Breast tumors exist in a complex milieu of components that make up the tumor microenvironment, which is composed of the extracellular matrix, various stromal cells, blood vessels, and numerous biochemical signals. Using multiphoton and intravital imaging of human breast biopsies, our lab has found that collagen fibers surrounding tumors become aligned and reorient perpendicular to the tumor boundary, which creates a biomarker that can be utilized to accurately predict patient outcome. Local collagen alignment has been shown to recruit other players into the tumor microenvironment including immune cells. Macrophage infiltration and recruitment in breast tumors has been correlated with poor prognosis in breast cancer patients and has been linked to tumor cell dissemination. Much of our understanding comes from animal models in which macrophages are labeled by expression of an extrinsic fluorophore. However, conventional extrinsic fluorescence labeling approaches are not readily applied to human tissue and clinical use. Exploiting endogenous fluorescence from the metabolic co-
factors NADH and FAD with quantitation from Fluorescence Lifetime Imaging Microscopy (FLIM) is a novel means to non-invasively identify tumor-associated macrophages in the intact mammary tumor microenvironment. Macrophages were both FADHI and demonstrated an increase in NADH-FLIM signature, which was readily separated from the intrinsic fluorescence signature of tumor cells. This non-invasive quantitative technique provides a unique ability to discern specific cell types based upon their metabolic signatures without the use of exogenous fluorescent labels. Not only does this technique provide high resolution of temporal and spatial views of macrophages in live animal breast cancer models, this approach can be extended to other animal disease models where macrophages are implicated and has potential for clinical applications.

Single-cell fluorescence thermometry visualizing intracellular events associated with heat production in brown adipocytes.
M. Suzuki1;
1PRESTO, Japan Science and Technology Agency (JST), Saitama, Japan

After the discovery of brown adipose tissue in adult humans, brown adipocytes (BAs) have attracted great interest to counteract obesity-related metabolic diseases. The strategies to promote their energy expenditure would benefit the ongoing efforts for the treatment of obesity and diabetes. BAs are characterized by a high metabolic capacity due to their high content of mitochondria. While mitochondrial pH is an important physiological factor that is regulated dynamically in response to stimulation and in return affects various cellular activities, how mitochondrial pH in adrenergically-stimulated BA is regulated is unknown. We have recently reported a thermosensitive dye targeted to the endoplasmic reticulum (ER), ERthermAC [Ex/Em; 560/580 nm (approx.)], to optically detect the thermogenesis in individual BAs upon stimulation [Sci. Rep., 7, 1383 (2017)]. The fluorescence intensity of ERthermAC decreases as the temperature increases, thus the heat production can be visualized under the fluorescence microscope. Here, we report our recent application of ERthermAC for dual-color imaging with a mitochondrial targeted pH-sensitive protein, mito-pHluorin [480/520] in BAs. Fluorescence imaging of mito-pHluorin with tetramethylrhodamine methyl ester (550/575 nm) showed a triphasic mitochondrial pH change in BAs upon adrenergic stimulation. ERthermAC revealed that phases 1 and 2 of the pH increase precede thermogenesis, while phase 3, characterized by a pH decrease, occurs during thermogenesis. The mechanism of pH increase was partially related to electron transport chain activity. Further analysis by using cells co-transfected with pHluorin and R-GECO (560/590 nm), a Ca\(^{2+}\) indicator, demonstrated that the mitochondrial pH increase occurs concurrently with an increase in mitochondrial Ca\(^{2+}\), and this Ca\(^{2+}\) increase was contributed by an influx from ER. Our results demonstrated that an increase in mitochondrial pH is implicated as an early event in adrenergically stimulated BAs, suggesting a role of this pH increase in the potentiation of thermogenesis [Mol. Metab., 6, 797-808 (2017)]. We will discuss the advantages, current limits, and future perspectives of the single-cell fluorescence thermometry.

Mechanisms of milk-lipid secretion in live mice unraveled by intravital subcellular microscopy (ISMic).
A. Masedunskas1, Y. Chen1,2, R. Weigert1, I.H. Mather1,3;
1National Cancer Institute, Bethesda, MD, 2Mechanical Engineering, Johns Hopkins University, Baltimore, MD, 3Animal and Avian Sciences, University of Maryland, College Park, MD

Throughout lactation, the mammary epithelium transports and secretes diverse nutrients, including proteins, lipids and carbohydrates for the nourishment of the suckling neonate. To develop this system for mechanistic studies of trafficking and secretory processes we used intravital imaging techniques employing transgenic mice, which express fluorescently-tagged marker proteins. Glands were surgically exposed under anesthesia and the formation and secretion of BODIPY-stained neutral lipid droplets followed by intravital subcellular microscopy (ISMic) over periods of 1-2 h. Lipid droplets arose from basal regions and were transported on apparent tracks to the cell apex by superdiffusive motion. Transit was slow (0-2 micrometers/min), intermittent and marked by numerous fusion events, especially in apical regions. On occasion, droplets caught up with and fused with droplets further along the same track or pathway. Lipid expansion was most pronounced in apical nucleation centers and continued as the droplets were budding from the cell enveloped by apical membranes. Droplet release into luminal spaces required oxytocin-mediated contraction of the myoepithelium. Thus milk-lipid secretion is regulated. This novel approach will have broad application for investigating mechanisms of intracellular transport and secretion across the mammary barrier.

Live-cell and single-molecule imaging reveal contrasting localization and kinetics of Tet proteins in naive mouse embryonic stem cells.
J. Ryan1, C.B. Mulholland1, S. Bultmann1, H. Leonhardt1;
1Biocenter, LMU Munich, Munich, Germany

Epigenetic modification of chromatin, such as DNA methylation and histone modifications, constitutes a fundamental mechanism of gene expression regulation in embryonic development. The Ten-Eleven Translocation (Tet) family of dioxygenases erase DNA methylation by the catalytically oxydizing methylcytosine to further oxidized derivatives, such as hydroxymethylcytosine (hmC), and have been shown to act as both transcriptional activators and repressors, especially during stem cell pluripotency maintenance and exit. While genome-wide studies have shown average genomic localization of Tet proteins in embryonic stem cells (ESCs), their distribution and kinetics in living cells and at the single-molecule level have not been investigated.

Here, we use live-cell imaging, single-molecule tracking (SMT), and super-resolution microscopy to investigate the localization and mobility of Tet1 and Tet2 in mouse ESCs. We used Cas9-mediated genome editing to insert Halo-, SNAP-, or mNeonGreen tags at the endogenous Tet1 and Tet2 loci, ensuring physiological expression levels. We show that Tet1 forms small, mobile foci which colocalize with low-density euchromatin areas, and are generally excluded from dense heterochromatin areas. Live-cell, single-molecule imaging revealed that Tet1’s C-terminal catalytic activity locally influences residence time at chromatin loci, enriching for residence times on the tens-of-seconds timescale.

However, FRAP and super-resolution microscopy revealed that the global localization of Tet1 is heavily dependent on the large unstructured N-terminal domain, which contains multiple PTM, protein-
chromatin-binding sites. In stark contrast, Tet2 shows a more diffuse localization pattern, a larger mobile fraction in FRAP assays, and shorter residence times in SMT experiments compared to Tet1, suggesting different target search mechanisms and binding site stoichiometry.

Taken together, we demonstrate markedly different kinetics between two enzyme paralogs in ESCs, Tet1 and Tet2, which function to maintain gene expression homeostasis. These data are consistent with accumulating evidence for the non-catalytic roles of Tet proteins. Future work will help elucidate how these differences in kinetics underlie these enzymes’ functions with regards to the transition from naive to primed pluripotency.

