integrity. Interestingly, we observed early inclusions in close association with epithelial cell-cell junctions, and the recruitment of additional tight junction proteins (e.g. ZO1). Consistent with the targeting of cell-cell
junctions, infection with TepP-expressing Chlamydia induces transient epithelial cell scattering. To validate these observations in primary cells, we developed a novel endometrial organoid infection model and examined the early infection process in a polarized, three-dimensional setting. In mock-infected organoids, Eps8 localizes to the apical cell surface and tight junctions, but re-locallizes to early inclusions in infected organoids, which show disrupted epithelial morphology and possibly integrity. Taken together, these studies demonstrate that TepP secretion during early infection regulates cytoskeletal organization by subverting Eps8 activity.

*Neisseria gonorrhoeae* modifies its infectivity based on the properties of human cervical epithelial cells.
Q. Yu\(^1\), L. Wang\(^1\), D.C. Stein\(^1\), W. Song\(^1\);
\(^1\)Cell Biology and Molecular Genetics, University of Maryland, College Park, MD

Gonorrhea, caused by *Neisseria gonorrhoeae* (GC), is one of the most common sexually transmitted infections. It has recently re-emerged as a public health crisis due to increases in multidrug resistant strains. However, the pathogenesis of this bacterium is not well understood due to a lack of infection models that mimic the human disease and the phase variation of multiple molecules on this bacterium, including opacity-associated protein (Opa). GC infection in the female reproductive tract starts from the cervix. The mucosal surface of the human cervix consists of three types of epithelial cells: non-polarized multilayer squamous at the ectocervix, polarized monolayer columnar at the endocervix, and transforming epithelial cells in between. This study examined the cellular mechanisms by which GC overcome the mucosal epithelial barrier to establish infection in the human cervix. We developed an ex vivo infection model using human cervical tissues and bacterial strains expressing no Opa or Opa proteins that cannot undergo phase variation. Using three-dimensional immunofluorescence microscopy, we found that GC that express phase variable Opa selectively penetrate into the subepithelium of the transformational zone and the endocervix but not that of the ectocervix. However, GC colonize the mucosal surface at all three regions, but the level of colonization at the transformation zone is higher than those at the ectocervix and endocervix. These findings are consistent with previous clinical observations using patients’ biopsies. The expression of phase invariant Opa that binds to the host adhesion molecules CEACAMs enhances GC colonization at the ectocervix and the transformation zone but inhibits GC penetration into the endocervical epithelium. In contrast, Opa expression does not affect GC infectivity in the transformational zone. Surprisingly, epithelial cells in the transformation zone do not express CEACAMs on their surface. GC break the cervical epithelial barrier by disrupting their adherens junction, which leads to GC penetration and epithelial cell shedding. Opa expression restores the epithelial adherens junction in a CEACAM-dependent manner, thereby inhibiting GC penetration and epithelial cell shedding. Our results collectively suggest that GC modify their infectivity based on the availability of the host cell receptors CEACAMs on cervical epithelial cells and the expression of Opa isoforms on GC. Our cervical tissue explant model is a useful tool for studying pathogenesis and developing treatments of sexually transmitted pathogens. This work has been supported by NIH grants.

**Toxoplasma gondii dysregulation of endothelial cell barrier function.**

A. Franklin-Murray\(^1\), M. Lodoen\(^1\), C. Schneider\(^1\), C. Tran\(^1\);

\(^1\)Molecular Biology Biochemistry, University of California, Irvine, Irvine, CA

*Toxoplasma gondii* is an obligate intracellular parasite that infects an estimated one-third of the global population causing significant morbidity and mortality. Humans are typically infected by consuming contaminated food or water, or through vertical transmission, at which point the parasite crosses formidable biological barriers to infect tissues of the central nervous system (CNS), such as the brain and the eye. Brain endothelial cells can provide a replicative niche for *T. gondii* and facilitate entry into the host CNS, where the parasite establishes a chronic infection. However, our current understanding of the molecular interactions occurring at the interface between endothelial cells and *T. gondii* remains limited. In the current study, we demonstrate that *T. gondii* induced marked reduction in filamentous actin (F-actin) stress fibers and the reorganization of the intermediate filaments and microtubules in primary human endothelial cells during infection in both static and shear stress conditions. In addition, parasite infection disrupted endothelial cell planar polarity and the localization of the Golgi apparatus under physiologic shear stress, reinforcing an effect of infection on the actin cytoskeleton. The destabilization of the cytoskeleton in infected endothelial cells was associated with a reduction in the localization of the adherens junction protein VE-cadherin and β-catenin to the cell periphery and a functional dysregulation of endothelial barrier integrity, as determined by TEER assays and increased permeability to low molecular weight polymers. Collectively, these findings reveal that *T. gondii* dysregulates endothelial barrier function and remodels the host cytoskeleton during infection. This study contributes to our understanding of *T. gondii* pathogenesis and more broadly, the regulation of endothelial barrier permeability, the dysregulation of which is a hallmark of many diseases.

**Studying the effect of the obligate endocellular bacteria Wolbachia on its host.**

C. Uribe-Alvarez\(^1\), N. Chiquete-Felix\(^1\), A. Peña\(^1\), S. Uribe-Carvajal\(^1\);

\(^1\)Molecular Genetics, Cellular Physiology Institute, Mexico City, Mexico

Wolbachia pipientis is an intracellular obligate α- proteobacteria present in 65-70 percent of insects. Depending on the host, Wolbachia can be a reproductive parasite or a mutualistic endosymbiont. Permanence within the host includes strategies such as feminization, parthenogenesis, cytoplasmic incompatibility and complementation of metabolic needs. Some hosts, such as filaria are unable to function properly when the bacterium is killed. In these cases different host mitochondrion-related proteins are overexpressed, suggesting that there is a close Wolbachia-mitochondrion interaction. In contrast, there are reports that Wolbachia is highly sensitive to ROS. The metabolism of isolated Wolbachia has not been studied probably due to the difficulty in obtaining large quantities of the bacterium, and also because as a true obligate endosymbiont, Wolbachia may survive outside a host cell for about a week, remaining capable of reinfesting new cells, but unable to divide. In cells infected with Wolbachia, mitochondrial oxidative phosphorylation activities are extended, suggesting that Wolbachia are determinant for longer mitochondrial survival. This is reflected in long-lasting high concentrations of cytochromes b, c, and a, in higher rates of oxygen consumption and in higher respiratory coupling during aging.

Shedding light on redox-sensitive MarR protein regulating EmrB and RND efflux pumps in B. thailandensis.

A. Sabrin\textsuperscript{1}, A. Gupta\textsuperscript{1}, A. . Grove\textsuperscript{1};
\textsuperscript{1}Biological Sciences, Louisiana State University, Baton Rouge, LA

Many species of the genus Burkholderia are opportunistic pathogens and are difficult to treat due to a high level of resistance to a wide range of antibiotics. Bacteria have intrinsic multidrug efflux pumps to withstand lethal doses of antimicrobials. Different efflux pump genes as well as virulence genes are regulated by multiple antibiotic resistance regulators (MarR). Since production of reactive oxygen species (ROS) is the first line of host defense and many transcription factors respond to such ROS, we set out to determine if BtMarR encoded by BTHI0021 contributes to oxidative stress responses. Our data suggest that in transposon mutant of marR, expression of rnd and emrB increases approximately 2.1 ± 0.1 and 25.2 ± 0.7 fold respectively indicating that BtMarR is a transcription repressor. Both rnd and emrB is upregulated in presence of H2O2 (2.6±0.2 and 3.5 ± 0.4 fold respectively). Conversely, CuCl2 treatment caused repression of both genes (0.47 ± 0.1 and 0.39 ± 0.01 fold respectively). SDS-PAGE analysis revealed that BtMarR forms different oligomeric species upon oxidation. By electrophoretic mobility shift assays we have determined that BtMarR binds to the intergenic operator DNA of its own gene and a divergently oriented gene, hypo (genomic locus BTHI0020) encoding a conserved hypothetical protein. marR deletion leads to the upregulation of this gene. Moreover in mutant strain, expression of rnd was upregulated by 4.6 ± 0.2, 3.5 ± 0.1 and 6.5 ± 0.1 fold after addition of 2mM H2O2, CuCl2 and ZnCl2 respectively while no change was seen in case of emrB. This data suggests that along with BtMarR, another transcription factor is involved in regulation of rnd. Differential expression of hypo under oxidative stress in wild type and mutant strain suggests that in addition to marR, hypo encoding a hypothetical protein of unknown function may play a significant regulatory role to control adjacent oriented rnd. Collectively, the above data suggest that BtMarR is the repressor of both rnd and emrB under reducing conditions and regulation of rnd might involve another transcription factor along with BtMarR. Further studies will uncover the impending regulation of RND and EmrB efflux pumps by targeting stress responsive transcription factor BtMarR.

Thermodynamic protein instability is a pathogen-associated molecular pattern targeted by human defensins.

E. Kudryashova\textsuperscript{1}, W. Lu\textsuperscript{2}, D.S. Kudryashov\textsuperscript{1};
\textsuperscript{1}Chemistry and Biochemistry, The Ohio State University, Columbus, OH, \textsuperscript{2}Biochemistry and Molecular Biology, University of Maryland School of Medicine, Baltimore, MD

Human defensins are innate immune defense peptides with a remarkably broad repertoire of activities. They disintegrate bacterial membranes and modulate immune response, inflammation, and angiogenesis. Moreover, remaining relatively benign towards human proteins, defensins inactivate bacterial toxins and intercept various viruses at different stages of their life cycles. We hypothesized that defensins recognize and target a common and essential property shared by many bacterial toxins and viral proteins – the intrinsically low thermodynamic stability. We showed that defensins inactivate susceptible proteins by taking advantage of their low thermodynamic stability and acting as natural
“anti-chaperones”, i.e. destabilizing the targets’ native conformations. To understand the detailed mechanisms of pathogen proteins inactivation by defensins, we have proposed a testable experimental model, where the initial transient interactions of defensins with proteins is mediated by electrostatic interactions; whether or not the electrostatic interactions advance to the unfolding stage will depend on the thermodynamic stability of a targeted protein. Due to the overall low specificity of these interactions, defensins integrated into disordered regions of thermodynamically unstable proteins would stabilize their partially unfolded states with high aggregation propensity. Stable proteins will remain either unaffected or stabilized by defensins. To test this model in the present study, we employed site-directed mutagenesis, chemical modifications, and other biochemical and biophysical approaches. Our data indicate that the initial electrostatic interactions can indeed account for different susceptibility of homologous toxins to defensins. Both C. difficile Toxins A and B (TcdA and TcdB) are thermodynamically unstable, but only TcdB with higher density of negative patches on its surface is effectively neutralized by defensins. Reduction of a net positive charge via acetylation of surface lysines on resistant TcdA increases its susceptibility to defensins. Next, a covalent stabilization of a toxin known to be both thermodynamically marginally stable and vulnerable to defensins (Actin Crosslinking Domain (ACD) of V. cholerae MARTX toxin) reduces its precipitation by defensins. In agreement with the proposed model, we show that the affinity of defensins to toxins is drastically increased near the melting temperature. Moreover, in complex mixtures, lower stability predisposes proteins for preferable precipitation by defensins. Understanding the defensins’ protective mechanisms is essential for rationally utilizing and boosting natural immune potentials of the human body and is expected to lead to a new generation of rationally designed synthetic therapeutic antimicrobials.

BPX-01 Topical Minocycline Gel Reduces P. acnes-induced Inflammatory Lesions in Mice.
M. Hermsmeier1, T. Sawant1, J. Sin1, K. Chowdhury1, X. Chen1, K. Chan1, U. Nagavarapu1;
1RD, BioPharmX, Menlo Park, CA

A novel, hydrophilic topical minocycline gel (BPX-01) has been developed for the treatment of inflammatory acne vulgaris. Minocycline, an antibiotic, is known to be effective against bacterium implicated in the pathogenesis of inflammatory acne, such as Propionibacterium acnes (P.acnes). Currently, minocycline is administered orally for this disease, but presents undesirable systemic side effects. Existing antibiotics used for the treatment of acne lesions (Clindamycin, Erythromycin, etc.) have already presented antibiotic resistance in patients.

The advance of a topical minocycline gel allows for direct delivery of the drug to the skin, significantly reducing or evading systemic exposure, thus potentially decreasing the incidence of antibiotic resistance. The topical minocycline also allows for targeted drug delivery into the affected areas (pilosebaceous unit) where P. acnes typically reside, potentially reducing the excess accumulation of bacteria and the inflammation caused. The efficacy of minocycline’s impact on P.acnes and lesion count was further evaluated in a Phase 2a and Phase 2b clinical trial, respectively. Furthermore, minocycline was detected in the plasma of only one subject out of the 259 tested in these studies. This indicates the potential for a decreased systemic antibiotic resistance risk with a topical minocycline gel.

In the present study, we investigated anti-inflammatory properties of minocycline in skin inflammation and hyper-proliferation induced by P. acnes using immortalized human keratinocytes (Ker-CT) and sebocytes. The anti-bacterial and anti-inflammatory effects of topically applied minocycline in vivo was further evaluated in an animal model. Live P. acnes were injected dermally into SKH1 mice resulting in inflammatory acne-like lesions. Physiological parameters including behavior, erythema and acne-like lesion features were observed. Histological examination of the lesions indicated characteristics.
commonly observed in clinical inflammatory lesions such as dermal inflammation, hyperkeratosis and inflammatory cell infiltrates, supporting the acne-like inflammatory aspects of the model. The daily application of BPX-01 reduced erythema and lesion size indicating a clearance of the P. acnes and inflammation in the skin. Other topical products, such as the antibiotic Clindamycin, were included. A high-resolution cross-sectional imaging method was also applied to provide a precise and less subjective approach to measure lesions. In conclusion, these data support the potential activity of minocycline for the treatment of acne vulgaris which may be attributed to its direct antimicrobial effect, and its ability to modulate the secretion of proinflammatory cytokines associated with acne pathology.

Innate immune variants of the surfactant protein in airway function after Klebsiella pneumoniae infection.
N. Thorenoor¹, X. Zhang¹, T.M. Umstead¹, S. Halstead¹, D.S. Phelps¹, J. Floros¹,²;
¹Department of Pediatrics, The Pennsylvania State University College of Medicine, Hershey, PA,
²Department of Obstetrics and Gynecology, The Pennsylvania State University College of Medicine, Hershey, PA

Surfactant Protein-A (SP-A) is a major surfactant protein component and plays a role in surfactant related function and innate immunity. The important contribution of SP-A in innate immunity becomes evident with increased susceptibility of SP-A knockout (SP-A-KO) mice to a variety of infections. Human SP-A consists of two functional genes, SP-A1 and SP-A2, and each is identified with a number of genetic variants. SP-A1 and SP-A2 variants are shown to differentially enhance bacterial phagocytosis, with SP-A2 being more effective than SP-A1. Here, we investigated the role of SP-A variants on airway function after Klebsiella pneumoniae (Kp) infection. We measured the lung function of transgenic mice each carrying different SP-A1 and SP-A2 variants using the forced oscillation technique (FOT). Lung mechanical parameters including total respiratory system resistance (Rrs), compliance (Crs), elastance (Ers), central airway resistance (Rn), tissue damping (H), and tissue elastance (G) were obtained by analyzing pressure and volume signals acquired in response to predefined, small amplitude, oscillatory airflow waveforms applied at the subject’s airway opening. Lung function was assessed after infection (baseline), and following inhaled methacholine dose response (0-50 mg/mL). We found that: 1) in the absence of methacholine (baseline) no significant differences were observed between SP-A1 and SP-A2 variants and/or KO. 2) In response to methacholine, i) SP-A2 (1A3) gene variant in males exhibited increased total and central airway resistance (Rrs and Rn) versus all other variants; ii) In females, SP-A2 (1A3) and SP-A1 (6A2) variants had similar increases in total and central airway resistance (Rrs and Rn) versus all other variants; iii) Allele specific differences were observed, a) with SP-A2 (1A3) exhibiting significantly higher total and central airway resistance (Rrs and Rn) versus SP-A2 (1A0), in both males and females, and b) SP-A1 (6A2) had significantly increased total and central airway (Rrs and Rn) lung function versus 6A4 in both males and females. We conclude, in response to infection and methacholine, SP-A variants differentially affect lung function and exhibit sex specific differences, consistent with previously reported findings of functional differences of SP-A variants. Thus, the changes in respiratory function mechanics provide insight into the role and importance of genetics of innate immune molecules, such as SP-A, in mechanical consequences in lung function after infection. This work is supported by the CHILD fund.

Plasma membrane remodeling by *Neisseria meningitidis* is driven by a wetting process along type IV pili fibers.

A. Charles-Orszag\(^1,2,3\), F. Tsai\(^4,5,6\), D. Bonazzi\(^1,3\), V. Manriquez\(^1,2,3\), M. Sachse\(^7\), A. Mallet\(^7\), C. Millien\(^8\), S. Goussard\(^1,3\), P. Lafaye\(^9\), J. Krijnse-Locker\(^7\), M. Piel\(^10,11\), F. Brochard-Wyart\(^4,5,6\), P. Bassereau\(^4,5,6\), G. Dumenil\(^1,2,3\);

*Neisseria meningitidis* is a bacterial pathogen that colonizes human blood vessels and causes septic shock and meningitis. Adhesion of meningococci to host endothelial cells via type IV pili is accompanied by a potent remodeling of the host cell plasma membrane, forming filopodia-like protrusions that intercalate between aggregated bacteria. While the mechanism behind plasma membrane remodeling remains unknown, the plasma membrane protrusions have been shown to increase microcolony resistance to shear stress. Here we first show that plasma membrane remodeling takes place during bacterial colonization of human blood vessels *in vivo*. In *vitro*, we find that remodeling occurs at the level of the single adhering bacterium as discrete short-lived protrusions, which then stabilize in between aggregated bacteria in the microcolony. Cortical actin polymerization is not necessary for protrusion formation but stabilizes them. Several observations point to a scaffolding mechanism exerted by type IV pili. First, plasma membrane protrusions disappear upon pilus retraction. Second, electron microscopy shows that membrane protrusions grow alongside type IV pili fibers. Third, perturbing the architecture of the type IV pili meshwork hinders plasma membrane remodeling. Accordingly, we show that wetting onto adhesive nanofibers can drive tubulation of phospholipid vesicles, and that the plasma membrane of human endothelial cells deforms locally in response to adhesive nanotopographical cues. Therefore, we propose that the human endothelial cell plasma membrane deforms onto type IV pili fibers through a linear wetting mechanism which reflects a general property of biological membranes in contact with adhesive nanofibrillar structures.

Cell-specific defense cascade in *Verticillium*-infected grafted tomato.

E.J. Robb\(^1\), X. Xu\(^1\), J. Blaya Fernandez\(^1\), H. Shittu\(^1\), A. Kurosky\(^2\), R.N. Nazar\(^1\);

\(^1\)Molecular Cellular Biology, University of Guelph, Guelph, ON, \(^2\)Department of Biochemistry and Molecular Biology, Department of Biochemistry and Molecular Biology, Galveston, TX

Although the hypersensitive reaction in foliar plant diseases has been described extensively, little is clear regarding plant defence strategies in vascular wilt diseases. *Verticillium* is a vascular fungus that affects more than two hundred economically important plants worldwide with billions of dollars lost. In *Verticillium* wilt, the tomato Ve-resistance locus is thought to encode a receptor (NLR), which binds a pathogen effector and sets off an immune cascade that curtails pathogen colonization. Breeding strategies have inactivated the Ve-R locus to improve yield and fruit quality. In turn, susceptible stems often are grafted on resistant roots to provide both an enhanced and resistant crop. To better
understand the contribution of genes in the grafted plants we have undertaken genomic and proteomic studies of defense/stress gene expression in grafted plants consisting of both susceptible (Ve1-) and resistant (Ve1+) tissue. Analyses indicate that in the susceptible plant a very heroic but unsuccessful systemic response occurs involving many known plant defense/stress genes, while surprisingly more modest changes occur in the resistant tomato. Since a number of the highly elevated proteins are known to participate in a plant hypersensitive response as well as natural senescence, the results suggest that some or all of the disease symptoms, including ultimate plant death, actually are the result of this exaggerated defense response. Analyses in grafted plants indicate that induction of the defense cascade is cell-specific, and not transduced throughout the plant. Instead, effectively curtailed fungal colonization in the root is sufficient to permit the enhanced crop production by susceptible tissue.

High Content Screening Implicates the PI3K-Akt Pathway in FAST Protein-Mediated Cell-to-Cell Fusion.