Development of BiFC system based on a bright and photo-stable fluorescent protein for detecting a limited number of protein-protein interactions.

S. Okada¹, S. Nakagawa¹, S. Kamino², T. Ito¹;
¹Department of Biochemistry, Kyushu University Graduate School of Medical Sciences, Fukuoka, Japan, ²Department of Medicine, Kyushu University School of Medicine, Fukuoka, Japan

Protein-protein interactions (PPIs) are essential for nearly all cellular processes. To understand the dynamic aspects of PPIs in action, it is important to visualize the PPIs in living cells. To achieve this purpose, bimolecular fluorescence complementation (BiFC) assay has been developed. To visualize a limited number of PPIs, it is required to utilize a bright and photo-stable fluorescent protein. In this study, we have developed a BiFC system based on a bright and photo-stable and fast-maturing green-yellow fluorescent protein, mNeonGreen. To determine split points of mNeonGreen, we based on the structural information of mNeonGreen, we estimated the positions of linker region without secondary structure. We used the known Net1-Sir2 interaction in nucleoli of budding yeast cells as a platform to evaluate the BiFC efficiency. The mNeonGreen fluorescence intensity in nucleoli of the budding yeast cells harboring Net1-mNeonGreen[N] and Sir2-mNeonGreen[C] was quantified. By use of this screening platform, we identified split points within the linker between the 8th and 9th beta-sheets of mNeonGreen for efficient BiFC. To demonstrate the capability of mNeonGreen BiFC system to detect a limited number of PPIs in living cells, we tried to detect the interaction between two Cse4 (CENP-A in budding yeast) incorporated in a centromeric nucleosome. Budding yeast has a point centromere on each chromosome. This means that a single budding yeast diploid cell has 32 chromosomes. Under the assumption that Cse4-ymNeonGreen[N] and Cse4-ymNeonGreen[C] are expressed at the same level, probabilistically 16 mNeonGreen molecules will be reconstituted by intranucleosomal BiFC. We confirmed that the Cse4-Cse4 mNeonGreen BiFC signal was detectable in living yeast cells. Also we confirmed that the Cse4-Cse4 mNeonGreen BiFC signal was co-localized with a kinetochore protein Mtw1 fused with a red fluorescent protein mRuby3. This results show that mNeonGreen BiFC is utilizable for detection of a limited number of PPIs in living cells. The Cse4-Cse4 mNeonGreen BiFC signal was bright and photo-stable sufficient for time-lapse live cell imaging covering a whole cell cycle of budding yeast. At bud emergence, the Cse4-Cse4 BiFC signal showed a transient disappearance. This phenomenon could result from cell cycle-dependent degradation of Cse4. To test this possibility we measured the dynamic change of Cse4-Cse4 BiFC signal in cells lacking Psh1, an E3 ubiquitin ligase required for degradation of artificially expressed excessive Cse4 proteins. In the cells lacking Psh1, a part of Cse4-Cse4 BiFC signal remained at bud emergence. This result indicates that Psh1 could be involved in degradation of the Cse4 proteins incorporated in endogenous centromeres.

Dissecting molecular determinants of signaling dynamics via optogenetic control of innate immunity.

H.R. Clark, M. DeFelice, S. Regot, M. Covert;

1Molecular Biology and Genetics, Johns Hopkins, Baltimore, MD, 2Biochemistry Cellular and Molecular Biology Graduate Program, Johns Hopkins, Baltimore, MD, 3Bioengineering, Stanford University, Palo Alto, CA

The innate immune system must prevent an infection without causing hyperinflammation; a balancing act that requires elaborate signaling networks to regulate gene activation. The Nuclear Factor-kB (NF-kB) network in particular, employs complex methods of gene regulation. Recent single cell studies reveal that the NF-kB pathway can regulate gene expression with temporal patterns of activity (i.e. oscillations). While it is clear that NF-kB signaling dynamics are receptor and stimuli specific, the molecular mechanisms that reinforce correct dynamics are not known. Using live single cell imaging we detected dampening of oscillations shared by the Toll Like and IL1 receptor branches of the pathway, indicating the presence of a negative feedback mechanism. To locate the source of the negative feedback we developed optogenetic tools that can activate the pathway at different nodes. Using combinations of light and cytokine stimuli, process of elimination revealed that Interleukin-1 Receptor-Associated Kinase1 (IRAK1) modification is correlated with negative feedback. Upon cytokine stimulation, fluoresently tagged IRAK1 forms transient clusters that are linked to both oscillations and tolerance. We find that in a kinase inactive mutant, IRAK1 post-translational modification and clustering are abolished. However, cells are still able to signal and show increased oscillations. Our work identifies IRAK1 activity to be dispensable for signaling but critical for dynamics.

EXPLORING THE POSSIBILITY OF CO-CULTIVATING THE GREEN MOSS PHYSCOMITRELLA PATENS WITH HUMAN FIBROBLASTS.

I. Chastukhina, E. Zakirova, L. Valeeva, A. Palotas, A. Rizvanov, E. Shakirov;

1Institute of Fundamental Medicine and Biology, Kazan (Volga region) Federal University, Kazan, Russia, 2Asklepios-Med (Private Medical Practice and Research Center), Szeged, Hungary, 3Department of Integrative Biology, University of Texas at Austin, Austin, TX

Plant-based biotechnologies represent a promising new strategy for the production of effective medical materials and pharmaceuticals. Biomolecule production in plants, including proteins, vaccines and antibodies, is a convenient, safe and cost effective alternative to expression systems based on microorganisms, animal tissue cultures or transgenic animals. A plant-based production has many advantages, such as the absence of human pathogens, viruses and prions, correct posttranslational modifications and sub-cellular localization, proper assembly and folding of recombinant proteins, increased stability and effective storage of expressed product in plant tissues without substantial losses in biological activity. One of such potential approaches is the introduction of a vital recombinant plant tissue expressing the target products directly into human cell cultures. The moss Physcomitrella patens is a well-established model system used in plant development, desiccation and drought tolerance research, as well as for the production of biopharmaceuticals. The aim of this work was to test the
feasibility of using the moss P. patens as a living supporting scaffold for mammalian cell culture in cocultivation experiments. Specifically, we tested the ability of P. patens cells and human skin fibroblasts to survive long-term in each other’s presence and the influence of moss protonema on cell culture characteristics. We observed that after co-cultivation of P. patens and human fibroblast at 37°C and 5% CO2 without light for 27 days human skin fibroblasts formed normal monolayer. At the same time, all moss cells remained green at the stage of protonema and gametophores were not formed. Overall, after co-cultivation with P. patens, the human cell culture retained fibroblast-like morphology and surface markers (CD 90, CD105, CD 44). Viability tests showed that human skin fibroblasts retained their proliferation ability after co-cultivation with moss protonema. Thus, our data indicate that prolonged co-cultivation of moss and human cells does not appear to induce detrimental changes in fibroblast culture. We suggest that our data may form the foundation for the future investigations aimed at the development of a new effective natural systems for stable pharmaceutical production based on live plant tissue from the model moss Physcomitrella patens. This study was conducted according to the Russian Government Program of Competitive Growth of Kazan Federal University.