D.P. MacKenzie¹, R. Duncan¹;
¹Microbiology and Immunology, Dalhousie University, Halifax, NS

Cellular fusion is central to many physiologic and pathophysiologic processes but remains a poorly understood phenomenon. The reovirus fusion-associated small transmembrane (FAST) proteins, the smallest proteins known to trigger cell-to-cell fusion, are useful tools in the dissection of this critical cellular process. High-content phenotypic siRNA and small molecule screens of FAST protein-mediated cellular fusion were developed to identify endogenous proteins and pathways involved in syncytium formation. HT1080 cells expressing the baboon reovirus p15 FAST protein were treated with a library of 258 small molecule kinase inhibitors (at 0.025, 0.25 and 2.5μM) and an automated fluorescence microscopy assay was developed to quantify syncytogenesis. In this fashion, phosphoinositide 3-kinase (PI3K) p110α subunit inhibitor Pik-75 and AKT kinase inhibitor A-443654 were identified as agents that dramatically inhibited syncytogenesis. A similar kinome screen based on RNAi also implicated the PI3K-AKT pathway in cellular fusion. The necessity and isoform specificity of the p110alpha/AKT signaling pathway to FAST protein-mediated cell fusion was validated through genetic intervention using shRNA (targeting p110 and p110 isoforms) and a transgenic knockout cell line DLD-1 (AKT1-/-/AKT2-/-), and via pharmacologic inhibition using PI3K isoform specific inhibitors TGX-221 (p110 inhibitor) and A525424(p110 inhibitor). Interestingly, Pik-75 and A-443654 also inhibited syncytogenesis mediated by the measles virus F+H fusion protein complex. The lack of structural and evolutionary relatedness between the FAST proteins and the measles virus F+H fusion protein complex suggests p110alpha/AKT involvement in a common cell-cell fusion mechanism. Immunoblot analyses indicate FAST protein expression leads to AKT activation through the PI3K p110α isoform, and fluorescence videomicroscopy revealed colocalization of AKT1-PH-GFP (a biosensor of phosphatidylinositol 3,4,5-phosphate) and the reptilian reovirus p14 FAST protein at areas of cell-to-cell contact, and this colocalization increased immediately prior to the formation of a cell-cell fusion synapse. Treatment with Pik-75 disrupted p14/AKT-PH-GFP colocalization and altered actin dynamics at areas of cell-to-cell contact resulting in a failure to form a cell fusion synapse. These studies identify the PI3K-AKT pathway as critical player involved in cell-cell fusion.

**c-Abl kinase in Niemann-Pick type A disease: its implication in the pathogenic mechanisms leading to neurodegeneration.**

T.A. Marín1, C. De la Fuente2, M.L. Acuña1, J.F. Castro1, A.R. Alvarez2, S. Zanlungo1;  
1 Facultad de Medicina, Pontificia Universidad Católica de Chile, Santiago, Chile, 2Facultad de Ciencias biológicas, Pontificia Universidad Católica de Chile, Santiago, Chile

**Introduction:** Niemann-Pick type A (NPA) disease is a lysosomal neurodegenerative disorder characterized by the deficiency in acid sphingomyelinase (ASM), accumulation of sphingomyelin and alterations in autophagy. Previously, we described that the c-Abl/p73 pathway is activated and mediates neurodegeneration in other lysosomal diseases. In addition, it has been recently described that c-Abl has a role in autophagy regulation. Our aim was to evaluate the participation of c-Abl in the autophagic alterations and neuronal pathology in NPA disease.

**Materials and Methods:** We used the ASM deficient mouse and desipramine treated-SHSY5Y neurons as *in vivo* and *in vitro* NPA models, respectively. We evaluated Purkinje cell loss, inflammation, markers of the autophagy flux and the c-Abl/p73 pathway at different ages in the NPA cerebellum. In treated SHSY5Y neurons we evaluated viability and c-Abl levels. The same parameters were evaluated in both NPA models using the c-Abl inhibitor Imatinib.

**Results:** We found progressive neurodegeneration, inflammation, alterations in the levels of autophagic markers and activation of the c-Abl/p73 pathway at the cerebellum of the NPA mice. Accordingly, the cellular neuronal NPA model presented activation of this signaling pathway. Treatment with Imatinib reduced neuronal death and caspase 3 active levels in the cellular neuronal NPA model and preserved Purkinje neurons and reduced inflammation in the NPA cerebellum.

**Conclusion:** c-Abl is activated and relevant in NPA neurodegeneration, supporting the potential use of Imatinib for clinical treatment of NPA patients.

**Analysis and modulation of cathepsin B and D in liver damage in *in-vitro* and *in-vivo* models of Niemann-Pick type C disease.**

J.E. Oyarzún1, M. Acuna1, J.F. Castro1, S. Zanlungo1;  
1Gastroenterología, Pontificia Universidad Católica de Chile, Santiago, Chile

**Introduction:** Niemann-Pick type C (NPC) disease is a genetic storage disorder, characterized by cholesterol accumulation in lysosomes. NPC patients present progressive neurodegeneration and liver damage. We are interested in understanding the mechanisms involved in liver damage in NPC disease. Interestingly, increases in cathepsin B and D, two proteases involved in liver fibrosis and apoptosis, have been reported on different NPC models. **Aim:** to study the contribution of cathepsins B and D on the liver damage in NPC.

**Material and Methods:** We used NPC1 deficient mice (Npc1/−) at different ages. *In-vitro* models; i) Pharmacological: Hepa1-6, LX-2 or primary cultures of hepatic stellate cells (HSC) from WT mice treated with U18666A (U18) and ii) Genetic: HSC primary cultures of WT and NPC mice. We modulated cathepsin B or D, using the CA074 and pepstatin A inhibitors, respectively, or shRNAs, and analyzed the pro-fibrotic phenotype.
**Results:** We found increases on cathepsins levels in several NPC models, and a correlation with the pro-fibrotic phenotype in the in-vitro NPC models. Inhibition of cathepsin B activity reduced the pro-fibrotic phenotype in hepatic in-vitro NPC models, and inhibition of cathepsin D activity or levels reduced the pro-fibrotic phenotype in hepatic in-vitro and in-vivo NPC models.

**Discussion:** Increased levels of cathepsins B and D were found in several hepatic NPC models analyzed. Modulation of these cathepsins decreased the hepatic pro-fibrotic phenotype. Cathepsins B and D are potential therapeutic targets for NPC liver disease.

Glutamate carboxypeptidase II (GCPII) is becoming to be recognized as an important diagnostic and therapeutic target. Overexpression of GCPII, also known as prostate-specific membrane antigen (PSMA), has been implicated in the prostate cancer while inhibition of GCPII activity has been shown to improve neuropathologies such as neurodegenerative brain damage, glutamate neurotoxicity and peripheral nerve neurodegeneration in animal models. GCPII is involved in several physiological processes as a transmembrane glycoprotein with large extracellular part possessing carboxypeptidase activity. Despite extensive research, the function of GCPII is understood only in the brain and small intestine but not in other GCPII-expressing tissues. Several different attempts to generate GCPII knock-out (KO) mice were reported with rather controversial results, ranging from embryonic lethality to generation of viable GCPII KO mice with no obvious phenotype. In order to dissect this controversy, we attempted to generate GCPII KO mice by targeting the active site of the enzyme using TALEN technology. We established reliable genotyping method based on nested PCR and show that no GCPII protein is expressed in our KO mice as determined by Western blot and carboxypeptidase activity analysis. Our GCPII KO mice are viable, breed normally and do not show any obvious phenotype. This reliable mouse model could be further used for revealing yet unknown physiological functions of GCPII in the kidney, prostate or elsewhere.

Monday-514
Our laboratory recently identified PYROXD1 as a novel genetic cause of congenital muscle disease (myopathy) that is characterized by generalized weakness, difficulty feeding and swallowing in the neonatal period, respiratory problems and distinctive nasal speech. Histologically, PYROXD1 myopathy is distinctive, with patient muscle biopsies bearing all of the pathological features that usually sub-classify the myopathies; internalized nuclei, zones devoid of mitochondrial activity, myofibrillar disorganization and protein inclusions. The two eldest patients (now aged 24 and 28) have emerging evidence for nerve and cardiac involvement.

PYROXD1 is an uncharacterized pyridine nucleotide-disulphide oxidoreductase (PNDR). PNDRs are a family of powerful reductases that reduce redox-reactive thiols in their substrates; often other crucial enzymes and signalling proteins that become oxidized as a result of their functional activity. Recent studies have identified PYROXD1 as one of ~1800 genes essential for cell survival, and our studies confirm targeted knock out of PYROXD1 results in embryonic lethality in mice. Therefore, PYROXD1 has a non-redundant reductase activity that no other reductase can compensate for. PYROXD1 myopathy highlights the power of rare, genetic disorders to impart new insight to basic biology. PYROXD1 either lends its reductive powers to a novel redox pathway, or alternately, PYROXD1 represents a new upstream regulator of a known redox pathway vital for cell viability. Both possibilities are of fundamental significance.

Our studies are now targeted on defining the oxidative pathway and vital substrates reduced by PYROXD1, using proximity-dependent biotin identification (BioID2) and comparative thiol proteomics. BioID2 utilizes a PYROXD1-biotinylase fusion protein, whereby a brief biotin pulse results in biotinylation of protein interactors. Using mass spectrometry, the PYROXD1 biotinylated interactome is then cross referenced with proteins showing differential thiol oxidation between wild-type and PYROXD1 knockout tissues.

PYROXD1 myopathy provides evidence that development of several pathological endpoints in the myopathies are linked to redox dysfunction, and gradual accumulation of oxidative stress in long-lived muscle fibers. Interestingly, we show that protein aggregates in PYROXD1 patient muscle also stain positively for markers of neurodegenerative aggregates. We are now studying mechanistic parallels in aggregate pathobiology between myopathies and neurodegenerative disorders using histological staining and biochemical assays with specific intent to evaluate clinical merit of existing anti-oxidant therapies for myopathy patients.

Inhibition of histone acetyltransferases specifically targeting H4K5 acetylation rescue myogenic differentiation of emerin-null myogenic progenitors.
K.A. Bossone\textsuperscript{1}, J.M. Holaska\textsuperscript{1};
\textsuperscript{1}Pharmaceutical Sciences, University of the Sciences, Philadelphia, PA

Emery Dreifuss Muscular Dystrophy (EDMD) is a disease characterized by skeletal muscle wasting, contractures of the major tendons, and cardiac conduction defects. The symptoms generally begin during adolescence and slowly worsen over time. As a result, it is predicted that the disease results from a failure of muscle fibers to properly regenerate after injury. The inability to properly regenerate skeletal muscle is predicted to result from impaired muscle stem cell differentiation. Mutations in the gene encoding emerin cause EDMD. In previous experiments, myogenic progenitors derived from emerin-null mice confirmed their impaired differentiation by observing cell cycle exit, myosin heavy chain expression, and myotube formation. The emerin-null myogenic progenitors showed decreased ability to exit cell cycle, decreased expression of myosin heavy chain, and decreased myotube formation. It was
previously shown that emerin interacts with and increases the catalytic activity of HDAC3. Treatments with theophylline, a HDAC3 activator, rescued myotube formation in differentiating emerin-null myogenic progenitors. Furthermore, addition of RGFP966, a HDAC3 inhibitor, decreased myotube formation. This suggests that HDAC3 is important for the later stages of myogenic differentiation. To confirm the deacetylation function of HDAC3 by theophylline treatment was responsible for rescue of myogenic differentiation in emerin-null progenitors, we tested inhibitors of H4K5 histone acetyltransferases (HATs). Nu9056, L002, and windorph were added to differentiating wildtype and emerin-null myogenic progenitors and differentiation was assessed using multiple assays. Treatments with the HAT inhibitors showed an increased formation of myotubes in emerin-null myogenic progenitors. Importantly, HAT inhibition rescued emerin-null myogenic progenitor differentiation. Thus, we conclude emerin regulation of HDAC3 activity is important for myogenic differentiation.

Myosin replacement in myofibrils is induced by Hsp90 activity.
K. Ojima, E. Ichimura, S. Muroya, M. Oe, T. Suzuki, T. Nishimura;
1Animal Products Research Division, Institute of Livestock and Grassland Science, NARO, Tsukuba, Japan,
2Research Faculty of Agriculture, Hokkaido University, Sapporo, Japan

Myosin is a fundamental force generating protein in skeletal muscles. In myofibrils, a single thick filament consists of approximately 300 myosin molecules, which are constantly substituted in myofibrils. Our previous study showed that myosin replacement rate is significantly reduced by an inhibition of myosin synthesis. However, it remains largely unknown which factor(s) regulates myosin substitution in myofibrils. In this study, we investigated whether myosin replacement rate was induced by the activity of heat shock protein 90 (Hsp90) which functions as myosin chaperone to correctly fold myosin subfragment-1. Fluorescence recovery after photobleaching experiments showed that the replacement rate of green fluorescence protein fused myosin heavy chain was significantly increased in myotubes overexpressing Hsp90. However, an inhibition of Hsp90 activity in the presence of geldanamycin reduced myosin replacement rate. These results indicate that Hsp90 activity is required for up-regulation of myosin substitution rate in myofibrils. To ask how Hsp90 promoted myosin replacement rate, unincorporated myosin content in the myocytoplasm was semi-quantified. The cytosolic myosin content was increased in myotubes overexpressing Hsp90 but not in geldanamycin treated myotubes. Furthermore, the gene expression level of myosin heavy chain was up-regulated by Hsp90 overexpression but down-regulated by inhibition of Hsp90 activity. Taken together, our results demonstrated that myosin substitution is facilitated by Hsp90 activity through elevated levels of the cytosolic myosin content and the myosin gene expression.

Mutational and biochemical analysis of the dual kinase region of UNC-89 (Obscurin).

Y. Matsunaga¹, H. Qadota¹, J.C. Moody¹, J.Q. Kwong², G.M. Benian¹;
¹Pathology, Emory University, Atlanta, GA, ²Pediatrics, Emory University, Atlanta, GA

In C. elegans, unc-89 loss of function mutants display reduced locomotion, disorganized myofibrils and lack of M-lines. The largest UNC-89 isoforms at approximately 900,000 Da consist of 53 Ig domains, 2 Fn3 domains, a triplet of SH3, DH and PH domains near their N-termini, and two protein kinase domains (PK1 and PK2) at their C-termini. Nematode UNC-89 is the founding member of the UNC-89/obscurin family of proteins. UNC-89 is localized to M-lines. Homology modeling suggests that PK1 is catalytically inactive, whereas PK2 is catalytically active. Although we have found that both PK1 and PK2 interact with SCPL-1, a novel CTD-type protein phosphatase, and that PK1 interacts with LIM-9 (FHL2), the actual functions of these protein kinase domains is unknown. To begin to explore the in vivo functions of UNC-89 kinase domains, we have used CRISPR/Cas9 gene editing to create nematodes having an in-frame deletion of PK1 (unc-89(sf23)), or a putative catalytically inactive PK2 (unc-89(sf22)). To make the catalytically inactive PK2, we changed a conserved lysine (K) that is involved in ATP coordination to alanine (A). We have shown that PK2 has catalytic activity in vitro, and we are in the process of verifying that this KtoA mutation eliminates kinase activity. unc-89(sf22) and unc-89(sf23) worms have normal sarcomere structure as assessed by immunostaining using antibodies to various sarcomeric proteins. Nevertheless, both these mutants display reduced whole body locomotion (swimming in liquid or crawling on agar). To help explain how these mutants move more slowly despite having normal myofibrils, we hypothesized that mitochondria might be defective in organization or function. We used two methods (Mitotracker staining, and muscle-specific expression of mitochondrial-localized RFP) to assess the organization of mitochondria. Each method shows that, as compared to wild type, unc-89(sf22) and unc-89(sf23) have mitochondrial networks that are broken or fragmented. The mitochondrial protein content (assessed by quantitative western blotting using antibodies to ATP synthase, ATP5A), however, is unaffected. As mitochondrial fragmentation usually indicates mitochondrial dysfunction, we are in the process of measuring ATP levels in these mutants.

Nuclear receptor interaction protein (NRIP) maintains Z-disc width through α-actinin-2 bound with CapZ.
S. Chen1;
1Microbiology, National Taiwan University, Taipei, Taiwan

Previously, we demonstrated a gene, nuclear receptor interaction protein (NRIP, also named as DCAF6 or IQWD1), which could interact with nuclear receptors such as androgen and glucocorticoid receptors. NRIP acts as a transcriptional cofactor to activate nuclear receptor-driven gene expression. NRIP is a Ca2+-dependent calmodulin binding protein to stimulate calcineurin phosphatase and CaMKII kinase for muscle contraction; hence global NRIP knockout mice (NRIP gKO) revealed muscle dystrophy (JCS, 2015). Here we further examined heart functions of gKO that revealed cardiac hypertrophy. Specifically, the muscle-restricted NRIP knockout mice (cKO) displayed the enlarged outlook of heart at 22 wk. The echocardiography assay showed the diminished fractional shortening [FS] and EF [the ration of end-systolic diameter to end-diastolic diameter [ESD/EDD] in cKO in comparison with WT; indicating loss of NRIP may cause cardiac hypertrophy. The sarcomere structure by using electronic microscopy revealed the reduction of I-band width, extension length of Z-disc and shortened sarcomere length in heart at age 10 wk. The calcium transient of primary cardiomyocytes from adult mice revealed that the deficiency of NRIP decreased the amplitude of calcium transient and shortened sarcomere contraction that was consistent with shorten length sarcomere by EM. To verify the regulatory mechanism of NRIP, we found that α-actinin-2 (ACTN2) (a biomarker of muscular Z-disc complex), was one of NRIP-interacting proteins from the yeast two-hybrid system using NRIP as a prey. In vitro and in vivo assays confirmed NRIP directly bound with ACTN2. Loss of NRIP, the ACTN2 bounded less CapZ than wild type; but CapZ expression was comparable between WT and cKO; indicating that NRIP might stabilize Z-complex formation at least through CapZ to anchorage actin in sarcomere structure. On the other hand, we are in progress to generate AAV encoding NRIP and will see the therapeutic effect on the model of NRIP cKO-inducing cardiomyopathy model. In conclusion, NRIP is a Z-disc protein and has function for maintenance of sarcomere integrity structure those involved in calcium transient and muscle contraction.

Myogenesis is a highly organized process involving cellular fusion of myogenic progenitors into multinuclear myotubes, a process requiring dynamic actin remodeling in response to appropriate regulation of intracellular signals including Rho-family small GTPases (Rac1, Cdc42, etc). Recently, we found that interleukin-1 (IL-1) α/β -double knockout (IL-1KO) mice exhibited impaired muscle regeneration after
cardiotoxin-induced muscle injury, characterized by delayed infiltrations of immune cells and delayed appearance of satellite cells as compared with those of wild-type (WT) mice. While sophisticated interactions between inflammatory microenvironments and satellite cells are apparently prerequisite in vivo, the potential direct involvement of IL-1s in the regulation of satellite cell functions has yet to be clarified. Herein, we took advantage of IL-1KO satellite cells obtained from the IL-1KO mice to directly investigate the regulatory role of IL-1 in the fundamental functions of satellite cells in vitro. We found that IL-1KO satellite cells displayed obvious impairments in growth and myogenic fusion in vitro as compared to WT satellite cells and that, importantly, these defects were both dose-dependently normalized by exogenous IL-1β. Despite the delayed myogenic fusion process in IL-1KO cells, they highly expressed key myogenic transcription factors such as myogenin and MyoD, indicating the transcriptional myogenic program to be appropriately activated in the absence of endogenous IL-1. On the other hand, biochemical analysis of intracellular signaling intermediates revealed the phosphorylation status of group I PAK proteins (e.g. PAK2/Thr402), direct effectors of Cdc42 and Rac1 involving myogenic regulation, to be persistently higher in IL-1KO than WT cells during the course of myogenesis, while cellular contents of N-WASP were slightly diminished. Furthermore, intravital imaging analysis of actin dynamics using LifeAct-Venus revealed that IL-1KO cells exhibited stable formation of micro-spikes with a quiescent state of actin remodeling activity under basal conditions, which differed strikingly from WT cells displaying active ruffling formation. As expected, administration of IL-1β markedly restored actin dynamics in IL-1KO cells as evidenced by vigorous remodeling of actin filaments underneath the plasma membrane, promoting membrane ruffling, which lasts at least for 16 hrs. Taken together, these data demonstrate that fundamental satellite cell properties are intrinsically regulated by endogenous IL-1α/β and that lack of IL-1 related signals results in derangements of their actin regulatory systems, most likely accounting for the compromised myogenic fusion process.

Glucose-dependent insulinotrophic polypeptide (GIP, also known as gastric inhibitory polypeptide), is an incretin, and is synthesized in K-cells of the duodenum and the proximal portion of small intestine. Oral ingestion-associated elevation of blood glucose level stimulates the secretion of GIP in to the circulation. Thereafter blood GIP binds GIP receptor (GIPR) expressed in pancreatic β-cells, induces insulin secretion from them, and facilitates uptake and utilization of glucose in targeting tissues, such as skeletal muscles. Secretion of glucagon from a-cells of the pancreas is also stimulated by GIP. It is reported that the inhibition of GIP as well as the silencing of GIPR impairs glucose homeostasis in mice. In addition, GIP directly stimulates glucose uptake in rat skeletal muscles via GIPR that is also expressed in skeletal muscle cells. Recently, we have demonstrated that the administration of GIP increases the protein content and myotube diameter of C2C12 cells. Therefore, GIP-GIPR intracellular signal(s) may play a role in myogenic differentiation. The purpose of this study was to investigate a physiological role of GIP-GIPR intracellular signal(s) in the myogenic differentiation using mouse myoblasts-derived C2C12 cells. Expression of GIPR was observed in not only myotubes but also undifferentiated myoblasts of C2C12
cells. The expression level of GIPR in C2C12 myoblasts cells was lower than that in C2C12 myotubes. In this study, GIPR of C2C12 myoblasts was knock down using small interfering RNA (siRNA) immediately before the initiation of differentiation. Knock down of GIPR induced the down-regulation of both MyoD and Pax7 in C2C12 myoblasts. Furthermore, GIPR-knock down-associated depression of both the increase in muscle protein and myotube formation of C2C12 cells were observed during differentiation. Evidences from this study strongly suggest that GIP-GIPR intracellular signal(s) might stimulate myogenic differentiation via inhibiting of proliferation of myoblasts. This study was supported, in part, by Grants-in-Aid for challenging Exploratory Research (16K13022), and Grants-in-Aid for Scientific Research (C, 17K01762) from the Japan Society for the Promotion of Science, the Science Research Promotion Fund from Promotion and Mutual Aid Corporation for Private Schools of Japan, the research grants from Graduate School of Health Sciences, Toyohashi SOZO University, and All Japan Coffee Association.

Effects of acute hypoxia on zebrafish cardiac tissue.
G. Hernandez, S. Britz, F. Frech, B. Schoffstall
1Department of Biology, Barry University, Miami, FL

Human cardiomyocytes are only capable of an inadequate proliferative and regenerative response to damaged cardiac tissue. In contrast, it is known that cardiomyocytes in damaged Danio rerio (zebrafish) hearts are capable of complete regeneration in response to pathological injury and stress. We have repurposed a simple anaerobic incubation tank to induce pathological hypoxia in zebrafish hearts. After exposing fish to a severely oxygen-depleted environment for 2 hours, we found that the dissolved oxygen (DO) in fish water is reduced by an average of 81%, when compared to water exposed to normal atmospheric conditions—presumably sufficient to cause detectable cardiomyocyte damage. Following re-exposure to normal oxygen levels, we dissect hearts to study specific effects on cardiac tissue. We have used fluorescent labels to detect nitroreductase activity and reactive oxygen species (ROS) production—both indicators of hypoxic damage. Repeatedly, Epicardial, pericardial, and myocardial tissues appear to exhibit detectable ROS production, while only myocardial tissue appears to demonstrate nitroreductase activity. When cardiomyocytes are damaged by prolonged hypoxia exposure, they are typically programmed for apoptosis, and should exhibit an increase in the level of mono- and oligonucleosomes in the cytoplasm prior to actual cell death and dissolution of the cell membrane. Here, we demonstrate our efforts to assess the level of cardiomyocyte damage inflicted using our hypoxia model, by testing for evidence of apoptosis programming with an ELISA assay to detect cytoplasmic histone-associated DNA fragments. If we can achieve detectable cardiomyocyte damage using our hypoxia model, we will conduct future investigations of the cardiac regeneration and cardiomyocyte proliferation process in zebrafish. These findings could be translatable into discovery of molecular targets for therapies to stimulate human cardiomyocyte regeneration and repair.
Nearly 30 years ago George Brooks proposed the existence of a lactate shuttle in skeletal muscle between fast twitch fibers and slow fiber. According to his model, what was previously considered a mere byproduct of glycolysis, had acquired a role in sustaining energy metabolism during exercise. The transporters responsible for shuttling lactate were discovered only a decade later. The monocarboxylate transporters (MCTs) are proton-coupled transporters expressed in the plasma membrane of different tissues. The preferential localization of MCT4 in the sarcolemma of fast, glycolytic fibers and of MCT1 in slow, oxidative fibers makes them important components of the lactate shuttle in skeletal muscle. Based on their distribution, affinity and capacity to transport lactate, MCT1 primarily regulates the transport of lactate into the cells, while MCT4 predominantly exports lactate outside the cells. However, their directionality can change according to local lactate ions gradient. MCT1 and MCT4 require an accessory protein, Basigin (Bsg), for maturation and translocation to the sarcolemma. It has been shown that in Bsg−/− mice the MCTs do not localize at the plasmamembrane. Given the importance of lactate for energy metabolism and muscle physiology, we hypothesized that interfering with the shuttle will impair muscle function and cause exercise intolerance. To test this hypothesis, we used a global SLC16A3 (MCT4) knock-out mouse model and an inducible skeletal muscle specific Bsg knock out model (iMS Bsg−/−) created by crossing Bsg+/− animals with the a-skeletal actin-MerCreMer mice. MCT4−/− and iMSBsg−/− 4 months old mice performed poorly on a treadmill assay, suggesting exercise intolerance. When tested for voluntary activity with running wheels, MCT4−/− animals showed a significant decrease in activity compared to controls. Surprisingly, iMS Bsg−/− mice activity was similar to control littermates. This suggest that in the MCT4−/− an additional behavioral component may play a role since MCT4 is expressed also in astrocytes. To study the effects of lack of MCT4 on muscle mechanical properties we assayed ex vivo contractile properties of isolated extensor digitorum longus (EDL) muscles. MCT4−/− muscles generated less force than controls. Analysis of compound muscle action potential (CMAP) showed a decreased in CMAP amplitude with normal latency and duration in MCT4−/−, suggestive of axonal degeneration. Further experiments are necessary to evaluate the functionality of the neuromuscular junctions of the animals. Our studies on the MCT4−/− mouse demonstrate for the first time the importance of the lactate shuttle in supporting motor function and energy metabolism during endurance exercise. Funding source: Grant EY012042 to NJP

Systemic iron homeostasis is maintained by regulation of iron absorption in the duodenum, recycling from erythrocytes, and mobilization from the liver and is controlled by the hepatic hormone, hepcidin.
Hepcidin expression is induced via the bone morphogenetic protein (BMP) signaling pathway that preferentially uses two type-I (ALK2 and ALK3) and two type-II (ActRIIA and Bmpr2) BMP receptors. Hemojuvelin (HJV), HFE, and transferrin receptor-2 (TfR2) facilitate this process presumably by forming a plasma membrane complex with BMP receptors. Matriptase-2 (MT2) is a protease and key suppressor of hepatic hepcidin expression and uses MT2 as substrate. Previous studies have therefore suggested that MT2 exerts its inhibitory effect by inactivating HJV. Here, we report that MT2 suppresses hepcidin expression independently of HJV. In Hjv/- mice, increased expression of exogenous MT2 in the liver significantly reduced hepcidin expression similarly as observed in WT mice. Exogenous MT2 could fully correct abnormally high hepcidin expression and iron deficiency in Mt2/- mice. In contrast to MT2, increased HJV expression caused no significant changes in wild-type mice, suggesting that Hjv is not a limiting factor for hepcidin expression. Further studies revealed that MT2 cleaves ALK2, ALK3, ACTRIIA, BMPR2, HFE, and to a lesser extent HJV and TfR2. MT2-mediated Tfr2 cleavage was also observed in HepG2 cells endogenously expressing MT2 and TfR2. Moreover, iron-loaded transferrin blocked MT2-mediated Tfr2 cleavage, providing further insights into the mechanism of Tfr2’s regulation by transferrin. Together, these observations indicate that MT2 suppresses hepcidin expression by cleaving multiple components of the hepcidin-induction pathway.

Central obesity (CO) is a systemic inflammatory condition linked to immunometabolic disease clusters promoting premature death. Health risk assessment associated with excess adiposity requires identification of predictors of human subclinical inflammatory obesity (SIO) and understanding the immune-metabolic regulation. Immune cells, neurons and adipocytes share the language of catecholamines (CA), potent modulators of neuro-endocrine-immune/inflammatory networks. We aimed to identify SIO and hypothesized CA immunomodulation in obesity. A low-cardiovascular risk population was studied concerning anthropometric, metabolic, endocrine and inflammatory parameters. Waist circumference (WC) measure defined CO after the International Diabetes Federation criteria. With a flow cytometry analysis, we studied monocyte subsets, staining for CD14, CD16, CD36 and CD11b. Expression of catecholaminergic receptors and tyrosine hydroxylase (TH) was assessed by real-time PCR in peripheral mononuclear cells (PBMC). A ratio (R) between adrenoceptors (AR), dopaminergic receptors (DR) and TH mRNA of CO and no-CO<0.5 was considered under and >2.0 over expression. CD16+ monocytes in CO showed a more inflammatory pattern without expansion, as compared to no-CO subjects. WC was sensitive to lipidemia and, in CO group, lipidemia was associated with a more inflammatory phenotype of CD16+ monocytes. In CO, adrenaline was correlated with CD16+ monocyte expansion with a lower inflammatory pattern. Leptin, VLDL-C plasma levels, and CD14 expression of CD16+ monocytes were found to be CO predictors (R² =0.337; Z (3) = 6.258; p=0.002).

Monday-522
\( \beta_2 \text{AR transcripts were under expressed in CO relatively to no-CO group (R=0.08; p=0.009). Logistic regression analysis (LRA) demonstrated a lower association for CO development if } \beta_2 \text{AR mRNA} \geq 2 \times 10^{-6} \text{[OR 0.177 (95%CI) (0.040-0.796)]}. \beta_2 \text{AR expression inversely correlated with plasma triacylglycerol, VLDL-C and leptin and positively with HDL-C. PBMC from CO subjects showed lower expression of DRD2, DRD4 and DRD5 as well as lower levels of TH mRNA in comparison to the counterpart. DRD2 and DRD5 expression strongly correlates with lower weight, BMI and WC, lower plasma levels of leptin and with a lower inflammatory pattern. In CO model, LRA showed a protective role for CO development for DRD2 mRNA \geq 0.0000000455 \text{[OR 0.018 (95%CI) (0.002-0.195)]. In conclusion, we identified predictors that explain SIO in more than 33%. Our work suggests that in SIO, dyslipidemia and leptin induce monocytes maturation rather than an independent arise of CD16+ monocytes. The expression of catecholaminergic receptors in PBMC has a different pattern in SIO and associate with a better metabolic profile and with a lower inflammatory state, suggesting CA immunomodulation in obesity.}

**Expression and regulation of the novel adipocyte enriched gene NRNP1.**

N.S. Cairl\(^1\), V. Kalman-Maltese\(^1\), C.M. Smas\(^1\);

\(^1\)Department of Cancer Biology, University of Toledo College of Medicine and Life Sciences, Toledo, OH

Obesity and Type II diabetes are co-morbidities that are increasing at an alarming rate in the United States. A thorough understanding of the function of white adipose tissue (WAT) is critical to attaining new insights into the development of these diseases. One approach to increase our understanding of adipose tissue function in health and disease is the identification and functional assessment of novel genes that are induced as preadipocytes convert to mature adipocytes. To identify new genes with potential importance in adipocyte function, we carried out transcriptional profiling studies using the 3T3-L1 *in vitro* model of white adipogenesis. Transcript for a novel gene, which we have named NRNP1 (Nutritionally Regulated Nuclear Protein 1), was found to be expressed at >20-fold higher in 3T3-L1 adipocytes vs. 3T3-L1 preadipocytes. NRNP1 was also similarly induced during preadipocyte to adipocyte conversion in an *in vitro* model of brown adipogenesis. Assessment of a panel of mouse tissues indicated expression in WAT depots and brown adipose tissue (BAT). Importantly, NRNP1 was enriched in the adipocyte cell fraction vs. the stromal vascular cell fraction of mouse WAT, indicating the adipocytes of WAT are the cell type expressing NRNP1. *In vivo* studies revealed an increase in NRNP1 transcript expression in subcutaneous WAT (12-fold) and BAT (3-fold) of mice that were fasted and then refed vs. NRNP1 transcript levels in fasted mice. We also noted increased expression of NRNP1 transcript in fatty liver of *ob/ob* mice vs. C57BL/6J mice. Transfection of an NRNP1-eGFP fusion protein revealed nuclear localization. Together, these data indicate that expression of the transcript for the novel nuclear protein NRNP1 closely parallels adipogenic conversion and states of lipid accumulation in *vivo*. Given the nuclear localization of NRNP1, we hypothesize that NRNP1 may have a regulatory role in these processes.

Blocking Ca\(^{2+}\)-channel \(\beta_3\) subunit reverses diabetes.
K. Lee\(^1\), J. Kim\(^1\), M. Köhler\(^2\), S. Ryu\(^3\), P. Berggren\(^3\);
\(^1\)Division of Integrative Bioscience and Biotechnology, POSTECH, Pohang, South Korea, \(^2\)The Rolf Luft Research Center for Diabetes and Endocrinology, Karolinska Institutet, Stockholm, Sweden, \(^3\)Life Science, POSTECH, Pohang, South Korea

Voltage-gated Ca\(^{2+}\) channels (\(\text{Ca}_n\)) has an important function in change of cytosolic Ca\(^{2+}\) ([Ca\(^{2+}\)]\(_i\)) level which lead to insulin exocytosis in the pancreatic islet. The \(\beta_3\) subunit of Ca\(_n\) (Ca\(_n\)\(\beta_3\)) is regulatory subunit of Ca\(^{2+}\) channel, Ca\(_n\)\(\beta_3\) is known to modify Ca\(^{2+}\) channel currents. In the previous report showed that islets from Ca\(_n\)\(\beta_3\)-deficient (Ca\(_n\)\(\beta_3^{-/-}\)) mice exhibited increased [Ca\(^{2+}\)], oscillation frequency, better insulin secretion, and more glucose tolerant compared to wild-type mice. However, there is lack of information about function of Ca\(_n\)\(\beta_3\) in Ca\(^{2+}\) dynamics and insulin secretion in diabetes. So we focused on function of Ca\(_n\)\(\beta_3\) in the diabetes model. Here, we observed that islets from ob/ob mice model and high fat diet feed mice showed decreased [Ca\(^{2+}\)], dynamics amplitude and oscillation, also impaired insulin secretion in glucose stimulation. Also overexpression of Ca\(_n\)\(\beta_3\) in islets alters Ca\(^{2+}\) dynamics and impairs insulin secretion. We implemented the reduced Ca\(_n\)\(\beta_3\) in ob/ob mouse’s islet using antisense oligonucleotide and then discovered the recovery of [Ca\(^{2+}\)], dynamics, insulin secretion. In the development of diabetes, to define the Ca\(_n\)\(\beta_3\) function, inducing diabetes to the Ca\(_n\)\(\beta_3\) knocking out mice. Feeding a high fat diet to the Ca\(_n\)\(\beta_3^{-/-}\) mice show more tolerance to glucose stimulated [Ca\(^{2+}\)], dynamics and insulin secretion compared to normal mice fed on high fat diet. In vivo study, we transplanted Ca\(_n\)\(\beta_3^{-/-}\) mice islet to the diabetic mice, we found improved glucose tolerance. So we could suggest that Cav\(\beta_3\) is crucial for regulation of islet function in diabetic condition. This study will discover the potential value of the VDCC Ca\(_n\)\(\beta_3\) as a target of diabetes treatment.

A role in olfaction for DLK in resistance to diet induced obesity.
H.N. Wong\(^1\), L.B. Holzman\(^1\);
\(^1\)Medicine, University of Pennsylvania, Philadelphia, PA

The physiological role of Dual Leucine Zipper Bearing Kinase (DLK)--a MAP 3-kinase that interacts with JNK--remains incompletely known. To investigate DLK function, we generated DLK hypomorphic mice that circumvent early neonatal death observed in DLK null mice. DLK hypomorphs (\(Dlk^{neo/neo}\)) were resistant to diet induced obesity. Our results showed that the difference in body weight gain observed on a hypercaloric diet in \(Dlk^{neo/neo}\) vs. control mice was due predominantly to a dramatic difference in adipose accumulation and not due to a difference in the rate of lean mass growth. While DLK hypomorphs had smaller body surface area than wild type, experiments done in a thermoneutral environment confirmed resistance to diet induced obesity (DIO). DLK hypomorphs exhibited increased energy expenditure that resulted from increased resting metabolic rate and increased spontaneous motor activity. They consumed less food than WT controls, (although \(Dlk^{neo/neo}\) mice consumed food at a rate similar to control when food consumption was normalized to either body mass or lean mass) and did not demonstrate intestinal fat malabsorption. In considering mechanisms by which DLK deletion results in resistance to DIO, we were intrigued by observations by Riera et al. (Cell Metab, July 2017) that loss of olfactory neurons in mice protects them against DIO by altering energy homeostasis. We found that DLK null and DLK hypomorphic mice lacked brain anterior commissures and DLK hypomorphs
had reduced olfactory bulb volume compared to wild type control. DLK null neonates had reduced milk bubbles yet attached normally when shown the mother’s nipple. Given these observations, we examined the hypothesis that DLK deleted mice exhibit an olfactory functional defect. In food finding assays, mature Dlk<sup>neo/neo</sup> mice demonstrated impaired olfactory function relative to wild type control. These observations were confirmed in adult conditional DLK null mice (Dlk<sup>lox/lox</sup> x Ubiquitin-Cre<sup>SRT2</sup>), where DLK was deleted following tamoxifen injection. We speculate that at least in part, DLK is necessary for normal olfaction dependent regulation of energy homeostasis.