Homoharringtonine enhances transdermal absorption in the skin by regulating epidermal tight junction barriers.
K. Yagi1, A. Watari1, K. Fujiwara1, N. Suzuki1, M. Kondoh1;
1Graduate School of Pharmaceutical Sciences, Osaka University, Suita, Japan

Objectives: The tight junction (TJ) is responsible for the epithelial barrier function of the skin. A TJ is composed of membrane proteins such as claudins, occludin, and ZO-1. It has previously been thought that only the stratum corneum is responsible for skin barrier function; however, knock-out mouse analysis has shown that claudin-1 is essential for skin barrier function. Furthermore, other TJ components including claudin-4 and occludin also contribute to the skin TJ-barrier. Homoharringtonine (HHT) is an alkaloid derived from the evergreen tree Cephalotaxus harringtonia. HHT reduces intestinal epithelial barrier function by inducing a change in the expression and localization of TJ components. However, the effect of HHT on the skin TJ barrier remains unclear. In the present study, we investigated HHT’s influence on the skin TJ barrier and the compound’s potential to enhance transdermal absorption.

Methods: The effect of HHT on the skin epithelial barrier was analyzed by measuring its effect on transepithelial membrane electrical resistance (TEER) and paracellular tracer flux analysis in Normal Human Epidermal Keratinocytes (NHEK), a human skin model. The effect of HHT on the expression of TJ components was analyzed by immunoblot assay. To examine the effect of HHT on mouse skin permeability, a filter paper impregnated with HHT and fluorescein isothiocyanate (FITC) -dextran (with molecular weights of 4,000 (FD-4), 10,000, or 20,000) were applied to mouse skin after removal of stratum corneum by tape-stripping, and then a blood time-course was collected. Results: HHT decreased TEER values and enhanced the paracellular flux of FD-4 in NHEK cells in a dose-dependent manner. The protein expression of TJ components such as claudin-1, claudin-4, and occludin was decreased by HHT. Examination of the transdermal absorption-promoting activity of HHT in vivo showed that the amount of FD-4 absorbed over 24 h of treatment was increased by HHT in a dose-dependent manner. A time-course of FD-4 absorption indicated that HHT increased the amount of FD-4 absorbed starting after about 6 h of treatment. Analysis using model dextrans showed that compounds with molecular weights of up to 10,000 were absorbed. Conclusion: We evaluated the transdermal absorption-promoting effect of HHT both in vitro and in vivo. HHT exhibited a transdermal absorption-promoting effect for macromolecules up to 10,000 Da in size, and reduced the expression of TJ components that are

Tuesday-21
important for construction of the skin TJ barrier, including claudin-1, claudin-4, and occludin. These findings indicated that HHT acts on the epidermal TJ barrier and may serve as a novel transdermal absorption-promoting agent that permits the passage of high-molecular-weight drugs such as biopharmaceuticals.

Development of a stretchable device for live-cell imaging.

N.A. Al-Maslamani¹, H. Horn¹;
¹College of Science and Engineering- Life Science Division, Hamad bin Khalifa University, Doha, Qatar

Cells are mechanically sensitive and respond to their physical environment by alterations in protein levels, function, and localization. Processes such as proliferation, locomotion, invasion and metastasis can affect the mechanobiology of a cell. In vitro studies that aim to simulate in vivo conditions have significantly helped our understanding of the mechanobiology underlying such cellular processes. The ability of cells to respond to mechanical changes in their environment, and to alter their own mechanical attributes is, at least in part, dependent on a physical link between the cytoskeleton and the nucleus, which is provided by LINC (Linker of Nucleoskeleton and Cytoskeleton) complex proteins. The LINC complex consists of an outer nuclear membrane (ONM) nesprin (Nuclear Envelope Spectrin Repeat Protein) protein, and an inner nuclear membrane (INM) SUN domain protein, which form a physical connection in the perinuclear space, the space between the ONM and INM. Studying LINC complex proteins in the context of mechanobiology can help elucidate the underlying biophysics of these proteins and provide insights into mechanotransduction mechanisms.

Our aim is to exert physical stress on cells by uniaxial stretching and observe in real time the cellular responses, in particular at the level of LINC complex proteins. Several cell stretching devices have been developed to investigate controlled stretch and the effects of mechanical stimuli on cellular behavior. For our work, an important factor in such devices is their compatibility with live-cell imaging, which is critical in understanding how physical forces affect the LINC complex dynamics and their role as mechanosensors/mechanotransducers. In addition, we sought to develop a device that would exert even, uniaxial force across the entire field of stretch to allow for more accurate quantitative analysis. In response to these requirements, we have developed a simple, 3D-printed, low-cost microscope stage insert that allows for live-cell imaging under controlled uniaxial stretching that can be continuous or intermittent with time-controlled intervals. As with previously published stretching devices, we used elastomeric polydimethylsiloxane (PDMS) as membrane material to plate and stretch the cells. The stretch parameters (such as amplitude and frequency) of this device are easily adjustable, allowing for intra- and inter-experiment variability. We will use this stretcher to look at changes in LINC complex proteins in response to mechanical stress.

Functional characterization of an in vitro generated 3-D nerve bundle using capillary alginate gel on a microelectrode array.
D.S. George¹, W.A. Anderson¹, A.J. Bosak², A.R. Willenberg³, F. Sommerhage³, B.J. Willenberg³, S. Lambert⁴;
¹Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL, ²Department of Internal Medicine, University of Central Florida, Orlando, FL, ³NanoScience Technology Center, University of Central Florida, Orlando, FL, ⁴College of Medical Education, University of Central Florida, Orlando, FL

Microelectrode arrays (MEAs) are a useful tool for monitoring the functional activity of electrically excitable cells. On an MEA, traditional 2-D neuronal cultures fail to provide detectable action potentials from individual axons, and instead, electrical readings are recorded largely from the neuronal cell body. Here, we show the functional characterization of an in vitro generated 3-D peripheral nerve bundle using a capillary alginate gel (Capgel™) from the dorsal root ganglion (DRG) of embryonic rats on an MEA. We demonstrate that, in the absence of neuronal cell bodies, bundling and outgrowth of axons within the gel lead to recordable action potentials. We also show that electrical readings can be recorded over several weeks and the well-wide mean firing rate of the 3-D nerve bundle is far superior to the 2-D control conditions. Further analysis of individual electrodes reveals the presence of multiple action potentials on the same electrode, indicating that several different axons within the same bundle are contributing to the electrical activity. This was further validated by treatment of the 3-D nerve bundles with capsaicin, a compound that elicits a response from nociceptive neurons. In response to capsaicin, we observe that some axons within the bundle have firing rates that are four times the basal readings, whereas other axons within the same bundle show no change in the firing rate. This supports the idea that the nerve bundles generated using Capgel™ are a heterogeneous population of axons which recapitulate the composition of in vivo nerve fascicles. Overall, we show here in the context of recording electrophysiological activity that a 3-D environment facilitates bundling of axons and yields enhanced recordable action potentials over longer periods of time. Clinically, hyperexcitability of the DRG is one of the important underlying mechanisms of neuropathic pain. We propose the use of this 3-D system for electrophysiological studies that may provide insight into cellular behaviors and serve as a platform for the development of new therapeutic targets.