**High Throughput Idiosyncratic Drug-Induced Hepatotoxicity and Investigations of Chronic Proliferation of Cells with a Non-Invasive Approach.**

C.T. Bot<sup>1</sup>, S. Stölzle-Feix<sup>2</sup>, K. Juhasz<sup>2</sup>, L. Dörr<sup>2</sup>, M. Beckler<sup>2</sup>, R. Haedo<sup>1</sup>, M. George<sup>2</sup>, A. Brüggemann<sup>2</sup>, N. Fertig<sup>2</sup>;

<sup>1</sup>Nanion Technologies Inc., Livingston, NJ, 2Nanion Technologies GmbH, Munich, Germany

Hepatic toxicity has accounted for 15 of the 47 drugs withdrawn from the market in the last two decades<sup>1</sup>. More specifically, Drug Induced Liver Injury (DILI) is the major cause of acute liver failure in the USA and Europe and is one of the main reasons for regulatory actions<sup>2</sup>. DILI is classified as intrinsic (or dose-dependent) or as idiosyncratic. A prominent example of idiosyncrasy is acetaminophen (paracetamol), with a variable time of onset and not directly dependent on dose. We present a non-invasive DILI assay approach based on impedance measurements in monocyte-derived hepatocyte-like (MH) cells from MetaHeps®. Although improvements have been made to cellular and animal models to predict intrinsic (dose-dependent) DILI, it is almost impossible to predict idiosyncratic DILI. MH cells have been developed as a tool to investigate long-term hepatotoxicity, metabolism and drug interactions. Furthermore, patient-derived MH cells could provide a tool for diagnosis or exclusion of idiosyncratic DILI, and provide the causative agent in polymedicated patients. MH cells were used on a 96-well screening system that monitors changes in impedance (or cell monolayer resistance). Once the monolayer is exposed to a cytotoxic agent, the impedance changes and measures of toxicity can be quantified long-term. Cells are monitored under physiological conditions for temperature, humidity and CO2 incubation. We investigated the hepatotoxic effects of paracetamol on MH cells when exposed for 24 and 48 hours. In agreement with other standard toxicity assays, such as lactate dehydrogenase release assay, low doses of paracetamol caused transient toxicity and ‘adaptation’ was observed. At higher doses, hepatotoxic effects of paracetamol could be reversed upon washout after 24 hours, but continued exposure caused increased hepatotoxicity. In addition to hepatotoxicity, another validation of the principle is shown for chronic proliferation of cancer cells. Traditional cell proliferation assays involve labeling cells of interest with compounds that become reduced in the environment of metabolically active cells, or by incubating cells with radioactive labels. In this study, murine mammary carcinoma cells (H8N8 and H8N8 T3.2) were used and changes in impedance, and therefore confluency, were used as a measure of toxicity. Intrinsic (dose-dependent) effects of the standard clinical treatment regimen cyclophosphamide, doxorubicin and 5-fluouracil could be identified consistent with other methods of live cell analysis systems. Therefore, the utilized 96-well impedance system in combination with murine mammary carcinoma cells provides a novel tool for investigating therapy resistance of cancer cells in vitro. Mutation of dgat2 uncouples lipolysis and lipoprotein synthesis in the zebrafish embryonic digestive organ resulting in excess ectopic lipid droplets.
M.H. Wilson1, J.H. Thierer1,2, S.A. Farber1,2;
1Embryology, Carnegie Institution for Science, Baltimore, MD, 2Biology, The Johns Hopkins University, Baltimore, MD

During zebrafish development, maternally-deposited yolk is the source of nutrients for embryogenesis prior to digestive system maturation. The yolk syncytial layer (YSL) is the cytoplasmic layer surrounding the yolk mass that metabolizes, re-packages and exports yolk nutrients to the developing embryo. Export of lipid from the YSL is via triglyceride-rich lipoproteins. We show that blocking lipoprotein production, by inhibiting the activity of microsomal triglyceride transfer protein (MTP), results in aberrant accumulation of lipid droplets in the YSL. The dense packing of lipid droplets refracts light such that the yolk takes on a dark appearance. Paradoxically, we have also found that zebrafish embryos with a nonsense mutation in exon 2 of diacylglycerol acyltransferase 2 (dgat2), an ER resident enzyme that synthesizes triacylglycerol from diacylglycerol and fatty acyl-CoA, also exhibit dark yolks indicative of excess lipid. mRNA in situ hybridization indicates dgat2 is expressed in the YSL, as well as in the intestine and liver at later developmental stages. Unlike DGAT2-null mice, which are lipopenic and die soon after birth, zebrafish dgat2 mutants are viable and fertile. Similar to inhibition of MTP, dgat2 mutant embryos have visible accumulation of lipid droplets in the YSL. These droplets vary in size, stain positively with oil-red-O and some can even persist after yolk depletion. Biochemical analyses reveal that the YSL still has remaining dgat activity and lipid droplets are rich in triglycerides and cholesterol esters. Residual dgat activity cannot be explained by the expression of other known dgat isoenzymes (e.g. dgat1a and dgat1b are not expressed in the YSL). Dgat2 mutant embryos synthesize fewer and smaller beta-lipoproteins, and transmission electron microscopy indicates the ER in the YSL of dgat2 mutants is abnormally swollen and electron dense, suggesting possible accumulation of lipid within the leaflets of the ER membrane. Experiments are currently underway to identify the source of the remaining dgat activity and determine why YSL triglyceride export is attenuated. These data suggest that blocking triglyceride export uncouples the rates of yolk degradation and lipid export, forcing the YSL to pack the accumulating lipid species into lipid droplets, likely to prevent lipotoxicity. Future work will be aimed at understanding whether the embryo, YSL and the yolk degradation machinery communicate to ensure the correct provision of nutrients to the body to promote proper embryonic development.

Targeting lipoprotein(a)-induced endothelial cell metabolic changes to reduce inflammation and leukocyte migration.
J.G. Schnitzler1, R.M. Hoogeveen2, I. Nicoescu1, M. Versluit1, E.S. Stroes2, J. Kroon1;
1Dept. of Experimental Vascular Medicine, Academic Medical Centre, Amsterdam, Netherlands, 2Dept. of Vascular Medicine, Academic Medical Centre, Amsterdam, Netherlands

Lipoprotein(a) [Lp(a)] is plasma lipoprotein composed of apolipoprotein(a) [apo(a)] covalently bound to apolipoprotein B-100 (apoB) of LDL. Lp(a) is an independent, genetically determined risk factor which is causally related to myocardial infarction, stroke and peripheral artery disease. Despite the fact that one-
fifth of the general population has elevated Lp(a) levels, the lack of established treatment may be attributed to little understanding of the pathophysiology of Lp(a) mediating cardiovascular disease. Recent research substantiated that activation of immune cells lead to metabolic changes due to altered glycolysis-associated gene expression. Although data exists showing Lp(a)-induced inflammation in endothelial cells (EC), the exact molecular pathways remain to be elucidated. Recent in vivo studies from our group showed that patients with elevated levels of Lp(a) had increased metabolic activity in plaque regions, as shown by 18F-FDG PET/CT imaging. This suggests that Lp(a), besides activating the inflammatory phenotype of immune cells, may also be crucial for increasing metabolic activity of the endothelium. Based on these data, we hypothesize that Lp(a) mediates endothelial activation via a marked metabolic shift, facilitating a pro-atherogenic environment. Here, we set out to investigate that endothelial cell inflammation can be reduced by altering EC metabolism. Lp(a) (100mg/dl)-induced endothelial gene expression of key-adhesion molecules E-selectin, ICAM-1 and VCAM-1, the chemokine MCP-1 and the cytokines IL-6 and IL-8 were all significantly upregulated when compared to low-level (10mg/dl) Lp(a)-stimulated EC. Additionally, Lp(a) exposure revealed a marked increase in the production of cytokines IL-6 and IL-8. Functional transendothelial migration (TEM) assays substantiated these findings and showed that Lp(a) stimulation led to increased leukocyte migration. Additionally, we showed that all these effects were attributed to the oxidized phospholipids that were bound to recombinant apo(a). These Lp(a)-induced changes coincided with increased metabolic activity, as shown by the increase in gene expression of key-glycolytic enzymes PFKFB3, HK2 and PFKM. Interestingly, partial glycolytic inhibition using 3PO, an inhibitor of PFKFB3, a concomitant decrease in inflammation was found, suggesting that glycolysis is driving lipoprotein-induced endothelial inflammation. To conclude, these data suggest that Lp(a)-induced inflammation and endothelial metabolic changes are closely intertwined. Inhibition or interference of glycolytic metabolic pathways would be of great clinical interest in order to reduce atherosclerosis.

Plasma sdLDL(small dense LDL) induced to modification of cellular cholesterol transport in foam cells.
M. Mori1, S. Takizawa1, R. Yamazaki1, Y. Yamamoto1, K. Imai1, J. kasahara1, K. Shimizu1, M. Takahashi1;
1Cellbiological Pathology, Chiba Inst. Sci., Chiba, Japan

[Objective] Plasma Small dense LDL (sdLDL) was often found in type IIB Hyper cholesterolemia and Hyper triglyceridemia patients, produced by TG rich VLDL. Some correlation between IHD (ischemic Heart Disease), convalescence of IHD, and sdLDL already reported. To elucidate a possibility of activation of ABC transporters and removing FC from foam cells, several PPAR agonists, ARB and vascular statins can be examined as activator to ABCA1 transcription and translocation. [Method] sdLDL was prepared from human plasma by KBr density gradient separation. Foam cells were prepared by J774 cells incubating with sdLDL for 24-72hr, and cultured up to 3-6 days in the presence of LPDS (Lipoprotein deficient serum) +/- HDL and PPAR agonists, ARB or statin. FC rich lipid droplets were detected by Filipin staining. [Results & Discussion] Plasma sdLDL strongly induced lipid droplets in foam cell, as well as acetylated LDL(AcLDL), especially, so many FC-rich lipid droplets were shown in filipin stained cells. HDL treatments activated reverse cholesterol transport in AcLDL-induced foam cells, whereas, FC-rich lipid droplets still remained in sdLDL-induced one. Maybe, HDL defects the FC-removing activity in sdLDL-induced one and its metabolites may reflect on cellular FC transport including ABC transporters transcription and/or translocation. Some ABC transporter activator were tested: PPAR a agonist (Fenofibrate, Ciprofibrate) had a potent activity of inducing ABCA1 and its translocation, was also
known to avoid foam cell death, FC rich lipid droplet formation in AcLDL-induced cells. However, these fibrates molecules did not enough to reduce cellular FC in sdLDL-induced cells. Vascular statin molecules (Simvastatin, Atorvastatin) were well known as a potent activator of ABCA1 translocation, also reduced FC-rich lipid droplet formation, and increase ABCA1 expression level in AcLDL-induced foam cells. However, reverse cholesterol transport activity was reduced in sdLDL-induced one. ARB molecules (Angiotensin II AT1 receptors blockers; Losartan, Irbesartan, Telmisartan) had a potent activity as well as PPAR α, γ agonists. sdLDL-induced foam cell resists to reduce FC from the cells, filipin stained FC-rich lipid droplets still remained. These signify relationship in cellular cholesterol transport in sdLDL-induced foam cells, show the possibility cellular cholesterol transport regulates by the property of lipoproteins and its lipid profiles (apoB modification, PC oxidation, etc) and also accumulation process( scavenger receptors). Among the FC-rich lipid droplet formation, regulation of reverse cholesterol transport and rupture of foam cells in lesion may reflect to development of atherosclerosis correlated in IHD patients. Oxygen Concentration-Dependent Regulation of Erythropoiesis in Human Erythroblasts.

It is estimated that approximately 2.3 million human erythroblasts extrude their nucleus every second in the hypoxic environment (5% O2 and its concentration) of the bone marrow. Enucleation requires multiple signal transduction pathways and local assembly of a contractile actomyosin ring. We have previously shown that human erythroblasts produce ATP by anaerobic glycolysis based on the following observations: i) the Ser300 residue in pyruvate dehydrogenase (PDH) is phosphorylated by PDH kinase 1 and 4 isozymes; ii) inhibition of lactate dehydrogenase by stiripentol reduces ATP level in the cells and decreases enucleation ratio. However, at which extent hypoxia-inducible factor (HIF1)-α regulates ATP production in human erythroblasts remains unknown. In the present study, we assessed the role of HIF1-α on ATP production in human colony-forming unit-erythroblasts (CFU-Es) and mature erythroblasts generated from purified CD34+ cells treated with the HIF1-α-specific inhibitor, KC7F2 (N,N'-(Dithiodi-2,1-ethanediyl) bis [2,5-dichlorobenzene-sulfon-amide]). CFU-Es cultured in a 5% O2 environment were capable of proliferating and extruding their nucleus as well as at 21% O2. In contrast, in a 1% O2 (hypoxic) environment, proliferation of CD34+ cells was impaired, the cell number being reduced by about 90% compared with a 5% O2 environment after 7 days in culture. Additionally, in a 1% O2 environment, cell morphology after the Day 7 CFU-E (terminal differentiation) stage was dramatically changed and the number of macropaghe-like cells was increased. These results supported that human erythroblasts require at least 5% O2 concentration for proper proliferation and terminal differentiation. HIF1-α expression was confirmed at the mRNA and protein levels during terminal differentiation (Day7 ~ Day13). KC7F2 blocked the proliferation of CFU-Es and enucleation rate in a dose-dependent manner (0 ~ 100 μM). The ATP concentration in CFU-Es was also significantly reduced by the inhibitor treatment. However, KC7F2 did not affect cell morphology nor expression of the erythroblast surface markers glycophorin A (GPA) and CD71. We conclude that human erythroblasts require 5% O2 concentration at least for proliferation despite their ability to produce ATP through anaerobic glycolysis. Our results also suggest that ATP production may be modulated by HIF1-α during terminal differentiation of human erythroblasts.

Pharmacological activation of LPA receptors regulates murine erythro-megakaryocytic differentiation in myeloid lineage.
J. Chiang¹, W. Chen¹, K. Lin¹, H. Lee¹;
¹Department of Life Science, National Taiwan University, Taipei, Taiwan

Myeloid cell differentiation is one of the most crucial physiological processes among hematopoiesis to form blood components and replenish blood system. Our previous studies demonstrated that lysophosphatidic acid (LPA) regulates myeloid cell differentiation through activating multiple G protein coupled receptors. However, the underlie mechanism in vivo remains unclear. In this study, we aimed to validate the effects of LPA and its corresponding receptors, LPA₂ and LPA₃ on erythropoiesis/megakaryopoiesis in vivo. By profiling LPA receptors in murine myeloid cells, LPA₂ and LPA₃ were found to express at different stages of progenitors. Mice injected with LPA₂ agonist, GRI977143, showed severe perturbation in both erythroid and megakaryocytic lineages. Further, GRI treatment suppressed populations of common myeloid progenitor (CMP) and megakaryocyte erythrocyte progenitor (MEP), suggesting that LPA₂ inhibited myeloid differentiation at early stage of myelopoiesis. In contrast, treatment with LPA₃ agonist, 1-oleyl-2-O-methyl-rac-glycerophosphoethionate (OMPT), skewed toward erythroid lineage with increased erythroid populations and RBC numbers at the expense of megakaryocyte populations. Finally, OMPT injection successfully restored PHZ-induced acute haemolytic anaemia. Taken together, this study demonstrated for the first time that LPA₂ and LPA₃ acted at different stages to regulate hematopoiesis in vivo, and provide a potential therapeutic strategy for future treatment of anemia.

Changes in the Proliferation and Gene Expression of HUVECs in Response to Treatment with Plant Secondary Metabolites.
C. Howard¹, D. Nofziger¹, P. Joyner¹;
¹Natural Science Division, Pepperdine University, Malibu, CA

Medicinal plants have historically been a valuable source of new drugs and Southern California possesses a rich collection of native plants which have been used as medicines by native people groups for thousands of years. Angiogenesis is the biological process of new blood-vessel growth from endothelial cells. It is an essential part of the wound-healing process, and increased angiogenesis has also been implicated in the growth of some types of cancerous tumors. In this study, extracts of the Southern Californian native plants Red shanks (Adenostoma sparsifolium) and the alkaloid extract of Jimson weed (Datura wrightii) were tested for their angiogenic effects in human umbilical vein endothelial cells (HUVECs) using a cell proliferation assay, nitric oxide production assay, and qRT-PCR. Treatment of HUVECs with extracts from Red shanks and Jimson weed increased proliferation at concentrations of 10 ng/µL and 1 ng/µL, but no changes in nitric oxide production were measured for any treatment. Changes in expression of the genes vegfr2 and mmp9 were measured by qRT-PCR and
suggested that proliferation may be induced by these plant extracts through factors that bypass normal nitric oxide-mediated proliferative signals.

Characterization of the mechanically-induced shape change of erythrocytes into polyhedrocytes.
V. Tutwiler¹, A.R. Mukhitov², A.D. Peshkova², G. Le Minh ², J. Vicksman¹, C. Nagaswami¹, R.I. Litvinov¹, J.W. Weisel¹;
¹University of Pennsylvania, Philadelphia, PA, ²Kazan Federal Research University, Kazan, Russia

Polyhedral structures have been observed in nature since the time of Aristotle; however, most research has focused on Platonic and Archimedean solids rather than irregular polyhedra. Moreover, these tightly packed cells were recently observed in contracted blood clots, where the highly deformable erythrocytes were compressed into the core of the clot and formed a tessellated network. This resulted in a shape change from the normal biconcave cell to a polyhedral shape; consequentially the terminology polyhedrocytes was coined. Since hemostatic and thrombotic disorders are leading causes of death and disability worldwide, exploring the nature of the shape change from biconcave erythrocytes to polyhedrocytes has the potential to inform therapeutic targets. Here, we use histology, transmission electron microscopy, scanning electron microscopy and confocal microscopy to visualize and quantify the mechanical deformation of erythrocytes. We determined that this shape change is linked to the presence of contractile forces that are generated by the platelets and highly influenced by the composition of the clot. The presence of more platelets or more platelet activity, as induced by a higher thrombin concentration, resulted in a direct correlation with the percentage of polyhedrocytes present. Likewise, the inhibition of contractile proteins or the ability of platelets to propagate contractile force resulted in softer clots with fewer polyhedrocytes present on the inside of the clot. Through the use of confocal microscopy, we were able to reconstruct the three-dimensional structure of erythrocytes from contracted blood clots and compare bioconcave cells, polyhedrocytes and intermediate forms. Interestingly, as the erythrocytes undergo deformation, there was no change in the surface area, volume, or sphericity of the cells. The deformed erythrocytes and polyhedrocytes became less oblate and more prolate than the biconcave cells. Collectively, these studies reveal that polyhedrocytes are convex, irregular polyhedra. The polyhedrocytes had a total number of faces that ranged from 10 to 16 with a median of 13 faces. The faces were made up of polygons with 3 to 6 sides, with the majority of the faces being quadrilaterals. Taken together, these results point to the importance of studying the deformation of erythrocytes as a result of clot contraction into a tightly packed network, since these structures could provide a key function of replicating the barrier function of the endothelial layer post injury and/or influence the outcome of thrombotic conditions.

Immunosuppressive drug causes Hepatic iron overload.
N. Sheikh¹, T. Akhtar¹;
¹Department of Zoology, University of the Punjab, Lahore, Pakistan

The introduction of calcineurin inhibitor tacrolimus greatly reduced the rate of allograft rejection. Along with having, immunosuppressive properties it can also cause adverse side effects. Recipient's iron status is an important determinant of clinical outcome in transplantation medicine. The current experimental
setup was designed to analyze the tacrolimus induced hepatic iron overload in wistar rats. Aqueous suspension of tacrolimus powder (3 mg/ml) was orally given to four experimental groups of wistar rats. While control group was provided with normal drinking water and dissections were done after 6, 12, 24 and 48 h of tacrolimus suspension administration. Real-time PCR, ELISA and Prussian blue iron staining were performed to evaluate hepatic iron contents. Real-time PCR analysis showed an initial upregulation in the expression of hepcidin at 6h (1.95±0.2 fold) and 12h (2.1±0.05 fold) time points. Ferritin-L expression found to be significantly upregulated at 6h (1.82±0.14 fold) and 12h (1.69±0.15 fold) time points in response to tacrolimus dose and after 12h start to decline towards baseline level. Ferritin-H expression was also found to be significantly upregulated at 12h (2.08±0.29 fold) and 24h (2.08±0.20 fold) time points when analyzed by one way ANOVA. Transferrin gene expression was found significantly upregulated at 12h (1.92±0.19 fold) time point. Early upregulation at 6h (1.81±0.19 fold) was also observed but this difference remained statistically non significant. An early statistically significant upregulation of transferrin receptor 1 expression was observed at 6h (5.30±0.9 fold) and 12h (4.89±0.56 fold) time points as compared to control. Serum Hepcidin concentration was measured via quantitative sandwich ELISA, showed no significant alterations in counter to toxic effect of tacrolimus (p=0.8968). Hepatic iron staining showed blue stained hemosiderin granules within the hepatocytes, sinusoidal spaces and portal areas at 12 and 24h time points. These clearly noticeable bluish granules were directed consideration towards the storage of iron in the liver. A mild level of iron deposition was also observed at 48h time point as compared to control. These findings indicate that tacrolimus use resulted in hepatotoxicity and causes iron overload in hepatic cells of wistar rats.

Apoptosis Signal-Regulating Kinase 1 (ASK1) is a novel regulator of heparin-induced thrombocytopenia and thrombosis in mice.
P. Patel1, Y. Zhou1, S. McKenzie1, U. Naik1;
1Cardeza Foundation for Hematologic Research and Center for Vascular Biology Research, Department of Medicine, Thomas Jefferson University, Philadelphia, PA

Heparin-induced thrombocytopenia and thrombosis (HITT) is a life-threatening (20-30% mortality risk) disease in which IgG antibodies against the heparin-PF4 complex bind and activate platelets via FcγRIIA. Our laboratory has identified that the Apoptosis Signal-Regulating Kinase (ASK1), a MAP3K, is present in both human and murine platelets and potentiates many platelet functions. Given that ASK1 regulates platelet function, and that platelets are known to play a major role in the pathogenesis of HITT, we hypothesized that ASK1 is a novel regulator of HITT.
To establish if ASK1 is activated downstream of FcγRIIA, we first stimulated washed human platelets with anti-CD9 (700ng/mL). Anti-CD9 induces the activation of FcγRIIA. We found that anti-CD9 induced a robust activation of ASK1, as measured by phosphorylation of ASK1 Thr845 (a marker of ASK1’s kinase activity). ASK1 exclusively activates p38 in platelets; therefore we also measured phosphorylation of p38 a marker of ASK1’s signaling activity. We found that anti-CD9 also induced a robust phosphorylation of p38.
To determine the role ASK1 plays in platelet-FcγRIIA signaling and HITT, we crossed Ask1−/− mice to FcγRIIA+/+ (hFcR) mice. We found that genetic ablation of Ask1 did not have any effect on anti-CD9-induced activation of PLCγ2 or Syk in hFcR/Ask1−/− (KO) platelets compared to hFcR/Ask1+/+ (WT).
However, loss of Ask1 did result in the complete absence of p38 activation in KO platelets following activation of FcγRIIA by anti-CD9 (500ng/mL). Further, we observed that anti-CD9-induced integrin αIIbβ3 activation, α-granule secretion, and platelet aggregation were all significantly attenuated in KO platelets.

Monday-531
(P<0.01). These in vitro results strongly suggested that ASK1 plays a prominent role in FcγRIIA-mediated platelet activation.

To further investigate the role of ASK1 in HITT pathogenesis, WT and KO mice were subjected to an in vivo model of HITT by injecting anti-CD9 IgG. Platelet counts were measured in samples of whole blood collected at various time points post-injection, and compared to resting platelet counts taken before HITT was initiated. We found that KO mice were significantly (P<0.01) protected from thrombocytopenia compared to WT mice when injected with 250μg/kg anti-CD9. However, when injected with 500μg/kg anti-CD9, both WT and KO mice displayed the same level of thrombocytopenia. Despite not protecting from thrombocytopenia, when observed for signs of shock, we found that KO mice were significantly (P<0.01) protected from anti-CD9 induced shock compared to WT mice regardless of the dose.

Taken together these in vitro and in vivo data strongly suggest that ASK1 regulates FcγRIIA-mediated platelet activation, and that ASK1 plays a key role in the pathogenesis of HITT.

Vitronectin regulates the fibrinolytic system and inflammation during the repair of cerebral cortex in stab-wounded mice.
K. Hashimoto1,2,3,4, M. Tanabe4, N. Ikeda1, M. Nakashima1,3, H. Ikeshima-Kataoka5,6, Y. Miyamoto1,3,4;
1Graduate School of Humanities and Sciences, Ochanomizu University, Tokyo, Japan, 2Research Fellow of Japan Society for the Promotion of Science, Tokyo, Japan, 3Institute for Human Life Innovation, Ochanomizu University, Tokyo, Japan, 4Program for Leading Graduate Schools, Ochanomizu University, Tokyo, Japan, 5Faculty of Science and Engineering, Waseda University, Tokyo, Japan, 6Department of Pharmacology and Neuroscience, Keio University School of Medicine, Tokyo, Japan

Vitronectin (VN), one of the serum proteins, is known to be involved in the regulation of blood coagulation, fibrinolysis, and cell migration. It has been proposed that the regulation of fibrinolysis by VN promotes the blood brain barrier (BBB) recovery from brain injuries such as traumatic injury and subarachnoid hemorrhage. However, the effects of VN on fibrinolysis in the injured brain remain unclear. Here, we examined the effects of VN on the fibrinolytic system in the stab-wounded cerebral cortex of VN-knockout (KO) mice. First, hemorrhage and recovery from BBB breakdown in the wounded regions were assessed by serum immunoglobulin G (IgG) extravasation. The level of IgG extravasation increased 3–7 days after the stab wound (D3–7) in the cortex of VN-KO mice, compared with that in wild type (WT) mice, indicating that VN deficiency inhibited the recovery from BBB breakdown. VN deficiency decreased fibrin fiber deposition at D1–3, suggesting that VN deficiency tilts the balance between fibrinogenesis and fibrinolysis towards fibrinolysis. Next, the effects of VN deficiency on the fibrinolytic factors were analyzed in the stab-wounded cortex. VN deficiency impaired the activity of plasminogen activator inhibitor-1 (PAI-1), an inhibitor of the fibrinolytic system, at D3–5. Moreover, VN deficiency up-regulated the mRNA and protein expression levels of tissue-type plasminogen activator (tPA), and urokinase-type plasminogen activator (uPA). Furthermore, we examined whether VN regulates the activity of astrocyte, which plays an important role in the recovery of BBB. To address this problem, we analyzed the expression level of GFAP in stab-wounded VN-KO mice. The expression level of GFAP mRNA was increased in VN-KO mice at D5, compared with that of WT mice. Then, immunostaining of GFAP around the lesion showed that activity of GFAP was increased in VN-KO mice at D3 - D7. It was suggested that VN regulates the expression level of astrocyte in the wounded cerebral cortex. Moreover, we analyzed the effect of VN loss on the mRNA expression level of pro-inflammatory cytokines, IL-1beta, TNFalpha, and IL-6 in the lesion at D0-7. These cytokine expression profiles in VN-KO mice were increased from these of WT mice, suggesting that VN deficiency affects the inflammation
after the stab wound. These results demonstrate that VN contributes to the regulation of the fibrinolytic system and the inflammation, and recovery from BBB breakdown in the wounded brain.

Neuropeptide Y induces hematopoietic stem/progenitor cell mobilization by regulating matrix metalloproteinase-9 activity through Y1 receptor in osteoblasts.
H. Jin¹, M. Park², J. Bae³, J. Lee², M. Jeong², S. Han³;
¹College of Veterinary Medicine, Kyungpook National University, Daegu, Korea, South, ²Physiology, Kyungpook National University School of Medicine, Daegu, Korea, South

Hematopoietic stem/progenitor cell (HSPC) mobilization is an essential homeostatic process regulated by the interaction of cellular and molecular components in bone marrow niches. It has been shown by others that neurotransmitters released from the sympathetic nervous system regulate HSPC egress from bone marrow to peripheral blood. In this study we investigate the functional role of neuropeptide Y (NPY) on this process. NPY deficient mice had significantly impaired HSPC mobilization due to increased expression of HSPC maintenance factors by reduction of matrix metalloproteinase-9 (MMP-9) activity in bone marrow. Pharmacological or endogenous elevation of NPY led to decrease of HSPC maintenance factors expression by activating MMP-9 in osteoblasts, resulting in HSPC mobilization. Mice in which the Y1 receptor was deleted in osteoblasts did not exhibit HSPC mobilization by NPY. Furthermore, NPY treatment in ovariectomized mice caused reduction of bone loss due to HSPC mobilization. These results suggest a new role of NPY on HSPC mobilization, as well as the potential therapeutic application of this neuropeptide for stem cell-based therapy.

Partial Refractoriness of Platelets in Thrombotic Conditions.
A.D. Peshkova¹, G. Le Minh ¹, I.A. Andrianova¹, J.W. Weisel², R.I. Litvinov²;
¹Institute of Fundamental Medicine and Biology, Kazan Federal University, Kazan, Russia, ²Department of Cell and Developmental Biology, University of Pennsylvania School of Medicine, Philadelphia, PA

Platelets, the smallest blood cells, play a crucial role in formation of thrombi associated with hemodynamic disorders and dysfunction of tissues and organs. In addition to the pro-coagulant membrane surface of activated platelets and their ability to adhere and aggregate, platelets can cause a volume shrinkage (contraction or retraction) of blood clots, driven by the contractile forces generated by activated platelets attached to fibrin fibers. Any changes in platelet count and functionality can lead to an increase or decrease of the risk of thrombosis and affect its course and outcome. The aim of this study was to assess the functional state of platelets in patients with venous thromboembolism (VTE) and arterial thrombosis, such as acute ischemic stroke (AIS). Platelets were isolated from the blood plasma by gel filtration. Using scanning electron microscopy, morphological signs of activation of platelets isolated from 4 patients with VTE, 6 patients with stroke and 7 healthy donors were examined. At least 10 randomly selected fields were analyzed for each platelet preparation and a total of 4211 individual cells from VTE patients, 892 cells from AIS patients, and 791 cells from healthy donors were examined. The functional state of quiescent and activated platelets was evaluated using flow cytometry by the expression of P-selectin (probed by fluorophore-labeled antibodies to CD62p) and the active αIIbβ3 integrin (probed using fluorophore-labeled fibrinogen) before and after addition of the thrombin receptor-activating peptide (TRAP). The fractions of platelets with morphological signs of activation
(formation of filopodia, loss of the discoid shape) were much greater in patients with VTE (75%) and AIS (34%) compared to healthy donors (9%, p <0.0001). Flow cytometry revealed that platelets both from the AIS and VTE patients displayed a reduced response to stimulation by TRAP. The fractions of TRAP-activated platelets expressing P-selectin in AIS (71±7%) and VTE (30±7%) were significantly smaller compared to normal platelets (84±4% P<0.0001). The fractions of stimulated cells expressing the fibrinogen-binding active αIIbβ3 integrin (43±7% in AIS and 41±8% in VTE) were also significantly smaller compared to TRAP-activated normal cells (60±7% p <0.01). The results show that platelets in thrombotic conditions, such as VTE and AIS, undergo chronic continuous activation, which can lead to their exhaustion and secondary dysfunction manifesting as the reduced responsiveness to a chemical stimulus, i.e., partial refractoriness and a decrease of the overall activation potential. A non-saponin fraction from Korean red ginseng prevents TNF-α-induced muscle atrophy via regulation of Akt/mTOR signaling in C2C12 myotubes.
M. Yeom1, D. Cho2, D. Hahn1,3;
1Acupuncture and Meridian Science Research Center, College of Korean Medicine, Kyunghee University, Seoul, Korea, South, 2Department of Biomedical Science, Graduate School, Kyunghee University, Seoul, Korea, South, 3Department of Physiology, School of Medicine, Kyunghee University, Seoul, Korea, South

Korean red ginseng is a representative tonic herbal medicine that help to strengthen body muscles and bones making them stronger. In this study, we investigated the effects of a non-saponin fraction from Korean red ginseng (RGNSF) on muscle atrophy and the underlying mechanisms involved. Tumor necrosis factor alpha (TNF-α)-induced myotube atrophy was accompanied by increased muscle specific ubiquitin E3 ligase markers, such as, Atrogin-1 and myostatin, and decreased MyoD in C2C12 myotubes. Co-treatment of RGNSF with TNF-α was significantly inhibited TNF-α-induced myotube atrophy in C2C12 myotubes. Consistent with these results, RGNSF effectively prevented atrogines atrogin-1 and muscle RING-finger protein 1 upregulations by TNF-α, and increased the expression level of myoblast differentiation markers (myoD and myogenin). Furthermore, RGNSF also resulted in the upregulation of the phosphorylation of Akt and mammalian target of rapamycin (mTOR). These findings suggest that RGNSF prevents TNF-α-induced muscle atrophy via regulation of Akt/mTOR signaling pathway, suggesting that RGNSF is invaluable for the development of therapeutic medicines to prevent disuse muscle atrophy and its accompanying muscle weakness.

Transmembrane BAX Inhibitor Motif-6 (TMBIM6) protects against Cisplatin-induced testicular toxicity.
H.K. Kim1, R.K. Yadav1, K.R. Bhattacharai1, H.W. Jung1, H.R. Kim2, H.J. Chae1;
1Pharmacology, Chonbuk National University, Jeonju-si, Korea, South, 2Graduate School, DGIST, Jeonju-si, Korea, South

Study question: What is the molecular mechanism by which cisplatin causes reproductive toxicity?
Summary answer: TMBIM6 protects against cisplatin-induced testicular toxicity through heme oxygenase-1 (HO-1)–associated ROS inhibition. Moreover, TMBIM6 maintains the levels of steroidogenic enzymes through control of ER redox balance and its associated ER stress.

What is known already: Testosterone production is highly suppressed as a main complication of cisplatin (cis-diaminedichloroplatinum) anticancer therapy.

Study design, size, and duration: After exposure to cisplatin for 3 days, testis and serum were collected from Tmbim6 knock-out (KO) and wild type (WT) mice. In the Tmbim6-lentivirus-mediated testicular expression-rescued KO mice, phenotypes were analyzed. Tmbim6-expressing TM3 mouse Leydig cells were also used in this study.

Participants/materials, setting, and methods: In this study, 8- to 10-week-old Tmbim6 KO and WT male mice received cisplatin (30 mg/kg, single IP). On the 3rd day, blood and testis tissue samples were collected. Testosterone level and testicular weight and structure were compared between the groups. Quantitative PCR, immunoblot, and assays for ROS, HO-1 activity, and PDI carbonylation were performed.

Main results and the role of chance: p-Akt, Nrf2, and its downstream heme oxygenase-1 (HO-1) and the levels of testosterone synthesis-associated enzymes, including steroidogenic acute regulatory protein (StAR), a rate limiting enzyme for testosterone production, were significantly expressed and maintained in the presence of Tmbim6. Excessive post-translational oxidation of protein disulfide isomerase (PDI), altered folding capacitance and ROS accumulation, and ER stress were also regulated in the presence of Tmbim6. Higher levels of ER stress and protein hypercarbonylation were consistently observed in KO testes compared with WT testes. In the Tmbim6 KO mice, lentivirus-mediated testicular expression of Tmbim6 rescued the above phenotypes. Furthermore, the regulatory role of Tmbim6 against testis toxicity was consistently shown in Tmbim6-overexpressing TM3 Leydig cells, testosterone producing cells. In this study, TMBIM6 is suggested to have a regulatory role against cisplatin-induced testis toxicity by inducing HO-1 and enhancing ER folding capacitance.

Wider implications of the findings: The findings implicate cisplatin as having a role in organ toxicity, including that of the kidney. Furthermore, ER stress and redox imbalance should be considered as other anticancer therapy-associated toxicity mechanisms.

Immune Enhancement of Fucoidan in Raw264.7 cells.
H. Kim1, H. An1, S. Ahn1, S. Yu1;
1Department of Microbiology Immunology, Pusan National University School of Medicine, Yangsan, South Korea

For a long time, some types of brown algae have been a regular part of the diet in many Asian countries, especially Japan and Korea. Fucoidan is a complex sulfated polysaccharide which is found in the cell walls of several edible brown algae. The compositions and structure of fucoidan vary among different brown seaweed species. But generally the compound consists primarily of L-fucose and sulfate, along with small quantities of D-galactose, D-mannose, D-xylene, and uronic acid. Many previous reports have shown that fucoidan exerts anti-bacterial, anti-viral, anti-coagulant, anticancer, antioxidant, anti-inflammatory, and immunomodulatory effects. We experimented with fucoidan samples separated into 80-90 kDa and 200 kDa (or more). We treated fucoidan in Raw264.7 at different concentrations and measured nitric oxide production using Griess Reagent. As a result, nitric oxide production increased at treatment of 200 kDa (or more) fucoidan, meaning that Raw264.7 cells were differentiated into M1 type macrophages. Based on this, mRNA and cytokines such as IL-1β, IL-6, IL-10 and TNF-α were measured in

Monday-535
supernatants of Raw 264.7. We also confirmed COX2 and NF-kB protein expression. Taken together, fucoidan could be used a potential nutrition therapeutic agent for immune deficiency patients.

In vivo cellular reprogramming to restore respiratory function after SCI.
S. Fernandes¹, L.V. Zhoduleva¹, M.A. Lane¹, P.W. Baas¹, L. Qiang¹;
¹Neurobiology and Anatomy, Drexel University College of Medicine, PHILADELPHIA, PA

The injured adult mammalian spinal cord is incapable of significant repair. This limitation is due in part to two major neuropathological consequences of spinal cord injury (SCI): i) the formation of growth-inhibitory glial scars, of which activated astrocytes are a key component, and ii) the destruction of intraspinal neuronal connectivity, contributed to by the loss of the interneurons in the spinal circuitry. Previous cell-based strategies have traditionally been focused on transplantation of various neural stem cells into the injury site to replace lost neurons, improve the inhibitory environment and modulate inflammation; however, there are significant hurdles to their applications. For example, obtaining sufficient amounts of purified cells for transplantation may be difficult; the procedure often requires the use of immuno-suppression, which has detrimental effects on the host; and successful implementation of such a strategy needs to address the challenges of cell survival and appropriate cell differentiation without formation of tumors. Here we applied an in vitro and in vivo direct conversion strategy to reprogram activated astrocytes to potential functional interneurons by introducing into the injured site a single lentiviral vector encoding Ascl1, which serves as a major neurogenic regulator CNS interneurons. Our in vitro data revealed that Ascl1 is a potent reprogramming factor that was able to convert more than 40% of the activated astrocytes into functional neurons in cultures. These cells not only were stained positive for pan-neuronal markers, but also were mature enough to bear typical neuronal electrophysiological properties. Successful in vivo conversions in adult rats were also achieved using the same strategy, yet with a much more diminished efficiency (On average, 4 converted neurons from each animal were identified) 6 weeks after the viral injection followed by the contusive cervical SCI. As we expected, functional examinations such as plethysmography and terminal diaphragm electromyography showed no significant improvement. However, a substantial reduction of the glial scars was identified in Ascl1 treated animals. Based on the data obtained so far, we posit that to achieve more efficient in vivo conversions, a longer duration may be required following the viral injection. Despite the lack of functional recovery from our current treatment strategy for SCI, our pilot study serves as a proof-of-concept for its potential translational applications. Meanwhile, we are adjusting our viral content in order to achieve a more efficient in vivo conversion for SCI therapies. (This work was funded by a grant from the Craig H. Neilsen Foundation to LQ).

The study of new quaternary ammonium compounds specific activity to gram positive and gram negative bacteria in vitro and in vivo.
M. Agafonova¹, R. Kazakova¹, A. Lyubina¹, N. Shtyrlin¹, M. Zeldi¹, Y. Shtyrlin¹;
¹Scientific and Educational Center of Pharmaceutics, Kazan (Volga region) Federal University, Kazan, Russia

Prevention and successful treatment of infectious diseases are the critical aspects of modern healthcare. Quaternary ammonium compounds (QAC) are currently one of the promising classes of antiseptics and
disinfectants. However, its common use for medical application is limited due to bacterial resistance to these compounds. Development of new antimicrobial agents by functionalization of QACs with different substituents can solve this problem. In this work, we studied new potential antiseptics based on quaternary ammonium pyridoxine derivatives. As part of this study, in vitro and in vivo bactericidal activity of the obtained compound against gram-positive (Staphylococcus aureus ATCC209p) and gram-negative (Escherichia coli CDCF-50) bacteria in comparison with benzalkonium chloride, miramistin and chlorhexidine digluconate was evaluated. The mechanisms of membrane-damaging action of these compounds and their influence on intracellular processes of bacterial cells were also studied. Bactericidal efficacy of quaternary ammonium pyridoxine derivatives against several museum strains of microorganisms was evaluated by serial dilution method, quantitative suspension test method, metal surface disinfection test, and in vivo rat skin test. For all compounds a relatively high bactericidal activity against gram-positive and gram-negative bacteria has been observed. The ability of the obtained compounds to change the electric potential of the bacterial membrane was studied using membrane-potential-sensitive cyanine dye DIOC2(3). Outer membrane permeability activity of gram-negative bacteria was determined using a fluorescent assay with N-phenyl-1-naphthylamine dye. It was demonstrated that the treatment by the studied compounds led to rapid and dramatic damage in structure of the bacterial membrane. In particular, a concentration-dependent response in permeabilizing the outer membrane was observed. It was also established that the synthesized compounds can cause/initiate strong depolarization of bacterial membrane. The obtained results suggest that the developed compounds are promising candidates for development of promising antiseptics and disinfectants.

Ametryn causes alterations of the prostatic components percentage of adult Wistar rats.
L. Cuquetto-Leite¹, F.J. Paiva da Silva¹, C. Capucho¹, I.B. Reis², K.M. Freitas², M.H. Dolder¹;
¹Department of Structural and Functional Biology, University of Campinas, Campinas, Brazil, ²Brazilian Agricultural Research Corporation, Embrapa, Seropédica, Brazil

Recently, investigations of the association of various diseases to environmental and/or occupational exposures to pesticides have increased substantially. Ametryn is one of the most widely used herbicides in the world, probably because of the excellent performance of its selective effect on weeds. However, knowledge of its effect on reproductive parameters is still scarce. Several natural compounds are traditionally used in popular medicine. Many have shown antitumor and antioxidant properties. Brazilian green propolis is a natural compound widely used by local populations and has been shown to act as an effective anti-free radical agent, DNA protector and immune system stimulant. Thus, the present study evaluated, through morphometric, stereological and biochemical analyses, the effect of ametryn herbicide on the prostate of adult Wistar rats and the possible protective effect of green propolis on the prostate in these rats treated with ametryn. 36 animals were used, distributed equally in 3 groups: C (control), A (ametryn), P+A (propolis + ametryn). The C group received distilled water (0.5 ml), whereas A group received ametryn (15 mg/kg/day) and P+A group received propolis and ametryn (6 and 15 mg/kg/day, respectively), all by gavage. The animals received commercial rat chow and water ad libitum and after 56 days, the animals were euthanized, the ventral prostate was collected, weighed and processed for histological analysis. Subsequently, it was photographed with a camera attached to a light microscope (Olympus BX-40). Morphometric and stereological analyses were performed with IMAGE PRO PLUS 6.0 software. Blood was collected in a vacuum tube (Vacuette) with a separator gel and centrifuged for serum separation, the samples were refrigerated (2 to 8°C) until analysis. Total serum PSA and testosterone levels were measured by the ELISA technique. All statistical analyses were
performed with PRISM 5 STATISTIC Program. No significant differences of PSA hormone or ventral prostrate weight were found for the groups evaluated. These results are consistent with the measurement of testosterone levels, which were also not significantly altered. Stereological evaluation showed a significant reduction in volumetric ratio (%) of Muscular Stroma found by comparing the A and P+A groups with the C group. Thus, it can be affirmed that the ametryn treatment used in this experiment, significantly affects rat’s prostatic tissue, therefore could cause reproductive abnormalities in males. Green propolis has no protective effect on the damage caused by ametryn.