Properties of Compressed Melanin Sheets.
C.H. Hou¹, Z. Trinh¹, J. Boligitz³, K. Wilson¹, A. Bhandari¹, Y. Zhu¹, S. Assari², K. Darvish², J.B. Sheffield², M.F. Kiani³, S.A. Baranowitz³;
¹Drexel University, Philadelphia, PA, ²College of Engineering, Temple University, Philadelphia, PA, ³Epismart, Philadelphia, PA

Melanin is an ancient biopolymer pigment which appeared shortly after the dawn of life and is present in most organisms. It is recognized as a unique nano-material and is being developed for a wide range of potential applications, including sensors, coatings, and electrical devices. We have fabricated the melanin in a novel form which may be practical for a range of uses, and we have surveyed some of the interesting material science properties of the melanin slabs created. This included the hardness, elastic modulus, failure stress, and radiation absorbing capacity of samples created with a range of hydration
and temperature parameters. We have also examined the fabricated samples with scanning electron microscopy. Sepia (cuttlefish) melanin was heated, dehydrated, milled and compressed into sheets 0.5-3 inches thick. The resulting material was rapidly vacuum packed, and remained sealed until the mechanical testing or radiation testing was performed. The x-ray testing was conducted using x-ray cabinet X-RAD 320 at 320 kV, 2 mA and 98 seconds. The mechanical testing (elastic modulus and failure stress) employed a Tinius Oslen 10000 tension compression machine at 5mm / min with test run until sample failure. Hardness testing used a durometer with a D2240 type A probe and set at 5 imprints with 0.24 inches apart. Electron microscopy employed the Agilent FESEM 8500, a compact field emission scanning electron microscope. Mechanical testing showed an elastic modulus range of the samples of 10.44 – 27.67 MPa and failure stress of 0.709 - 12.72 MPa. The hardness range was 48 - 75 HV. The x-ray absorption testing revealed that the melanin had 11% more x-ray absorption than water. Scanning electron microscopy demonstrated spherical melanosomes, which remained generally intact in spite of the compressive forces applied during the preparation of the samples. Basic material science properties of a novel formulation of melanin were successfully measured, and will serve as the basis for further studies to enhance its applicability to a variety of applications.

**Cell culture confluence estimation using embedded application on the InCellis® Smart Cell Imaging System.**

O. Varet¹, S. DUBACQ¹, L. Antanaviciute¹;
¹Bertin Instruments, Rockville, MD

In cell biology related studies, accuracy and efficiency in cell culture quality checks are crucial in order to avoid any potential complications in the downstream analysis. Usually, different cell parameters such as cell counting and cell size measurement are assessed and estimated visually in a subjective way. However, visual assessments are unreliable, a time consuming and often yielding inaccurate results which lead to incorrect conclusions and incorrect recommendations. This also adds to the end cost of the analysis with regards to consumables such as costly reagents. One of the most common and important cell culture parameters is cell culture confluence. As the name suggests, confluence is the proportion of the area that is covered by cells and is the key parameter for most cell biologists. Similar to cell counting, cell confluence estimation is also based on a visual cell line assessment. In this study, cell confluence application was used to accurately estimate the proportion of adherent cells in an automated manner using a cell culture confluence application available on the InCellis® Smart Cell Imaging System (Bertin Technologies). HeLa cell lines were plated on the petri dish and incubated at 37°C for in appropriate cell culture media (DMEM). Cell confluence application installed on the InCellis® was then used to calculate cell culture confluence every 24 hours for three consistent days. A series of images of the cell line were taken in phase contrast mode using 10x and 20x objectives on day-1, day-2 and day-3 at the same time in order to check the accuracy of cell confluence. The cell line confluence ranged from 24% on day-1 to 58% on day-3. The results obtained showed consistent and accurate percentage of confluence across images taken using different objectives without affecting the cell lines. The cell confluence application supplies robust results with a staining free method. The application ensured a rapid and efficient quality control of the cell lines before use in other analysis such as transfection, cell-based assays or any other cellular analysis. The automated estimation of the cell
confluency not only provides consistent results but also significantly reduces the hands-on time for all cell-based assays.

Efficient microscopy image visualization and cell tracking analysis of multi-gigabyte datasets. M. Jones¹, H. Lai¹, V.T. Chou², J.B. Long³, M. Arnes³, K. Obbad³, S.V. Alworth⁴, C. Huang⁵, L.A. Lucas⁶, D. Van Vactor⁶, J.S. Lee⁶;
¹DRVision Technologies LLC, Bellevue, WA, ²Cell Biology, Harvard Medical School, Boston, MA, ³Columbia University, New York, NY, ⁴AcuraStem Inc, Los Angeles, CA

Characterizing the molecular and cellular migration behavior is critical for understanding the complex protein interactions that drive brain development and neurodegeneration. Light sheet microscopy coupled with modern sample clearing techniques enable the visualization of multi-millimeter samples (e.g., a mouse brain) with high spatiotemporal resolution. Efficient display and accurate analysis of multi-gigabyte datasets remain a major bottleneck. Traditionally, the analysis pipeline of these datasets (visualization followed by tracking) is accomplished using open-source tools (such as FIJI or ICY) with an off-the-shelf algorithm (such as Brownian motion) or a custom algorithm tailored to a specific application (such as plusTipTracker plug-in for Matlab). However, neither approach is suitable for tracking the wide range of motion types that exist in a developing neuronal circuit. We have developed a new volume rendering pipeline which is capable of handling and displaying data sets that can be hundreds of gigabytes (GBs) for a 3D image, and multiple terabytes (TBs) for a 3D time lapse. The new renderer leverages the advantages of using an internal multi-resolution, multi-block architecture. Moreover, we have optimized the memory management system which ensures real-time high definition rendering and interaction after the file is loaded. We have also developed a general-purpose 3D+time particle tracking algorithm that enables tracking objects with complex spatiotemporal features with good specificity. Our tracking algorithm combines the tracking stability of the Hungarian algorithm and the tracking sensitivity of the greedy algorithm for matchmaking. The algorithm is further enhanced with self-correction that updates track matchmaking using temporal information from previous frames. We have applied our tracking algorithm to analyze the dynamics of EB1-GFP labeled microtubules in *Drosophila* neuromuscular junctions and sensory dendrites, and to the developing *Drosophila* embryo reference dataset from the Cell Tracking Challenge 2015. This allowed us to validate the performance of our algorithm when tracking complex particle motions in both 2D and multi-GBs 3D time-lapses. Efficient real-time handling of multi-TBs 3D time lapse data sets coupled with accurate cell tracking of a range of motion types is critical for the analysis of microscopy images. The present work describes a pipeline which covers both visualization and analysis of very large multi-dimensional images. This pipeline can aid in the advancement of research in neurosciences, developmental biology, cancer biology as well as systems biology.

High-throughput open source analysis of 3D structures using CellProfiler.
A. Goodman⁷, C. McQuin⁷, S. Singh⁷, A.E. Carpenter⁷;
⁷Imaging Platform, Broad Institute of MIT and Harvard, Cambridge, MA

Increasingly, researchers create complex biological model systems involving three-dimensional structures, including organoids, tumor spheroids, and even whole organisms. Imaging this biology in 3D
creates datasets that are volumetric, high-resolution, and orders of magnitude larger than typical 2D images. High-content screening systems enable acquisition of 3D images in high-throughput, yet the software to analyze crucial metrics from these images has lagged behind. We have added 3D segmentation, registration, and measurement capabilities to CellProfiler, open-source software for high-throughput image analysis. We are testing these new features in several experimental situations including 3D images of live gene-edited human induced pluripotent stem cells labeled with cellular and nuclear dyes.

Assessing autophagic flux in 2D and 3D cell culture models with a novel plate-based assay.
1 Promega Corporation, Madison, WI, 2 University of Wisconsin, Madison, WI

The importance of autophagy in cell health, both in normal and diseased states, has become increasingly clear. Although autophagy is a growing target of screeners in areas such as cancer, neurodegeneration, inflammation and immunology, there is a need for more convenient and effective assays for screening applications. Here we utilize NanoLuc® Binary Technology (NanoBiT™) to develop a homogeneous plate-based assay to measure autophagic flux in both 2D and 3D cell culture models. In this approach, LC3B (Atg8) protein was tagged on its N-terminus with an 11 amino acid peptide, HiBiT, as well as an intervening “spacer” sequence. When stably expressed at low to moderate levels in mammalian cell lines, this LC3-based reporter is subject to degradation by the autophagic pathway. Following compound treatment, cellular levels of this novel autophagy reporter is determined by addition of a lytic detection reagent containing Large BiT (LgBiT). LgBiT rapidly associates with HiBiT in the cell lysate, producing a bright, luciferase activity in the presence of substrate that is proportional to the amount of autophagy reporter present in the assay well (R² = 0.99). Assay signal following reagent addition is stable (T1/2 > 3h), allowing assay of multiple 96- or 384-well plates in the same experiment. In U2OS cells stably expressing this autophagy reporter, assay signal following mTORC inhibitor treatment decreased by 25% (rapamycin) to 60% (PP242, AZD8055), consistent with compound stimulation of autophagic flux and consequent degradation of autophagy reporter. In contrast, treatment with autophagy inhibitors (bafilomycin A1, chloroquine) produced a 70-80% increase in assay signal, consistent with accumulation of autophagy reporter following blockade of basal autophagy. Similar results were obtained in HEK293 cells stably expressing the reporter. Mechanism of action of autophagy modifiers was confirmed through blockade of effects by 50nM bafilomycin cotreatment. Multiplex with a cell necrosis detection agent allowed for same-well determination of cytotoxic effects that might undermine analysis of a compound’s discrete effects on autophagic flux. When assayed in 384-well plates with automation, U2OS and HEK293 autophagy reporter cells produced Z’ values of 0.6-0.7 in response to autophagy induction (PP242), and Z’ values of 0.7-0.8 by subsequent blockade of autophagy (PP242 + bafilomycin A1). In HEK293 reporter cell spheroids, both induction and inhibition of autophagic activity was easily observable following reference compound treatment. Therefore, using this novel plate-based assay system for the determination of autophagic flux, it is possible to screen test agents and quantitatively assess their effects in both 2D and 3D cell culture models.

Combining impedance-based viability measurements and flow cytometric analyte quantitation to evaluate effector cell killing of T lymphocytes.
L. Jachimowicz1, G. Guenther1, W. Tang1, P. Ye1, M. Lei1, F. Cerignoli1, B. Xi1, L. Zhao1, Y. Abassi1; 1Acea Biosciences, San Diego, CA

Cancer immunotherapy is increasingly being evaluated as an approach to cancer treatment by harnessing the immune system to attack cancer cells. Moving this research from the bench to the clinic is critically important but reliable tools are needed to translate in vitro protocols and results for use in vivo. Here, we have used a combination of impedance-based technology and flow cytometry to evaluate both the target and effector cells in an T-cell mediated B cell killing assay. Impedence based Real Time Cell Analysis (RTCA) technology with the xCELLigence® system provides a continuous readout of target cell viability while flow cytometry allows measurement of specific responses such as target cell viability and cytokine/cytolytic production by cells throughout the course of the assay. Here, we investigated the role of CD19-BiTE® to enhance the cytotoxic effect of T lymphocytes on a B-cancer cell line, Daudi cells. In conjunction, cytokine and cytolytic protein concentration measurements were determined to enhance our understanding of the T cell response. CD19-BiTE treatment dramatically enhances T cell-mediated B cell killing which can be assayed on both the xCELLigence RTCA and NovoCyte® flow cytometer. The addition of CD19-BiTE also leads to increases in the production of important cytokines and cytolytic proteins crucial for a robust cytotoxic T cell response such as IFNγ, IL-2, TNFα, sFASL, Granzyme B, and Perforin.

Expansion and Optimization of DIVA DNA Sequence Validation Services.
A.L. Large1, N. Kaplan3, J. Chiniquy3, G. Goyal2, N. Hillson2,3,4; 1University of Tennessee, Knoxville, TN, 2DOE Joint BioEnergy Institute, Emeryville, CA, 3DOE Agile BioFoundry, Emeryville, CA, 4DOE Joint Genome Institute, Walnut Creek, CA

Advances in DNA sequence validation technology has enabled the Joint BioEnergy Institute (JBEI) to offer high-throughput plasmid sequencing to its researchers. However, the types of compatible samples have not significantly expanded. This lack of compatibility leads to time and materials wasted on purifying or transforming a plasmid into E. coli. Here, we sought to update the current sequencing protocol to include the most utilized species and plasmid types, including E. coli cultures with medium and low copy plasmids, A. tumefaciens, P. putida, S. cerevisiae, and P. pastoris. Based on previous runs, the laboratory determined that a baseline coverage greater than 60x over the whole plasmid yielded the most accurate reads. This project showed that E. coli was the most robust species, with sequencing succeeding for all liquid cultures, regardless of copy number, and for resuspended colonies picked directly from agar plates. The remaining species experienced varying levels of coverage failure. However, minimal modification to the existing sequencing workflow, such as longer lysing times or the use of higher copy plasmids, could increase overall coverage. Overall, the sequence validation services provided by JBEI have numerous advantages over traditional Sanger sequencing with third-party companies. By expanding the compatible sample types, we are making this efficient, cost-effective sequencing service more accessible to JBEI’s research community.

High-affinity single-domain antibodies, like VHH, represent indispensable tools for research and clinical applications. To access VHH without Llama immunization, we have built a fully synthetic humanized naïve Llama VHH library containing 3x10^9 antibodies, based on a unique scaffold with random complementary determining regions (CDRs). Using phage display, we successfully selected antibodies from this library against a variety of antigens from large proteins to haptens, soluble proteins and receptors directly selected from cell surface expression. The affinity of the VHHs obtained from this library is similar to the affinity of antibodies selected after animal immunization. A combination with subsequent exhaustive yeast two-hybrid (Y2H) screening allows to further favor the selection of intrabodies – antibodies working inside living cells. The VHH clones are directly accessible and the recombinant antibodies can be produced as fusions to different Fc domain (human, mouse, etc.). We will present here the selection of single-domain antibodies from our synthetic library against p53, USP7 and a cell surface antigen.

Engineering Vero Cell Line to Enhance Vaccine Production.
A. Sicam¹, J. Pickens², L. Jones³, S. Bell¹, R. Tripp³;
¹Proventus Bio, Athens, GA, ²Department of Infectious Diseases, University of Georgia, Athens, GA

Worldwide, the ability to control infectious diseases requires improved vaccines, increasing their production capacity and reducing manufacturing costs. Using genome-wide small interfering RNA (siRNA) screens, we validated for NEU2, COQ9 and BTN2A1 genes in Vero cells as essential for rotavirus, dengue virus, enterovirus 71 and yellow fever virus replication. In this study, we used the CRISPR/Cas9 system to edit these genes in Vero cells. Following transection of the CRISPR/Cas9 plasmids, we observed average transfection efficiencies of 14.85%, 13.54% and 14.64% for the NEU2, COQ9, and BTN2A1 genes, respectively. Putative knockout clones will be validated through sequencing and testing of phenotypic increase of viral production. Results will demonstrate the applicability of genetic engineering in increasing the production output of vaccine cell lines.