Expansion of the polyglutamine (polyQ) stretch within the first exon of the huntingtin protein (Httex1) above 36-37 glutamines leads to Huntington’s disease (HD). The existence of a pathogenic polyQ-length threshold has led to the hypothesis that monomeric Httex1 undergoes a sharp conformational change when the polyQ length crosses 36-37 residues. Poor solubility of Httex1 has prevented the testing of this hypothesis using high-resolution structural studies. We overcome this limitation by performing single molecule Förster resonance energy transfer measurements on site-specifically labeled Httex1 proteins of five different polyQ lengths. By integrating the results of these measurements with atomistic simulations, we find that irrespective of polyQ length, monomeric Httex1 adopts tadpole-like architectures. Our results argue against a sharp, polyQ-length-dependent conformational change within monomeric Httex1 — a result that is further supported by hydrogen-deuterium exchange mass spectrometry experiments. Instead, we propose that the continuous increase in surface area of the polyQ domain with increasing polyQ length modulates the drive to form homotypic and heterotypic interactions. Particularly, we find that increasing the polyQ length decreases the concentration threshold at which Httex1 aggregation is observed. Together these results suggest structure-based drug design is a challenging route to pursue for HD therapeutics. Alternatively, specifically targeting distinct aggregation phases has the possibility to homogenize the underlying aggregation distribution and shift the distribution away from toxic species. Profilin, an abundant cellular protein, has been shown to reduce Httex1 aggregation and toxicity in cells. We find that profilin reduces Httex1 aggregation by preferentially binding and thus stabilizing one of Httex1’s soluble aggregation phases. This result suggests that the use of ligands to shift phase boundaries might be a promising route to designing therapeutics for treating diseases associated with protein aggregation.

Human adipose-derived multipotent mesenchymal stromal cells as a new target for a cell-mediated drug delivery.

L.S. Litvinova¹, V.V. Shupletsova¹, O.G. Khaziakhmatova¹, K.A. Yurova², V.V. Malashchenko³, N.M. Todosenko¹, A.S. Timin², V.L. Kudryavtseva², G.B. Sukhorukov²,³, A.J. Gow²,⁴, E.N. Atochina-Vasserman²,⁵, I.A. Khlusov¹,⁶,⁷;
¹Department of Immunology and Cell Biotechnology, Immanuel Kant Baltic Federal University, Kaliningrad, Russia, ²RASA Center in Tomsk, Tomsk Polytechnic University, Tomsk, Russia, ³School of Engineering and Materials Science, Queen Mary University of London, London, United Kingdom, ⁴Department of Pharmacology and Toxicology, Rutgers University, Piscataway, NJ, ⁵RASA Center, Kazan Federal University, Kazan, Russia, ⁶Department of Morphology and General Pathology, Siberian State Medical University, Tomsk, Russia, ⁷Department of Polymers and Composite Materials, Tomsk State University, Tomsk, Russia

Rationale: Lately, a number of preclinical and clinical studies have demonstrated the efficiency of mesenchymal stromal cells to serve as an excellent base for a cell-mediated drug delivery system. Cell-based targeted drug delivery has received much attention as a delivery systems to facilitate the incorporation and transfer of active substances to specific organs and tissues with high efficiency. Human adipose-derived multipotent mesenchymal stromal cells (AMMSCs) represent an ideal target cell because of their ease of isolation and phagocytic function.

Methods: AMMSCs were isolated from the adipose of healthy donors with signed informed consent according to the guidelines approved by the Ethics Committee, Immanuel Kant Baltic Federal University (Kaliningrad, Russian Federation). Isolated AMMSCs in culture exhibited positive staining for osteoblast, chondroblast and adipocyte markers, confirming their origin. Capsules, with average size of 5 microns were made using alternated adsorption of polyelectrolytes (calcium carbonate) to generate microparticles labeled by FITC-BSA. The isolated AMMSCs were incubated with FITC-labeled capsules at various ratios for 16 hrs, then cells were either analyzed for surface markers by flow cytometry or were cultured for up to 190 hrs. Cultured cells were enumerated and analyzed for viability, motility and phagocytosis using Cell-IQ v2 MLF integrated platform for a continuous real-time phase-contrast imaging. AMMSCs incubated with FITC-labeled antibodies to CD90 were used as control.

Results: AMMSCs incubated with FITC-capsules at ratio 1:5, 1:20 and 1:45 did not change their phenotype profile, however at ratio 1:90 cells shifted their phenotype towards macrophages (increased CD45, CD34, CD14, CD20 and decreased CD90, CD105, CD73). FITC-capsules were taken up by AMMSCs cells at all time points up to 30 hrs. Cell motility (pxl/h) was capsules-loading dependent. Cells with ratio 1:45 capsules per cell exhibited 94, 90, 88 % and cells with ratio 1:90 exhibit 89, 87 and 84 % of motility from control for 2, 6 and 10 hours incubation post phagocytosis, respectively.

Conclusions: Here we identified that human AMMSCs can be efficiently labeled with microencapsulated FITC-BSA with up to 90 capsules per cell. Further, capsules loaded cells can survive up to 6 days in vitro, maintaining their motility up to 30 hrs post phagocytosis. Thus, the strategy of using AMMSCs cells as a drug delivery vehicle across the tissue-blood or tumor-blood barrier to facilitate treatment of stroke, cancer or inflammatory diseases may open a new prospective therapeutic approach.

Ultrastructural studies of phagocytosis of synthetic microcapsules by human polymorphonuclear leukocytes.

T.A. Nevzorova1, M.Y. Nikitina1, A.A. Ponomareva1, Y.V. Tarakanchikova2, A.J. Gow3,4, G.B. Sukhorukov4,5, E.N. Atochina-Vasserman1,4, R.I. Litvinov1,6;

1RASA Center, Kazan Federal University, Kazan, Russia, 2Saratov State University, Saratov, Russia, 3Department of Pharmacology and Toxicology, Rutgers University, Piscataway, NJ, 4RASA Center in Tomsk, Tomsk Polytechnic University, Tomsk, Russia, 5School of Engineering and Materials Science, Queen Mary University of London, London, United Kingdom, 6Perelman School of Medicine, University of Pennsylvania, Philadelphia, United States

Rationale: Neutrophils or polymorphonuclear leukocytes (PMNLs) are the most abundant leukocytes in human blood and are potential carriers of diagnostic or therapeutic agents to areas of acute inflammation. A neutrophil-based drug delivery system, therefore, has great potential for the treatment of several types of brain disorders that involve neutrophil infiltration, such as multiple sclerosis, Alzheimer’s disease, stroke and traumatic brain injury.

Methods: Human PMNLs were isolated from the blood of healthy donors with signed informed consent according to the guidelines approved by the Ethical Committee of Kazan State Medical Academy (Kazan, Russian Federation). Capsules with an average size of 2 microns were fabricated using alternating adsorption layers of polyelectrolytes onto calcium carbonate micro-particles used as a sacrificial template. Capsule shells were labelled either with FITC-BSA or with gold nanoparticles incorporated in between polyelectrolyte layers. The isolated PMNLs were enumerated and then incubated with labeled capsules at various cell/capsule ratios ranging from 1:1 to 1:10 for 20 minutes at 37°C. Immediately after incubation, the cells were washed with cold phosphate-buffered saline and collected by centrifugation. PMNL incorporation of capsules was analyzed by flow cytometry and transmission electron microscopy.

Results: Flow cytometry analysis of PMNLs demonstrated successful intracellular capsule incorporation at all ratios, with maximum yield at a cell/capsules ratio of 1:6. Transmission electron microscopy demonstrated that 1-5 capsules were observed per cell and appeared as variable oval (deformable) structures ~0.5-2.5 µm in size with an electron-dense contour. Some capsules were located inside phagolysosomes, while others were in the cytosol. At a cell/capsule ratio of 1:5 or less various signs of cell damage were observed, such as reduction of microvilli, rounding of the cell contour, condensation of heterochromatin in the nucleus, and partial disintegration of the plasma membrane.

Conclusions: Here, we have demonstrated that capsules can be successfully incorporated into human PMNLs. Further, we have established the appropriate conditions to maximize the internalization without damaging cell integrity. These steps establish the possibility of using patient-derived neutrophils as a vehicle for microencapsulated drug delivery. This may be a promising strategy for targeted therapies in human diseases in which PMNLs play a role, such as stroke and traumatic brain injury.

Inhibitory effects of oleuropein on interleukin-4-induced asthmatic inflammation and emphysema in a smoke/OVA mouse model.
Y. Kim¹, Y. Kang¹;
¹Food science and Nutrition, Hallym University, Gangwon-do, South Korea

Chronic obstructive pulmonary diseases such as chronic bronchitis and emphysema are progressive lung diseases characterized by irreversible airflow obstruction and chronic inflammation of the airways. The current study investigated that oleuropein, a phenylethanoid found in olive leaves, inhibited eosinophilic airway inflammation and emphysema in interleukin (IL)-4-exposed airway epithelial cells and in cigarette smoke/OVA-exposed BALB/c mice. Nontoxic oleuropein at 1-20 μM attenuated the induction of eosinophil chemotactic protein eotaxin-1 and its receptor CCR3 in 50 ng/ml IL-4-stimulated epithelial cells. The IL-4 production and CCR3 induction increased in smoke/OVA-induced emphysema. Oral supplementation of 10-20 mg/kg oleuropein reduced the number of eosinophils and neutrophils elevated in bronchoalveolar lavage fluid of cigarette smoke/OVA-exposed mice. In addition, oleuropein suppressed the induction of CD11b(+), F4/80(+) and mucin SAC with inhibition of small airway destruction in cigarette smoke/OVA-exposed mouse airways and lungs. These results demonstrated that oleuropein inhibited eosinophilia and inexorable emphysema associated with asthmatic inflammation prompted by cigarette smoke and OVA irritants. Therefore, oleuropein may be a potential agent targeting against inflammation-associated obstructive pulmonary disease.

Developing Novel Inhibitors of Gamma-Glutamyl Transpeptidase.
M.H. Hanigan¹, N. Wakeham¹, B.H. Mooers², S.S. Terzyan³;
¹Cell Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, ²Biochemistry and Molecular Biology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, ³Laboratory of Biomolecular Structure and Function, University of Oklahoma Health Sciences Center, Oklahoma City, OK

Inhibitors of gamma-glutamyl transpeptidase (GGT1, a.k.a. gamma-glutamyl transferase) are being sought due to their therapeutic potential in the treatment of asthma, reperfusion injury, cardiovascular disease and cancer. GGT1 is a cell surface enzyme that cleaves extracellular gamma-glutamyl compounds including oxidized and reduced glutathione and glutathione S-conjugates. Among the many substrates of GGT1 is leukotriene C₄, which GGT1 metabolizes to leukotriene D₄, a potent mediator of inflammation. GGT1 on the surface of the renal proximal tubules functions in the reclamation of cysteine from glutathione as the blood is filtered through the kidney, and metabolizes glutathione S-conjugates as part of the mercapturic acid pathway. The inhibitors of GGT1 that have been evaluated in the clinic are glutamate analogs and are too toxic for clinical use. To pursue a structure-based drug-design strategy in the development of less toxic inhibitors, we determined the first crystal structure of human GGT1 (hGGT1). We have co-crystallized human GGT with a series of compounds that bind within the active site and identified residues within the active site that are critical for inhibitor binding. We are developing new classes of GGT inhibitors that are not glutamate analogs. These structural data provide new insights for continued development of a potent, specific, non-toxic inhibitor of GGT that can be used clinically. Supported by an Institutional Development Award (IDeA) from the National Institutes of Health under grant P20GM103640.

Differentiation of human induced pluripotent stem cells (hiPSCs) with a 57 kb ctns deletion.
M.L. Taub1, R. Thiyagarajan1, R. Duve2, J. Mulkin1, A. Kocaj1;
1Biochemistry, University at Buffalo, Buffalo, NY

Cystinosis is an autosomal recessive disease caused by mutations in the ctns gene, which encodes for cystinosin, a membrane transport protein responsible for the extrusion of cystine from lysosomes. In cystinosis, the cystine levels increase in all cells in the body due to defective cystinosin function. However, infantile cystinosis is characterized in particular by defective renal proximal tubule (RPT) reabsorptive function. Infants with this disorder to exhibit increased urination, thirst, dehydration, and ultimately a limited lifespan. To develop new therapies, we developed hiPSCs from cystinotic fibroblasts with a 57 kb deletion in ctns (as well as normal counterparts), having transduced the fibroblasts with 3 vectors (pCXLE-hUL encoding for L-myc and Lin28; pCXLE-hSK encoding for Sox2 and Klf4, and CXL encoding for Oct3/4). The resulting normal and cystinotic hiPSCs exhibited a morphology typical of hiPSCs, and an infinite lifespan. However, the cystinotic hiPSCs exhibit some differences, including an altered morphology, and a decreased growth rate (presumably due to oxidative stress, as indicated by their differing ascorbate requirements). Indicative of their pluripotent state, both mutant and wildtype hiPSCs not only express pluripotent markers (Oct3, Sox2, SSEA4 and Tra-1-60), but also exhibit the capacity to form embryoid bodies with 3 germ layers (as indicated by the expression of α-fetoprotein (endoderm), β3-tubulin (ectoderm), and α-smooth muscle actin (mesoderm)). Both the normal hiPSCs as well as hiPSCs with the 57 kb deletion have been differentiated into RPTs, by treatment first with CHIR99021 (to form mesoderm), then with FGF2 and retinoic acid (to form inner mesoderm), and finally with insulin and transferrin alone (to form proximal tubules) (Lam et al., JASN 25:1). RPTs derived from normal hiPSCs possess the polarized morphology and brush border typical of this nephron segment, as well as transport markers including the Sodium/Phosphate cotransport system (NPT2a), and the associated NHE3 Regulatory Factor (NHERF). While cystinotic hiPSCs have been observed to form tubule by fluorescence microscopy, the relative level of expression of transport markers including NPT2a still needs to be determined. Long-term goals include correction of the genetic defect in the ctns gene so as to achieve normal renal function in vivo.

Microencapsulation has proven to be a useful technique for the construction of drug delivery vehicles for use in vascular medicine. However, the possibility of using these techniques within the lung as an inhalation delivery mechanism has not been previously considered. A critical element of particle delivery to the lung is the degree of penetration that can be achieved with respect to the airway tree. In
this study we examined the effectiveness of labelled particles of 5, 1.3, and 0.7 μm diameter in reaching the respiratory portion of the lung. Microparticles, coated with Cy7 labelled Albumin as a model compound, were delivered to mouse lungs via tracheostomy with subsequent imaging performed 24, 48, & 72 hours after delivery by in vivo fluorescence. Subsequently the distribution of the particles 45 mins after administration was examined by serial section and S.E.M. The delivery of fluorophore to the blood was assessed using Cy7 labelled 0.7 μm particles. Pulmonary fluorescence was observable at 24, 48, and 72 hrs post administration of 0.7 μm particles, with secondary fluorescence in the kidney and liver. The predominance of fluorescence was observed in the gut following use of 5 μm particles. Biodistribution was confirmed by IVIS imaging of excised organs post 72 hrs. 45 mins post administration particles of all three sizes were visible in the lung, with the deepest penetration observed with 0.7 μm particles. S.E.M. images show 0.7 μm particles reaching the alveolar space and associating with surfactant in aggregates as large as 7.2 μm. 5 or 1.3 μm particles were only found in the upper airways. Cy7 labelled 0.7μm particles efficiently delivered fluorescent material to the blood with a peak 3 hrs after particle administration. The kinetics of delivery will be shown. These studies establish that by using 0.7 μm microencapsulation particles we can efficiently access the respiratory portion of the lung, which represents a potentially efficient delivery mechanism for both the lung and the vasculature. This work was partially supported by the Russian State project «Science», № 4.5752.2017/8.9 and by the Program for Competitive Growth at Kazan Federal University.

Overproduction of biologically active human bone morphogenetic protein-4 in Chinese hamster ovary cells.

N. HAN1, J. PI1, K. Baek1, J. Yoon1;

1Graduate School of Biotechnology, kyunghee university, yongin, South Korea

Bone morphogenetic protein-4 (BMP-4), originally identified as one of the growth factors inducing new bone formation, has been demonstrated to have therapeutic potential for various diseases including cancer. In spite of increasing demands of recombinant human BMP-4 (rhBMP-4) for therapeutic purposes, efficient production procedures of biologically active BMP-4 have not yet been developed. In the current study, a recombinant Chinese hamster ovary (rCHO) cell line overexpressing rhBMP-4 as well as a pilot scale manufacturing process using 7.5-l bioreactor (5 l working volume) were established. We selected the optimized combination of a chemically defined (CD) medium and a nutrient supplement solution for high expression of rhBMP-4 in bioreactor cultures. The production rate was 32 mg/l from the 11-day fed-batch cultures of the established rhBMP-4-expressing rCHO cells. The mature rhBMP-4 was purified to homogeneity from the culture supernatant using a two-step chromatographic procedure, resulting in a recovery rate of approximately 55% and a protein purity greater than 95%. The mature purified rhBMP-4 has been proved to be functionally active with an effective dose concentration of EC50 of 2.93 ng/ml.

Single molecule localization based super-resolution microscopy offers a unique opportunity for quantifying protein copy numbers at the nanoscale level [1,2]. While fluorescent proteins have been extensively characterized for quantitative imaging using calibration standards, similar calibration tools for small organic fluorophores used in conjunction with immunofluorescence-based super-resolution techniques are missing. The development of a suitable calibration method represents the best way to address the challenges of molecular counting using super-resolution [3,4]. Here we demonstrate that DNA origami in combination with GFP antibodies is a versatile platform for quantifying protein copy number in immunofluorescence-based super-resolution microscopy. We show that this calibration method, besides quantifying the average protein copy number in a cell, allows determining the abundance of different oligomeric states. Furthermore, we apply this calibration method to quantify nucleoporins (NUP107) [5] and molecular motors (dynein intermediate chain) [6] in vivo. Overall, we provide a versatile strategy [7] for quantifying a large number of proteins of interest using various labeling approaches.

A New Methodology for Quantitative Measurements of Single Cell Mechanics.
G. Liu1;
1Chemistry, University of California, Davis, CA

Using modified atomic force microscopy (AFM), a new method is developed for measurements of single cell mechanics as well as applying designed mechanical perturbation. Attaching a hard microsphere to an AFM probe and compressing the cell at a designated location, this method enables force-deformation profile to be measured for living cells under incubation conditions. The optical microscopy guides the location of an AFM probe and then monitors the deformation of cell shape, while micro-sphere modified AFM probes compress the cell while acquiring force-deformation profiles. In conjunction with viable mechanics models, such as Hertzian model, one could extract quantitative information such as Young’s modulus of the cellular membrane, cytoskeleton, as well as the bending constant of the membrane at single cell level. Combined multimodal imaging and analysis provide important readouts of cellular biostatus, including migration, activation, and malignancy. Combined readouts lead to a much higher degree of accuracy and completion of cellular status, and provide new insights into cellular signaling processes. This presentation will also provide several specific examples form primary cells and cell lines to demonstrate the enabling aspects and advantages of this new approach.