A novel rapid cell ablation model for eliminating one or two maker-labelled cell populations in mice—a model for studying the pathogenesis of human diseases.
F. Liu¹, S. Dai², D. Feng³, A. Kearns³, X. Peng³, B. Gao³, X. Qin³;
¹Neuroscience, Temple University School of Medicine, Philadelphia, PA, ²Laboratory of Liver Diseases, National Institute on Alcohol Abuse and Alcoholism, Bethesda, MD

Loss-of-function (LOF) studies using conditional targeted cell ablation have been widely used in vivo to study cell functions and interactions, tissue repair and differentiation though to date they can only target a single labelled cell population. Therefore, there is an unmet need to develop a tool that is able to specifically eliminate a subset cells that require more than one marker to appropriately identify in animals for LOF studies. To this end, we propose to generate an interleukin-12 (IL12)-mediated subset cell ablation model by targeting cell subsets with two markers. ILY, a toxin secreted by Streptococcus intermedius (SI), exclusively binds to the human cell membrane protein CD59 (hCD59), but not to CD59 of any other species. Once bound, ILY rapidly and potently lyses the cells. Taking advantage of these features, we recently established a Cre-inducible floxed STOP-hCD59 transgenic mouse (ihCD59) where hCD59 expression only occurs after Cre-mediated recombination (Feng D, et al. JCI 2016). Administration of ILY to various lines of Cre+ihCD59+ mice resulted in rapid and specific ablation of single marker immune, epithelial or neural cells without any off-target effects. Importantly, ILY has a large pharmacological window, which allows us to perform dose-dependent study. We also tested ILY/ihCD59-mediated cell ablation in several disease models, including inflammatory diseases, hepatocyte and/or biliary epithelial damage and regeneration. This line (ihCD59) targets only one marker-labelled cell population, and cannot be used for ablating subset cell populations. To further advance this tool towards subset cell ablation, using the well-established Cre-loxP and Flp-Frt systems, we have successfully developed a double inducible mouse strain: CAG-floxSTOP-floxP-Frt-STOP-Frt (LSL-FSF)-hCD59 (DihCD59) where the transgene (hCD59) expression occurs only following Cre- and Flp-mediated combinational events. To investigate whether Cre and Flp-mediated combination are required to induce hCD59 expression in DihCD59, we crossed DihCd59 with ROSA29Flp+/-, a germ line Flp expressing strain, and Foxp3CreER+/-, a Foxp3 (Treg marker) promoter-controlled Cre expressing strain to generate the triple transgene positive mice (DihCD59+/−-ROSA29Flp+/-Foxp3CreER+/-). We documented that hCD59 expression in Treg depends on both Cre and Flp-induced recombinational events to remove the two Floxed STOP cassette in triple transgene positive compound mice but not Cre or Flp-induced single recombination. ILY injection resulted in ablating the hCD59 expressing Treg cell population but not any other cells. Together, these results document we have successfully generated a novel rapid cell ablation model for eliminating one or two maker-labelled cell populations in mice.

Antibiotic-resistance genes are now widely used as markers for gene transfer in many organisms and have greatly contributed to biological experiments. Antibiotic selection, such as puromycin, hygromycin and geneticin selection, has been applied to nematode Caenorhabditis elegans (C. elegans) to create
transgenic worms. However, from perspectives of efficiency, facility and cost, developing another choice is valuable and expected.

Nourseothricin (NTC) is an aminoglycoside glycopeptide antibiotic of Streptothromycin class. Because of its nephrotoxicity, NTC is not used for therapeutic purpose. However, it has already been reported as a marker for genetic modifications in yeast, plants and mammalian cells. By trying NTC resistance genes in *C. elegans*, we found one of the resistant gene *Sat2* works in *C. elegans* and established this system as a new transgenic marker for *C. elegans* genetics.

To determine the critical concentration of NTC for antibiotic selection, we added certain concentration of NTC solutions to NGM plates already seeded with OP50, then put adults or synchronized L1 worms on them. Control worms without a resistant gene died in the presence of NTC. The critical concentration of NTC was lower than Hygromycin. Next, we developed nematode transformation vector carrying *Sat2* under the control of universal promoter of *C. elegans* ribosomal protein gene *rps-27*. *Sat2* carrying worms could grow on NGM plates containing NTC. Now we are trying to combine this NTC-*Sat2* system with CRISPR/Cas9 system and establish new genetic methods.

As NTC has no cross-reactivity with other aminoglycoside antibiotics such as Hygromycin or Geneticin, resistance genes for these drugs can be used with *Sat2* simultaneously. The efficiency and cost of NTC selection is comparable to widely-used Hygromycin selection. Thus, combining with other drugs will enable the development of wider range of powerful applications. In this poster, I will show the method of NTC-*Sat2* screening and discuss its possible application.

**SUMO-TARGETING OF A STRESS-TOLERANT SUMO PROTEASE.**

R. Yin¹, J.L. Peek², D. Gray³, C. Harvey¹, R. Levy-Myers¹, D. Rosenberg¹, L. Kolla¹, J. McMurry², O. Kerscher⁴;

¹Biology, The College of William Mary, Williamsburg, VA, ²Biochemistry, Kennesaw State University, Kennesaw, GA

SUMO proteases of the SENP/Ulp family are master regulators of both sumoylation and desumoylation and regulate SUMO homeostasis in eukaryotic cells. SUMO conjugates rapidly increase in response to cellular stress, including nutrient starvation, hypoxia, osmotic stress, DNA damage, heat shock, and other proteotoxic stressors. Nevertheless, little is known about the regulation and targeting of SUMO proteases during stress. To this end we have undertaken a detailed comparison of the SUMO-binding activity of the budding yeast protein Ulp1 (ScUlp1) and its ortholog in the thermotolerant yeast Kluyveromyces marxianus, KmUlp1. We find that the catalytic UD domains of both ScUlp1 and KmUlp1 show a high degree of sequence conservation, complement a Ulp1Δ mutant in vivo, and process a SUMO precursor in vitro. Next, to compare the SUMO-trapping features of both SUMO proteases we produced catalytically inactive recombinant fragments of the UD domains of ScUlp1 and KmUlp1, termed ScUTAG and KmUTAG respectively. Both ScUTAG and KmUTAG efficiently bind a variety of purified SUMO isoforms. Specifically, they bound immobilized SUMO1 with nanomolar affinity. However, KmUTAG showed a greatly enhanced ability to bind SUMO and SUMO-modified proteins in the presence of oxidative, temperature and other stressors that induce protein misfolding. We also investigated whether a SUMO-interacting motif (SIM) in the UD domain of KmULP1 that is not conserved in ScUlp1 may contribute to the SUMO-binding properties of KmUTAG. In summary, our data reveal important details about how SUMO proteases target and bind their sumoylated substrates, especially under stress conditions. We also show that the robust pan-SUMO binding features of KmUTAG can be exploited to detect and study SUMO-modified proteins in cell culture systems.

Development and functional analysis of novel PEI-based mammalian cell transfection reagents.

T. Suk-in¹, A. Tan¹, B. Franca², A. Gemma², S. Granados-Focil², R. Bellin²;
¹Chemistry, Clark University, Worcester, MA, ²Biology, College of the Holy Cross, Worcester, MA

As novel research and therapeutic techniques are developed that require the delivery of nucleic acids into mammalian cells and tissues, the need for highly effective transfection reagents that display minimal toxicity is essential. Cationic polymers, whose architecture can be chemically altered to control their functionality, have become a particularly attractive target for further development. Among cationic polymers, polyethylenimine (PEI) has shown promising DNA complexation and transfection efficiency rates, but also exhibits relatively high cell toxicity. In this project, we have worked to develop easily-tailorable, non-toxic, nucleic acid delivery systems based on PEI functionalized with polyethylene glycol molecules. We have studied the toxicity and transfection ability of a pair of novel, chemically-related polymers in range of cell lines, including utilizing fluorescently-tagged polymer and plasmid DNA to enable the detailed monitoring of the DNA-delivering complexes in cells via confocal microscopy. These studies demonstrate that minor differences in the chemical architecture of functionalized PEI can have significant effects on cell toxicity, and point the way towards the development of effective, targeted cationic polymer-based reagents.

Matching refractive index of mounting media improves axial resolution and image quality in 3D biological samples.

O. Golub¹, M. Wickman¹, A. York¹, D. Cash¹;
¹Molecular Probes Labeling Detection, Thermo Fisher Scientific, Eugene, OR

Axial resolution in light microscopy can be improved by matching the refractive index (RI) between the biological specimen and the microscope objective. The path of a photon emitted by a fluorophore in a biological sample passes through 1) the mounting media in which the sample is embedded, 2) a glass coverslip, 3) immersion oil, and finally 4) the microscope objective. While the optical path between the objective and coverslip (2-4) typically has a matched RI of 1.52, the majority of biological specimens are mounted in media of substantially lower RI, ranging from 1.42 - 1.47, causing a loss in axial resolution due to refractive index mismatch. Here, we use laser scanning confocal microscopy to demonstrate the deleterious effects of mismatched refractive index in conventional mounting media by measuring the point spread function (PSF) of sub-diffraction sized fluorescent microspheres. We then compare these results with specimens prepared in ProLong™ Glass mounting media, featuring an optimized refractive index of 1.52. Our data indicates that at depths beyond 20 μm, an RI-mismatched mounting media suffers significant losses in axial resolution, whereas the RI-matched mountant maintains optimal axial resolution throughout, enabling up to a 75% improvement in axial resolution at focal depths of 100 μm and beyond. By eliminating unwanted refraction, ProLong™ Glass also maximizes the light reaching the objective lens, thus providing higher sensitivity and a brighter image when imaging thick biological samples, such as spheroid cultures that mimic tumor microenvironments. Combined with photobleach protection antifade properties in the visible and near infra-red spectra, the optimized refractive index of ProLong™ Glass mounting media measurably increases fidelity and image quality for bright, high-resolution 3D analysis of any cell/tissue type.

Engineered Cell Penetrating Peptides for Molecular Delivery.
N. Chada¹, W. Ma¹, W.H. Suh¹;
¹Department of Bioengineering, Temple University, Philadelphia, PA

Cell penetrating peptides (CPPs) are a unique non-viral vector for delivery of molecules into cells. The earliest CPPs were based on natural protein sequences such as TAT from HIV-1 and Antp from Drosophila. These peptide sequences contain many positively charged amino acids (i.e. arginine and lysine) which allow for interactions with the negatively charged plasma membrane of cells. Later, synthetic and designer CPP sequences were developed for specific applications such as drug delivery, imaging, and gene therapy. These synthetic sequences are typically amphiphilic (or amphipathic), containing a hydrophilic and a hydrophobic region. Our lab has developed a novel amphiphilic CPP, called PepB, which is able to internalize into various cell types including stem cells and cancer cells. Depending on the number of repeats PepB can form α-helices and the number of repeats will modulate the cell penetrating capabilities. In this presentation, uptake and cytotoxicity properties of PepB will be correlated to the peptide sequence lengths. We, in addition, will provide live-cell fluorescent microscopy data utilizing multiple mammalian cell types.

POST-STIM1 interactions modulate Ca²⁺ oscillation frequency via modulation of PMCA4 function.
T. Cangoz¹, C.K. Go¹, J. Soboloff¹;
¹Fels Institute for Cancer Research and Molecular Biology, Temple University, Philadelphia, PA

Ca²⁺ oscillations control both NF-kB and NFAT activity and are therefore essential for T cell activation. Ca²⁺ oscillations reflect a combination of ER Ca²⁺ release, Ca²⁺ entry and Ca²⁺ pumping; as a regulator of both Ca²⁺ entry via Orai1 and Ca²⁺ pumping via PMCA4, STIM1 would be expected to serve a critical role in the generation of Ca²⁺ oscillations. The ER membrane protein Partner of STIM1 (POST) was found to bind both PMCA4 and STIM1; how this affects oscillation frequency is less clear. To address this question, Jurkat T cells were transfected via electroporation with a POST plasmid for overexpression or siRNA for knockdown. These cells were then stimulated with activating antibodies directed against human CD3/CD28 and loaded with Fura-2 AM. Stimulated and unstimulated T cells were placed in a Ca²⁺ containing imaging buffer and oscillations in cytosolic Ca²⁺ were observed for ten minutes. The variance in cytosolic Ca²⁺ concentration under of each condition was compared. Surprisingly, Ca²⁺ oscillations were observed even in unstimulated Jurkat T cells. As expected, activation with anti-CD3/CD28 antibodies increased oscillation variance under all conditions. In unstimulated conditions, POST expression was correlated with the fraction of non-oscillating cells. In stimulated conditions, POST expression shows a Goldilocks effect with both POST overexpression and knockdown having smaller fractions of non-oscillating cells as compared to cells with endogenous levels of POST. Considered collectively with POST-mediated regulation of PMCA4 function, these findings reveal important roles for POST and STIM1 for control of PMCA4 activity in the generation of Ca²⁺ oscillations for control of T cell activation.

A Novel Approach for Characterizing the Cell-Implant Adhesion.

J.Y. Chen1, Y. Pan2, L.S. Penn1, N. Xi1, J. Xi1;
1Department of Chemistry, Drexel University, Philadelphia, PA, 2Department of Biology, Drexel University, Philadelphia, PA, 3Department of Industrial and Manufacturing System Engineering, The University of Hong Kong, Pok Fu Lam, Hong Kong

Cell adhesion is essential to cell communication, cell regulation, and the development and maintenance of tissues. We have developed a non-invasive real-time approach based on the use of the quartz crystal microbalance with dissipation monitoring (QCM-D) for monitoring and characterizing the adhesion process of human epidermal keratinocytes to the titanium surface, a common material for medical implants. With this approach, we have investigated the effects of chemical, electrical and biochemical treatments on the adhesion process, particularly on the level of the cell adhesion. A further understanding of the cell adhesion process and the alteration of such process in responding to exogenous stimuli may provide leads on the development of therapies for enhancing adhesion of cell on medical implants and promoting wound healing and tissue regeneration.

Arp2/3 complex- and formin-mediated actin networks tune actin-binding protein sorting in fission yeast.