An algorithm to obtain blinking-corrected super-resolution images.
C.H. Bohrer1, J. Xiao1;
1Biophysics, Johns Hopkins, Baltimore, MD

In super-resolution microscopy techniques PALM and STORM, the fluorophore can stochastically switch between an activated state and dark states, leaving gaps in the temporal emission of the single molecule before photobleaching. These gaps create multiple localizations belonging to the same molecule, a phenomenon known as blinking. Blinking distorts the true image leading to the appearance of fake nanoclusters, which are often incorrectly interpreted as real biological structures. Here we present a model-free method to eliminate blinking without the need of additional experiments or arbitrary thresholds. The approach relies on the observation that the true pairwise distance distribution can be obtained using the distances of localizations separated by a time longer than the survival time of the fluorescent molecule. The approximate probability for a molecule being a blink is then determined from the deviation of the distance distributions at varying frame differences. Using this information and performing a phase space search to minimize the differences between the pairwise distance distributions for all frame differences, results in an accurate reconstruction of the true image. To test this new methodology, we used simulated PALM data with different underlying true structures and compared our methodology with traditional methods to eliminate blinking. We then applied the algorithm on real experimental data, which show identical trends as simulation, justifying the new approach.

Distinguishing Biological and Non-Biological Networks in Single Molecule Localization Super Resolution Microscopy.

I. Khater\(^1\), Y. Liu\(^2\), Q. Liu\(^3\), F. Meng\(^2\), K.C. Chou\(^3\), I.R. Nabi\(^2\), G. Hamarneh\(^1\);
\(^1\)Computing Science, Simon Fraser University, Vancouver, BC, \(^2\)Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, \(^3\)Chemistry, University of British Columbia, Vancouver, BC

Single molecule localization microscopy (SMLM) is based on the repeated activation (blinking) of small numbers of discrete fluorophores whose precise localization is determined using a Gaussian fit of the point-spread function (PSF). However, repeated blinks derived from the same molecule form non-biological nano-clusters or networks (NBNs). Distinguishing NBNs from biological networks (BNs) that reflect the distribution of component molecules of the biological structure is a major challenge for SMLM.

Importantly, in contrast to BNs, NBNs are related to the physical properties of the fluorophores and the labeling process and therefore similar and homogeneous. Further, while the number of molecules or proteins in a BN is constant, additional blinks acquired during the imaging process are centered and spread around a molecule to form a NBN with a particular spatial scale due to microscope drift and localization error. As more blinks are collected, the scale plateaus and we perform multi-scale, dynamic network analysis to estimate this scale. Spatial and iterative merging of blinks within that scale effectively eliminates repeated blinks, thereby differentiating between BNs and NBNs.

We validated our approach, first, on synthetic data. We position a set of in-silico molecules on a 3D grid and generate repeated blinks with known Gaussian distribution parameters around each synthetic molecule. The distance between the molecules is modified to mimic the different levels of overlap between neighboring molecules in real biological settings. Using our network analysis method, we retrieved the NBN scale of the repeated blinks even with moderate levels of overlap between blinks of different molecules. Applying the NBN scale in the iterative merging module accurately estimated the location of synthetic molecules on the grid. We then validated our approach using a real dataset of caveolin-1 antibody labeling of HeLa cells imaged using a home-built dSTORM microscope with real time drift-correction (Tafteh et al., Opt Exp 24:22959, 2016). After scale-detection and merging, the estimated number of caveolin-1 molecules per caveolae was on average 142, very similar to the reported 145 (Pelkmanns et al., Nature, 436:78, 2005). Multi-threshold modularity analysis of Cav1 domains in HeLa cells described the molecular structure and architecture of non-caveolar scaffolds that group together to form the caveolae coat.

Finding NBNs and their features is important for many applications in SMLM. We foresee our method being useful for molecular counting, providing non-biased bio-signatures for subcellular structures, defining imaging parameters (e.g. stopping criteria based on the saturation of the collected blinks), etc. Supported by grants from the CIHR, NSERC and CFI/BCKDF.

A Cryosectioning Technique for the Observation of Intracellular Structures and Immunocytochemistry of Tissues in Atomic Force Microscopy.
E. Usukura¹, A. Yagi², N. Sakai³, U. Yoshitsugu², Y. Imaoka², J. Usukura¹;
¹Graduate school of science, Nagoya University, Nagoya, Japan, ²Olympus, Hachioji, Japan

The use of cryosectioning enabled the morphological analysis and immunocytochemistry of cells in tissues in atomic force microscopy (AFM). The cantilever could access all parts in cryosection of a tissue sample after the embedding medium (sucrose) has been replaced with phosphate-buffered saline, and this approach has enabled the production of a type of high-resolution image. The images resembled those obtained from freeze-etching replica electron microscopy (EM) rather than from thin-section EM. In retinal tissue, the AFM images showed disks stacked and enveloped by the cell membrane in rod photoreceptor outer segments at EM resolution. In addition, three-dimensional architecture of synaptic ribbons, and the surface of the post-synaptic membrane facing the active site were revealed, which were not apparent using thin-section EM. AFM could depict the molecular binding of anti-opsin antibodies conjugated to a secondary fluorescent antibody bound to the disk membrane. The specific localization of the anti-opsin binding sites was verified through correlation with immunofluorescence signals in AFM combined with confocal fluorescence microscope. To prove reproducibility in other tissues besides retina, cryosectioning-AFM was also applied to elucidate molecular organization of sarcomere in a rabbit psoas muscle. In particular, Z-band M line and cross bridges between myosin heads and actin filaments were observed more clearly than in thin section EM.

The Stoichiometry of AMPA Receptors Measured By Single Molecule Imaging.
C. Yu¹, M.H. Ulbrich¹²;
¹BIOSS Centre for Biological Signalling Studies, Freiburg, Germany, ²Internal Medicine IV, Medical Center of the University of Freiburg, Freiburg, Germany

AMPA (α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid) receptors, which are ionotropic glutamate receptors, conduct fast excitatory synaptic transmission at the postsynaptic membrane of neurons. It is known that AMPA receptors are tetramers and are assembled from four subunits GluA1-4 either as homomers or heteromers. The assembly and the stoichiometry of AMPA receptors are fundamental to fast neuronal signal transduction. However, existing studies of AMPA receptor stoichiometry either suffered from the ensemble measurement or disrupted the functionality of the receptors. To directly measure the stoichiometry of AMPA receptors, we employed a single molecule imaging technique to count the number of different subunits labeled with different fluorescent proteins. With this method, we are able to measure the stoichiometry of heteromeric AMPA receptors at the single molecule level. We found that in GluA1/A2 heteromeric receptors, a 2:2 stoichiometry is preferred. Unlike NMDA receptors which have an obligatory heteromeric assembly, our results showed the existence of 3:1 and 1:3 stoichiometries for AMPA receptors. By measuring chimeras with swapped domains, we find that the transmembrane domain is decisive for the 2:2 preference. Our data suggests possible assembly mechanisms and helps us to understand synaptic integration in the central nervous system.

Visualization of transcriptional dynamics at single-cell resolution with a genetically-encoded fluorogenic RNA.
T. Ariyoshi1, Y. Okada1;
1QBiC, RIKEN, Suita, Osaka, Japan

Advancement of single-cell analysis techniques enabled the monitoring of the transcriptional activity at single-cell resolution. However fluorescent or luminescent protein has been mostly used for the indirect monitoring of the gene transcription living cells so far, because practical probes for direct monitoring of RNA transcription have been missing. Combinations of fluorescent protein-tagged RNA-binding proteins and RNA stem-loops, such as MS2 or PP7 stem-loop, have been developed for the visualization of RNA in living cells, but there is a drawback that their total fluorescence reflects the amount of the expressed protein, not of the target RNA. Fluorogenic RNA would be ideal for measuring the transcriptional activity, because its fluorescence signal directly reflects the amount of the target RNA. Spinach, Broccoli and their derivatives have been developed as fluorogenic RNAs that emits green fluorescence upon binding to a small molecule 3,5-difluoro-4-hydroxybenzylidene imidazolinone (DFHBI). However, their application was limited, mainly because their fluorescence signal was too weak to detect mRNA in living mammalian cells. Here we report a new fluorogenic RNA probe Romanesco, an improved version of Broccoli. The improved brightness of Romanesco enabled us to measure transcription activity in living mammalian cells in culture. Reporter constructs that contains a coding sequence of iRFP followed by Romanesco at the 3′ end successfully reported the rise and fall of green fluorescent signal from Romanesco reflecting the promoter activity, while the iRFP signal was delayed. The linearity of Romanesco signal was verified by qPCR analysis, but the iRFP signal intensity was not proportional to the Romanesco signal, which would demonstrate the cell-to-cell variance in the translational activity. Transcriptional activity of endogenous genes was also visualized by knocking-in Romanesco at the 3′-UTR of the target genes. Furthermore, the subcellular localization of the fluorescent signal visualized the RNA translocation from nucleoplasm to cytoplasm as well as the accumulation of newly synthesized RNA molecules around the nuclear speckles. Thus, Romanesco would serve as a versatile visualization probe for the transcription, dynamics and localization of RNA in living cells.

Single-molecule Fluorescent Amplification of RNA using ClampFISH Probes.
S.H. Rouhanifard1, A.J. Cote2, B. Emert3, I. Mellis1, A. Raj1,2;
1Bioengineering, University of Pennsylvania, Philadelphia, PA, 2Genetics, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA

RNA signatures can be used to define cell types, cell states, and disease phenotypes. However, RNA expression within a given cell population is heterogeneous and these differences can be important for cellular function. The ability to separate cells based on their RNA signatures would provide sufficient material to perform biochemical assays that will help to tease out the functional differences between cells. However, the current state of RNA imaging technology (i.e. single-molecule FISH) provides signal that is too weak for current separation methods such as flow cytometry. We present a new method for the fluorescent detection of RNA that combines the specificity of oligonucleotides and bioorthogonal click chemistry in order to achieve highly specific and high-gain signal amplification. Using this method, we have achieved >400-fold signal amplification of individual transcripts while maintaining minimal off-
target binding. The signal intensity is so strong that it can detect and separate cells based on RNA signal using flow cytometry and low-magnification microscopy, enabling the analysis and separation of large numbers of cells. This method circumvents enzyme-based amplification schemes that suffer from poor cell penetration and exceeds the reported amplification of nucleic acid based amplification methods. Perhaps most importantly, the chemical ligation step enables stringent wash conditions to reduce background. Our results demonstrate the power of RNA amplification in situ and open up the single-cell and RNA fields for mechanistic studies using high-throughput, analytical methods.

Optical imaging and labelling of individual biomolecules in dense clusters.
M. Dai1,2,3, R. Jungmann1,2,4, N. Liu1,2, P. Yin1,2,
1Wyss Institute for Biologically Inspired Engineering, Harvard University, Boston, MA, 2Department of Systems Biology, Harvard University, Boston, MA, 3Biophysics Program, Harvard University, Boston, MA, 4Max Planck Institute of Biochemistry, Munich, Germany

Recent advances in fluorescence super-resolution microscopy have allowed sub-cellular features and synthetic nanostructures down to ~15 nm in size to be imaged. However, direct optical observation of individual molecular targets (~5 nm) in a densely packed biomolecular cluster remains a challenge. Here, we show that such discrete molecular imaging is possible using DNA-PAINT (points accumulation for imaging in nanoscale topography) - a super-resolution fluorescence microscopy technique that exploits programmable transient oligonucleotide hybridisation - on synthetic DNA nanostructures. We examined the effects of high photon count, high blinking statistics, and appropriate blinking duty cycle on imaging quality, and developed a software-based drift correction method that achieves <1 nm residual drift (r.m.s.) over hours. This allowed us to image a densely packed triangular lattice pattern with ~5 nm point-to-point distance, and analyse DNA origami structural offset with angstrom-level precision (2 Å) from single-molecule studies. By combining the approach with multiplexed Exchange-PAINT imaging, we further demonstrated an optical nano-display with 5x5 nm pixel size and three distinct colours, and with <1 nm cross-channel registration accuracy. Combined with photo-activated crosslinker, we further demonstrated selective labelling on single molecule targets with custom patterns and sub-diffraction (~30 nm) resolution. These methods open up possibilities for direct and quantitative optical observation and perturbation of individual biomolecular features in crowded environments.

Developing a single-molecule imaging technology for early cancer detection in blood samples.
S. Wang1, C. Mao2, Y. Su3, J. Chang2, C. Hung2,3, T. Wu2,3,4,5, J. Xiao1;
1Biophysics and Biophysical Chemistry, Johns Hopkins School of Medicine, Baltimore, MD, 2Pathology, Johns Hopkins School of Medicine, Baltimore, MD, 3Oncology, Johns Hopkins School of Medicine, Baltimore, MD, 4Obstetrics and Gynecology, Johns Hopkins School of Medicine, Baltimore, MD, 5Molecular Microbiology and Immunology, Johns Hopkins School of Medicine, Baltimore, MD

Over 40% of people will develop cancer during their lifetimes, and nearly 600,000 die of cancer each year in the United States. It is estimated that over 90% of cancer cases can be managed effectively if found early on. However, early cancer detection, especially for solid tumors, remains an elusive goal. In our recent studies using mouse tumor models, we discovered that the solid tumor releases a trace amount of its cytoplasmic and nuclear contents into the peripheral circulation, possibly through
apoptosis or unconventional secretion processes. Thus, the tumor projects a “molecular shadow” of itself into the bloodstream. Because the nucleocytoplasmic proteins of cancer cells—including oncoproteins, signaling complexes, tumor suppressor proteins and transcription factors—are in general the ultimate mediators of oncogenesis and progression, they in principle provide the most definitive identification of the tumor. Therefore, we are developing an ultra sensitive, single molecule imaging-based technology, which we term as SMAC (for single molecule analysis and counting), to detect the molecular shadow of tumor cells in the peripheral circulation. We have demonstrated that cytoplasmic GFP expressed in tumor cells is released to bloodstream in mouse preclinical models. We also successfully applied SMAC assay to detection of multiple biomarkers in ovarian cancer samples. We believe that the concept of probing the molecular shadow of tumor cells in blood samples represents a paradigm shift in the field of cancer detection and diagnosis, and opens the door to the prospect of true tumor-specific (in contrast to tumor-associated) biomarkers.

Obtaining 3D Super-resolution Information from 2D Single-molecule Localizations through a 2D-to-3D Transformation Algorithm.
A. Ruba1, J. Kelich1, W. Luo1, W. Yang1;
1Department of Biology, Temple University, Philadelphia, PA

Currently it is still challenging to obtain three-dimensional (3D) super-resolution information in studies of structures in fixed specimens as well as transport kinetics in live cells with a high spatial resolution (< 10 nm). Without using real-time 3D particle tracking or making extensive optical microscopy modifications, here we introduce an approach to achieve 3D super-resolution information with resolution ~ 1 nm by converting 2D single molecule localizations to 3D spatial density maps through a 2D-to-3D density transformation algorithm. The method has been successfully applied to obtain structural and functional information for 25-300 nm bio-channels that have rotational symmetries. In this article, we will provide a comprehensive analysis of this new method by using experimental data and computational simulations.

Absolute Quantification of Transient Membrane Protein Interactions in Single Living Cells Using Co-Immunomobilization.
S. Park1, D. Kim1, D. Kim2, M. Jeong3, J. Noh1, Y. Kwon1, K. Zhou1, N. Lee6, S. Ryu1;
1Department of Life Sciences, POSTECH, Pohang, South Korea, 2School of Interdisciplinary Bioscience and Bioengineering, POSTECH, Pohang, South Korea, 3Division of Integrative Biosciences and Biotechnology, POSTECH, Pohang, South Korea, 6Department of Chemistry, Seoul National University, Seoul, South Korea

Quantitatively understanding protein-protein interactions in living cells holds a key to unravel how diverse cellular processes are properly generated in space and time. Equilibrium dissociation constants (K<> of protein-protein interactions must be determined in living cells to objectively compare and rank the strengths among the interactions. However, this remains challenging because of the transient nature of protein-protein interactions, which has hindered their quantitative analysis using conventional methods. Single-particle tracking (SPT) allows to capture rapid molecular events and provide diffusional information, yet biochemical interpretations of trajectory data are complicated because multiple
molecular processes are convoluted in single trajectories. Here, we develop a direct method enabling the absolute quantification of transient interactions between membrane proteins by utilizing the synergy between SPT and antibody-induced protein immobilization. Interaction moments of a interaction partner with specifically immobilized a protein of interest was visualized as co-immunoimmobilization (Co-II) using single-particle tracking photoactivated localization microscopy (sptPALM) and counted to calculate the in vivo $K_D$ value of protein-protein interactions in the membrane of single living cells. Using Co-II, we revealed that epidermal growth factor receptor (EGFR) and beta-2 adrenergic receptor (β2-AR) homodimerization are dominantly regulated by the intramolecular conformation and membrane microenvironment, respectively.

High Depth, High Precision, Three-Dimensional Super-Resolution Imaging and Particle Tracking with the Double Helix SPINDLE™ Module.
K. Heiser¹, A. Agrawal¹, S. Gaumer¹, L. Kimerling¹, R. Piestun²;
¹Double Helix LLC, Boulder, CO, ²Electrical, Computer, and Engineering, University of Colorado at Boulder, Boulder, CO

Double Helix Light Engineering™ modifies the response of a microscope such that, instead of an Airy Disc, the image of each point source is in the form of two well separated lobes. The two lobes rotate around their midpoint as the emitter is moved along the axial dimension. Thus, the center of the pair of lobes determines the lateral position of the emitter and the angle between the lobes determines the axial position. We present an implementation of this technique in the form of an add-on module, the Double Helix SPINDLE™, that can be attached between most scientific microscopes and a high sensitivity camera. The SPINDLE™ in conjunction with the Double Helix TRAX™ software extends the imaging capabilities of most scientific microscopes to nanometer scale 3D localization for imaging and tracking. In conjunction with single molecule localization microscopy (SMLM) methods, such as Stochastic Optical Reconstruction Microscopy (STORM) or Photoactivated Localization Microscopy (PALM), the SPINDLE™ enables high precision 3D reconstructions. Double Helix Light Engineering™ also extends the depth of field over which emitters can be localized, enabling collection of more data with high precision axial information. Similarly, in single particle tracking applications, the Double Helix SPINDLE™ facilitates collection of tracks over an extended depth with high precision 3D information. Here, we show super-resolution reconstructions of sub-cellular structures using the SPINDLE™ module and TRAX™ software. With this method, we were able to achieve average precision values for the localizations below 20 nm laterally and below 25 nm axially. Reconstructed images represent more than two microns of depth of field with no axial stitching. Additionally, we show 3D super-resolution reconstructions of stress granule cores, which were first visualized using Double Helix Light Engineering™. Finally we show results from 3D particle tracking of beads traversing in an inverse opal structure. We demonstrate improved tracking precision and accuracy of diffusion measurements using the Double Helix. In both these applications, Double Helix Light Engineering™ enables researchers to collect more information with high axial and lateral precision with up to three times the depth of conventional methods.

Imaging Minimally-Engineered mRNA and long non-coding RNA transcripts at the single-molecule level using phosphorothioate-optimized 2'-O-methyl RNA molecular beacons.

M. Chen1,2,3, C.J. Krueger1,4, A.K. Chen5;  
1Department of Biomedical Engineering, College of Engineering, Peking University, Beijing, China,  
2Peking-Tsinghua Center for Life Sciences, Peking University, Beijing, China,  
3Academy for Advanced Interdisciplinary Studies, Peking University, Beijing, China,  
4Wallace H Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, United States

Recently, we developed a new molecular beacon (MB) architecture composed of 2'-O-methyl RNA (2Me) and a fully phosphorothioate (PS)-modified loop domain with a phosphodiester stem (2Me/PSLOOP MB) and showed that this new MB exhibits a marginal false-positive signal in living cells. In addition, 2Me/PSLOOP MB could accurately image the dynamics and localization of single mRNA molecules harboring 32 tandem repeats of an MB target sequence without affecting gene expression or cell viability. In this study, we evaluated the sensitivity of MBs for detecting minimally engineered RNAs in cells, and found that the MBs can detect single mRNA transcripts containing as few as 8 tandem target repeats without compromising accuracy. In both the nucleus and the cytoplasm, mRNAs harboring 8 repeats moved faster than those with 32 repeats, suggesting that intracellular activities are less impeded in RNA molecules with smaller engineered insertions. The MB/8-repeat system was then further shown to enable, for the first time, live-cell visualization of long non-coding RNAs (lncRNAs) and could do so without altering their expected physiological activities. We envision the proposed MB-based technology for live-cell single RNA imaging can be useful for discovering new RNA functions and activities.

Genetically Encoded Tools to Control and Reveal Cellular Dynamics in IPSC Disease Modelling and Drug Screening.

Y. Chang1, F. Brook1, J. Wu2, R. Campbell2, M. Daniels1;  
1Cardiovascular Medicine, Oxford University, Oxford, United Kingdom,  
2Chemistry, University of Alberta, Edmonton, Canada

Induced pluripotent stem cells (iPSC) models hold great promise for disease modeling and drug discovery. Genetically encoded light emitting reporters offer the prospect of multichannel resolution of events within subcellular compartments. Optogenetic technology allows us to control neurons depolarisation and heart coupling with the aid of photo-controllable proteins, channelrhodopsin2 (ChR2), which is a cation channel activated by blue light irradiation. Combining genetically encoded optogenetic control and spectrally compatible calcium indicator tools into a single adenoviral vector allows the analogous capability for cell control with simultaneous cellular phenotyping without the need for contact. This combination can be applied to human stem cell derived cardiomyocytes as single cells enabling contactless small molecule evaluation in isolated stem cell derived cardiomyocytes for inhibitors of sodium, potassium and calcium channels suggesting it may be useful for early toxicity studies. We also reveal cellular disease phenotype in dish by using iPSC patient specific model. A family
carrying the point mutation in L-type calcium channel Cav1.2 display long-QT syndrome or hypertrophic cardiomyopathy will be discussed briefly.

Immunoprecipitation high performance liquid chromatography (IP-HPLC) analysis in the postoperative exudate of bisphosphonate related osteonecrosis of mandible.
S. Kim1, M. Eo1, Y. Cho1, Y. Kim2, S. Lee3;
1School of Dentistry, Dental Research Institute, Seoul National University, Department of Oral and Maxillofacial Surgery, Seoul, South Korea, 2Cheongju University, Department of Dental Hygiene, Cheongju, South Korea, 3College of Dentistry, Gangneung-Wonju National University, Department of Oral Pathology, Gangneung, South Korea

Recurrent bacterial infections in cases of bisphosphonate-related osteonecrosis of jaw (BRONJ) frequently occur. Therefore, BRONJ are usually treated by radical saucerization followed by intensive antibiotic medications without bisphosphonate therapy. The postoperative exudate (POE) from BRONJ lesions may directly indicate the inflammatory status of osteomyelitis in patients, but so far, the POE has rarely been examined for its expression of various cytokines and wound healing proteins. A total of 27 cases of BRONJ, which involved the mandible, were selected and their individual POE collected 6 h, 1 day, and 2 days after surgical intervention was analyzed by immunoprecipitation high performance liquid chromatography (IP-HPLC). The different protein expressions in the BRONJ POE were compared with findings from ten cases of chronic mandibular osteomyelitis (CMO) exudate as the control group. For the protein expressions for inflammation, osteogenesis, and angiogenesis, in the 6 h POE sample, the BRONJ exudate exhibited more expression of IL-10, IL-28, OPG, and osteocalcin, but less expression of TNFa and LL-37 than the control. In the 1 day POE sample, the BRONJ exudate showed more expression of TNFa, IL-6, 8, 12, 28, a1-antitrypsin, VEGFA, and VEGF-C, but less expression of CD68, lysozyme, bFGF, RANKL, bFGF, and ALP than the control. In the 2 day POE sample, the BRONJ exudate consistently showed more expression of LL-37, b-defensin-1, and VEGF-A than the control. The present BRONJ POE revealed the rapid progress of bony wound healing through increased molecular signaling for inflammation, angiogenesis, and osteogenesis compared to the control. Therefore, it was suggested that the POE obtained from the postoperative bony lesions should be collected and analyzed by the IP-HPLC method to predict the prognosis of seriously complicated inflammatory bony diseases such as BRONJ. *This study was supported by a Grant of the Korean Health Technology R&D Project, Ministry of Health and Welfare, and Republic of Korea (HI15C0689).

Engineering the MS2 System to follow the Life Cycle of Single mRNAs.
M. Vera1, E. Tutucci1, J. Biswas1, R. Parker2, R.H. Singer1;
1Anatomy and Structural Biology, Albert Einstein College of Medicine, New York, NY, 2Chemistry and Biochemistry, University of Boulder, Boulder, CO

The MS2-MCP system allows imaging multiple steps of the mRNA life cycle with high temporal and spatial resolution. However, for short-lived mRNAs, the tight binding of the MS2 coat protein (MCP) to the MS2 binding sites (MBS) protects the RNA from being efficiently degraded, confounding the study of mRNA regulation. Here, we describe a reporter system (MBSV6) with reduced affinity for the MCP, allowing mRNA degradation while preserving single molecule detection determined by smFISH or live
imaging. Highly-regulated mRNAs endogenously tagged with MBSV6 in S. cerevisiae degrade normally and were imaged throughout their complete life cycle. The MBSV6 reporter revealed that coordinated recruitment of mRNAs at specialized structures such as P-bodies during stress did not occur. MBSV6 provided single molecule detection of the molecular chaperone HSP70 mRNA in live mammalian cells. Supported by NIH GM57071 to RHS.

Microfluidic Imaging Windows: A New Method for Imaging and Controlling the Tumor Microenvironment.

L. Butt¹, L. Sfakis¹, Y. Wang²,³,⁴, D. Entenberg²,³,⁴, J. Castracane¹, J.S. Condeelis²,³,⁴;
¹Nanobiology Constellation, SUNY Polytechnic Institute, Albany, NY, ²Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, ³Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, ⁴Integrated Imaging Program, Albert Einstein College of Medicine, Bronx, NY

Intravital Windows are powerful tools capable of elucidating the complex tumor microenvironment. Advancements in protocols for intravital windows have recently led to rapid development in the ability to observe structures and mechanisms of metastasis in vivo. The utility of intravital window technology has been amplified by modifying the window itself to feature microfluidic functionality. Microfluidic Intravital Windows (MFIWs) have been engineered to contain pre-loaded drug reservoirs and microchannels capable of controlling the tumor microenvironment through factors delivered locally into the tumor microenvironment. Two modes of devices have been developed: the Passive MFIW (P-MFIW) and the Active MFIW (A-MFIW). P-MFIWs were fabricated using soft-lithography techniques and utilize hydrogel-facilitated diffusion as the mechanism for drug delivery. Elongated channels control the timeframe of the experiment and allow drug-release from multiple reservoirs both in parallel and in series. The P-MFIW has been validated for imaging, drug-release and collection. Imaging was conducted through windows installed in mice under a multiphoton microscope. Drug release was characterized using for diffusion studies and gradient formation studies using fluorescent hepatocyte growth factor (fHGF). Release dynamics were characterized in vitro as well as through solid tumors harvested from chorioallantoic membranes (CAMs). fHGF was loaded in 4% alginate hydrogels for hydrogel-mediated release. A microneedle protocol has been optimized to allow controlled depth-of drug release from the P-MFIWs, as well as for uptake of metastatic cells. The Active MFIW utilizes light energy to control the spatial and temporal release of factors. Azobenzene liquid crystal polymer (LCP) films have been generated in LCP photopolymerization cells made using soft-lithography techniques. These LCP films demonstrate stress localization and macroscopic bending when exposed to 488 nm light. The degree and extent of bending is determined by light intensity and polarization. Normally Open (NO) microfluidic valves have been fabricated with azobenzene functionality. Valves have been validated to demonstrate discrete “ON” and “OFF” states. Induction of GFP expression in human epidermoid carcinoma (T-HEp3) tumors via the release of doxycycline from the A-MFIW at controlled timepoints will be reported.

Fluorescent cell-labelling strategies live-cell analysis.
D.M. Appledorn1, D. Trezise2, H. Campwala3, M. Roddy3, J. Rauch1, T. Dale3, K. Wicklund1;
1Essen BioScience, Ann Arbor, MI, 2Essen BioScience, Welwyn Garden City, United Kingdom

In the pursuit of more relevant and translational cell-based assays, researchers are increasingly turning to real-time live-cell analysis for their studies. Live-cell analysis provides cell biologists with greater insight and productivity by enabling quantification of cell function over hours, days and weeks via time-lapse image analysis, all automatically and within the controlled environment of the incubator. Many cell functions, such as proliferation, migration and neurite outgrowth, can be quantified in simple monocultures without fluorescent cell labels by analyzing features of phase-contrast images. This ‘label-free’ approach is desirable since it avoids complications associated with cell labels. However, there are limitations to what can be achieved without cell labels. For example, it is difficult to extract true cell count metrics from phase-contrast images in dense cultures, and in co-culture models cell labels are absolutely required to identify different cell types to observe their interactions. Accordingly, a range of different cell-labelling strategies for live-cell analysis have been developed. Protein-based fluorophores have been used for several decades to label cells and are ideally suited to real-time live-cell analysis. Fluorescent proteins (FPs) provide long-term and stable-cell labelling, are generally non-toxic and not depleted by repeated fluorescent excitation. By using specific targeting sequences in the expression constructs, proteins can be directed to label different cell types or organelles. Via this approach, we have developed a range of different vectors and delivery methods including nuclear-targeted FPs, cytoplasmic FPs and neuronal-specific FPs. These are packaged for delivery with either lentiviral or baculoviral (BacMam) expression constructs. Alternatively, in certain scenarios, it may be difficult or undesirable to transduce cells with fluorescent proteins. In these cases, cells can be labelled with cytoplasmic or nuclear specific fluorescent dyes. When used correctly, these chemical probes are non-perturbing to cells and produce uniform and homogeneous labelling. These dyes have very different properties and use protocols to each other, and to the protein labels, and are best aligned with different applications. In this poster, we will describe the use of these fluorescent protein and dye-based labelling strategies and how they can be used most effectively in live-cell analysis applications including cell proliferation, cytotoxicity, apoptosis, immune cell killing, and neurite outgrowth in both primary rodent and human iPSC-derived neurons.

An enclosed system for long-term brain slice culture: viral-mediated transgene expression and precisely localized repetitive cell imaging.
B.B. Fixman1, I.W. Babcock1, L.S. Minamide2, A.E. Shaw2, M.I. Oliveira da Silva3, J.J. Field2, J.R. Bamburg1,2;
1Molecular, Cellular and Integrative Neuroscience, Colorado State University, Fort Collins, CO,
2Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO, 3Nerve Regeneration Group, University of Porto, Porto, Portugal

Cultured rodent brain slices are useful for studying the cell biology and behavior of neurons and glia in an environment that maintains many of their normal interactions. Expression of fluorescently tagged proteins or reporters by infection with replication deficient virus in wild-type hippocampal slices allows for high-resolution imaging by fluorescence microscopy. Although several methods have been developed for imaging brain slices, combining slice culture with repetitive high-resolution imaging of
identical cells in live slices over long time periods has posed problems. This is especially true when viral vectors are used to express exogenous proteins since viruses are best used in an enclosed system to protect users and prevent cross contamination. Here we report simple modifications made to the roller tube brain slice culture method that allows for repetitive high-resolution imaging of slices over many weeks/months. Furthermore, culturing slices on photo etched coverslips provides the fiducial marks required for precise localization and imaging of the identical field of cells over time before and after different treatments. Applications are shown for the use of this method combined with specific neuronal staining and expression to observe long-term maintenance of hippocampal architecture, viral-mediated neuronal expression of fluorescent proteins, and, in response to slice treatment with oligomers of amyloid-β peptide, the development of coflin pathology observed in brains of human and mouse models of Alzheimer disease.

Flagella standards for quantitative fluorescence microscopy.
Y. Liu1, P. Yang1;
1Biological Sciences, Marquette University, Milwaukee, WI

Despite available quantitative analytic programs, it remains challenging to estimate molecule numbers based on fluorescent intensity. To address this challenge, we converted a ruler-like microtubule-based structural scaffold in flagella into fluorescent intensity standards, akin to protein or DNA markers for electrophoresis. Specifically, we engineered transgenic biflagellate green algae, Chlamydomonas, expressing fluorescent proteins tagged to a cytoskeletal protein of a defined periodicity throughout the length of flagella. The fluorescent intensity had at least a 10 fold linear range. Carrier effects were not evident for four fluorescent proteins and two carrier proteins tested. Quantitative applications were demonstrated by comparing fluorescent flagella with fluorescent objects in Chlamydomonas and Saccharomyces cerevisiae. Methanol fixation, which diminished chloroplast fluorescence, improved the signal/background ratio. These observations demonstrate the feasibility of broad applications of biologically inert fluorescent flagella as microscopy intensity standards.

Properties of Near-Infrared Fluorescent Proteins Engineered From Bacterial Photoreceptors in Mammalian Cells.
A.A. Shemetov1,2, O.S. Oliinyk3, V.V. Verkhusha1,2,3;
1Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 2Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY, 3Department of Biochemistry and Developmental Biology, Faculty of Medicine, University of Helsinki, Helsinki, Finland

Non-invasive in vivo imaging demands for near-infrared (NIR) fluorescent probes. Numerous NIR fluorescent proteins (FPs) were recently engineered from bacterial photoreceptors but lack of their systematic comparison makes researcher’s choice rather difficult. We evaluated side-by-side several modern NIR FPs, such as blue-shifted smURFP and miRFP670, and red-shifted mIFP and miRFP703. We found that among all NIR FPs, miRFP670 had the highest fluorescence intensity in various mammalian cells. For instance, in common HeLa cells miRFP703, mIFP and smURFP were 2-, 9- and 53-fold dimmer than miRFP670. Co-expression of heme oxygenase, producing biliverdin chromophore for NIR FPs from heme, either via IRES sequence or via T2A peptide, as well as incubation of cells with heme precursor,
decreased the cellular brightness of NIR FPs, however, in the latter case elevated cellular autofluorescence. Exogenously added chromophore substantially increased smURFP brightness but only slightly enhanced brightness of other three NIR FPs. mIFP showed an intermediate while monomeric miRFP670 and miRFP703 exhibited a high binding efficiency of the endogenous biliverdin chromophore. Thus, a quality of the initial molecular engineering rather than an insufficient amount of the endogenous BV chromophore is the key factor determining the NIR FP brightness in mammalian cells. This feature makes them easy to use as GFP-like proteins for spectral multiplexing with FPs of visible range.

Light-activated protein interaction with high spatial subcellular confinement.
L. Benedetti1,2,3,4,5, A.E. Barentine2,6, M. Messa1,2,3,4, H. Wheeler1,2,3,4, J. Bewersdorf2,3,6,7, P. De Camilli1,2,3,4,5, 
1Department of Neuroscience, Yale University School of Medicine, New Haven, CT, 2Department of Cell Biology, Yale University School of Medicine, New Haven, CT, 3Kavli Institute for Neuroscience, New Haven, CT, 4Program in Cellular Neuroscience, Neurodegeneration and Repair, New Haven, CT, 5Howard Hughes Medical Institute, New Haven, CT, 6Department of Biomedical Engineering, Yale University, New Haven, CT, 7Nanobiology Institute, Yale University, West Haven, CT

Methods to acutely manipulate protein interactions at the subcellular level are powerful tools in cell biology. Several blue-light-dependent optical dimerization tools have been developed. In these systems one protein component of the dimer (the bait) is directed to a specific subcellular location, while the other component (the prey) is fused to the protein of interest. Upon illumination, binding of the prey to the bait results in its subcellular redistribution. Here we compared the ability to control dimer occurrence in small, subcellular volumes, of three such tools: Cry2/CIB1, iLiD, and Magnets. We show that both the location of the photoreceptor protein(s) in the dimer pair and its(their) switch-off kinetics determine the subcellular volume where dimer formation occurs. Magnets, a system in which both bait and prey are photosensitive elements, can induce and maintain protein dimerization in the smallest volume, although this comes at the expense of the total amount of dimer. These findings emphasize the importance of choosing an optogenetic system with qualities matched to the desired application.

Optogenetic systems for regulation of cellular metabolism with near-infrared light.
A.A. Kaberniuk1, A.A. Shemetov1, T.A. Redchuk2, V.V. Verkhusha3,4, 
1Department of Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY, 2Department of Biochemistry and Developmental Biology, Faculty of Medicine, University of Helsinki, Helsinki, Finland, 3Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

Light-mediated control of protein–protein interactions to regulate cellular metabolism is an important application of optogenetics. Earlier, we have developed an optogenetic system based on reversible light-induced heterodimerization of bacterial phytochrome BphP1 and its natural partner PpsR2 from R. palustris bacteria. Characteristics of the BphP1–PpsR2 optogenetic system include its sensitivity to near-infrared (NIR) light of 740–780 nm, ability to utilize an endogenous biliverdin in eukaryotes including mammals as a chromophore, and spectral compatibility with blue-light-driven optogenetic systems, such as LOV, CRY and channelrhodopsins.
We characterized the BphP1–PpsR2 interaction both in vitro and in mammalian cells. Structural and biochemical analysis of PpsR2 resulted in truncation of PpsR2 to 3-fold smaller fragment, termed Q-PAS1, which was able to bind BphP1. Q-PAS1 lacks the undesired PpsR2 oligomerization behavior and possesses faster kinetics of heterodimerization. BphP1 interaction with PpsR2 and Q-PAS1 was exploited to develop NIR light-controllable transcription activation and inhibition systems. We achieved 40-fold activation contrast in cultured cells, 32-fold in subcutaneous mouse tissue, and 5.7-fold in deep tissues in mice. The developed transcription regulation systems are compatible with reporter systems based on Tet response element and Gal4 upstream activation sequence and can be used to control non-invasively the expression of intracellular proteins. Moreover, PpsR2 and Q-PAS1 can be used to translocate target proteins to different cellular compartments upon NIR light-induced interaction with BphP1. We showed light-inducible control of cell morphology by targeting of DPH domain of Cdc42 to the plasma membrane. Simultaneous use of BphP1–Q-PAS1 and LOV-based optogenetic systems demonstrated their negligible spectral crosstalk. By further integrating Q-PAS1 and LOV domains in a single optogenetic tool, we achieved tridirectional protein targeting between nucleus, cytoplasm and plasma membrane controlled by NIR and blue light. This approach opens a possibility to engineer multicomponent optogenetic tools to regulate cellular metabolism by light-controlled targeting of metabolically active proteins to desired cellular compartments.

Development and application of designable RNA-binding protein for live-cell imaging and manipulation of authentic RNAs.
A. Takai¹, Y. Okada¹²; ¹Quantitative Biology Center, RIKEN, Suita, Japan, ²Graduate School of Science, The University of Tokyo, Tokyo, Japan

RNAs do not only serve as the blue print for the protein assembly, but also play wide variety of essential functions in cells. Thus, visualization and manipulation of RNAs in living cells would beneficial for both basic and applied sciences. MS2 and PP7 systems are now widely used for this purpose. However, a tandem repeat of stem loop sequence should be introduced into the target RNA as the binding sites for MS2 or PP7 proteins, which could potentially affect the function, localization or stability of the target RNA. In situ hybridization can detect unmodified, authentic RNAs, but is difficult to apply to living cells. Here, we report the development of designable RNA-binding protein. We have first established an ELISA-like in vitro assay system using our bright bioluminescent protein, Nano-lantern (Takai et al., PNAS 2015). The proteins we have designed showed high affinity (1-10 nM) specifically to the target RNAs. We, then, designed the probes for beta-actin mRNA and examined their avidity to bind to the target mRNA in living cells. Immunoprecipitation of the probe followed by quantitative PCR analysis demonstrated that the target, authentic beta-actin mRNA is specifically recognized in vivo. We also showed that the same probe can be used for the visualization of the dynamics of the authentic beta-actin mRNA in living cells. Furthermore, manipulation of the localization of the beta-actin mRNA using the probe fused to constitutively active kinesin resulted in the neurite-like elongation of cellular processes. These data collectively suggests that our new probe for RNA would serve as a powerful tool for the imaging and manipulation of unmodified, authentic RNAs in living cells or organisms.

In utero electroporation is a powerful tool for introducing plasmid DNA into neurons and neuronal precursors that are located adjacent to ventricles. This technique traditionally relies on collecting matched sections from littermate controls to determine differential effects of knockdown or overexpression of desired proteins. Creation of knockout animals also requires matched sections to determine the effects of gene deletion. We have developed a new and improved methodology, allowing for expression of either a green fluorescent protein (GFP) or a red fluorescent protein (RFP) in addition to a gene or microRNA to a gene of interest (control and experimental respectively) within the same region of the same brain. This system uses a Cre/LoxP approach to stochastically express either GFP (control) or RFP coupled with overexpression or knockdown (experimental) in separate populations of neurons. We also show this system does not have any leakiness, which would result in expression of RFP and the gene of interest in the absence of Cre. Importantly, the eventual “fate” of a neuron as green or red is pseudo-randomly determined, avoiding complications that arise from some plasmids being more amenable to electroporation, and some cell types having a differential likelihood of being electroporated. As proof of principle, we demonstrate that misexpression of CIP4, an F-BAR protein that induces lamellipodia-like protrusions in neurons, results in migration defects of cortical neurons.