K.E. Homa1, C. Suarez1, D.R. Kovar1,2;
1Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, 2Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL

F-actin networks are diverse and specialized to carry out specific cellular processes, such as polarization, endocytosis, and cytokinesis. Each F-actin network is tightly regulated by a unique set of actin-binding proteins (ABPs) that initiates and maintains the organization and dynamics of actin filaments. However, the general mechanistic principles by which specific ABPs sort to particular F-actin networks remain largely unclear. By combining in vivo fluorescence microscopy and in vitro reconstitution, we discovered that two actin assembly factors, Arp2/3 complex and formin Cdc12, tune the binding of ABPs fimbrin and tropomyosin to specific F-actin networks in fission yeast. Disruption of F-actin networks by small molecule inhibitors or genetic manipulation revealed that fimbrin is preferentially recruited to Arp2/3-complex mediated actin patches, while tropomyosin is preferentially targeted to the contractile ring by Cdc12-mediated filaments. To investigate the role of Arp2/3 complex and Cdc12 in this sorting, we used four-color in vitro TIRF microscopy to reconstitute ABP sorting with purified proteins. We discovered that either fimbrin or tropomyosin alone binds similarly to Arp2/3 complex- and Cdc12-mediated actin filaments. Conversely, sorting of these ABPs to their preferred actin filaments occurs when Arp2/3 complex- and Cdc12-mediated filaments are assembled together in the presence of both fimbrin and tropomyosin. Under these conditions, fimbrin accumulates ~2-fold more at Arp2/3 complex branch points, while tropomyosin association is enhanced 3.5-fold on filaments assembled by Cdc12. This result suggests that competition between fimbrin and tropomyosin is necessary for their sorting to different F-actin networks. In summary, these findings reveal for the first time that the F-actin assembly factors...
Arp2/3 complex and formin Cdc12 facilitate the recruitment of specific ABPs, thereby tuning ABP sorting and subsequently establishing the identity of a given F-actin network.

Arp2/3 complex and the nucleation promoting factor Wash are involved in the formation of MTOC-TMA during Xenopus oocyte maturation.
Y. Yamagishi1, H. Abe1;
1Dept. of Nanobio., Grad. Sch. of Advanced Integration Sci., Chiba univ, Chiba, Japan

During maturation of Xenopus oocytes, the microtubule organizing center and transient microtubule array (MTOC-TMA) forms at the vegetal side of the nucleus and we have previously demonstrated that this formation requires ADF/cofilin dependent actin reorganization. However, the molecular mechanism that coordinates actin filaments with microtubule (MT) during oocyte maturation wholly remains to be clarified. Here we show that Arp2/3 complex and its nucleation promoting factor Wash are involved in the MTOC-TMA assembly. Overexpression of Arp2/3 complex subunits increased actin filament formation inside the yolk free region and generated additional MTOC-TMA- like structures along the edge of yolk free region. Wash depletion disrupted actin and MT alignments at the base of MTOC-TMA. In vitro co-sedimentation assay revealed that the Xenopus Wash VCA domain which is the actin and Arp2/3 complex binding domain directory bound to MT. However, the WHD2 domain that previously reported to be a MT-binding domain of mammalian Wash did not bind to MT. Interestingly, injection of the WHD2-deleted mutant into oocytes caused drastic accumulation of actin filaments in the cytoplasm and malformation of MTOC-TMA, suggesting that WHD2 domain negatively regulates the VCA domain activity and is responsible for precise localization of Wash during oocyte maturation. Our results suggest that Wash-Arp2/3 complex-nucleated actin filaments are involved in the assembly of MTOC-TMA during Xenopus oocyte maturation.

Abp1 stimulates Arp2/3 complex nucleation of actin filament branches and protects them from debranching by GMF.
S. Guo1, O.S. Sokolova2, J. Chung3, S. Padrick4, J. Gelles3, B.L. Goode4;
1Department of Biology, Brandeis University, Waltham, MA, 2Department of Biology, Moscow State University, Waltham, MA, 3Department of Biochemistry, Brandeis University, Waltham, MA, 4Department of Biochemistry and Molecular Biology, Drexel University, Philadelphia, PA

Abp1 (also known as mAbp1, HIP55, SH3P7, or Drebrin-like protein) is a multi-domain actin binding protein that is highly conserved from yeast to humans. Abp1 binds to actin filaments through its conserved N-terminal ADF (Actin depolymerization factor homology) domain and links endocytic machinery to the actin cytoskeleton through its C-terminal SH3 domain. Yeast Abp1 alone shows no effects on actin filament dynamics but has nucleation-promoting factor (NPF) activity on Arp2/3 complex despite lacking actin monomer binding affinity like other NPFs (Goode et al., 2001). Here, we examined Abp1’s effects on Arp2/3 complex-mediated actin assembly and actin filament branch turnover using single molecule TIRF microscopy. In contrast to its close relative ADF/cofilin, Abp1 interacted with actin filaments non-cooperatively and with a sub-second resident time. Abp1 also interacted dynamically with Arp2/3 complex in the absence of actin, using its two acidic (A) motifs. However, Abp1 bound strongly, with a residence time of tens of seconds, to Arp2/3 complex in filament
branch junctions. These properties could allow Abp1 to scan filaments and find branch junctions in vivo. Through direct visualization of fluorescently labeled Arp2/3 complex, we confirmed a longstanding hypothesis that Abp1 stimulates daughter filament nucleation by recruiting Arp2/3 complex to the sides of mother filaments. Further, single particle EM analysis revealed that two Abp1 molecules bind to Arp2/3 complex. We also observed a competitive relationship between Abp1 and GMF, another ADF-like protein that interacts with Arp2/3 complex. Abp1 directly competed with GMF for Arp2/3 binding, and attenuated GMF’s ability to prune branches. Taken together, this evidence points to a novel mechanism of stimulating daughter branch nucleation and branch stabilization, completely distinct from the canonical ‘VCA pathway’.

Arp2 Phosphorylation is Not Essential for Arp2/3 Complex Activity in Fission Yeast.
A. Epstein¹, S. Espinoza², T.D. Pollard¹²;
¹Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, ²Molecular Biophysics and Biochemistry, Yale University, New Haven, CT

A 2008 study of Arp2/3 complex proposed that three conserved amino acids of the Arp2 subunit must be phosphorylated to activate the complex in Acanthamoeba castellanii. (LeClaire et al. 2008) However, these sites are not phosphorylated in crystal structures of purified Bos taurus Arp2/3 complex, which is highly active and polymerizes branched actin filaments in vitro.

We tested whether Arp2 phosphorylation is necessary to activate the fission yeast (Schizosaccharomyces pombe) Arp2/3 complex. The proposed phosphorylation sites are conserved in S. pombe as Y198, T233, and T234, and mass spectrometry revealed that Y198 and T233 are phosphorylated in vivo. We replaced one, two, or three of these amino acids in the S. pombe genome with alanine, which cannot be phosphorylated. Arp2/3 complex activity is essential for viability in fission yeast, yet all generated mutants remained viable. Therefore, phosphorylation at these sites is not necessary for the essential activities of S. pombe Arp2/3 complex. Interestingly, when T233 was replaced with aspartic acid, which mimics constitutive phosphorylation, the resulting mutant displayed a growth defect at high temperature. Replacing both threonines with aspartic acid was lethal.

In S. pombe, the Arp2/3 complex continuously assembles branched filaments in actin patches, generating force to internalize endocytic vesicles. These patches are consistent in size and can be labeled by GFP-tagging the actin crosslinker Fim1, facilitating automated image segmentation and tracking. We used quantitative fluorescent confocal microscopy to observe the time course of actin patch assembly in vivo. Replacing all three proposed phosphosites of Arp2 with alanine slowed actin patch assembly by 42%, demonstrating that the mutations reduce Arp2/3 complex activity. However, replacing T233 with aspartic acid had a similar effect. Therefore, we propose that phosphorylation of Arp2 at Y198, T233 and T234 is not required for the Arp2/3 complex to be active in fission yeast. Instead, mutations at these sites may reduce the activity of the complex by altering its structure. If these mutations serve an important regulatory function in A. castellanii, it is not conserved in fission yeast. However, phosphorylation at other sites, such as the widely conserved residue Y218, may still play an important role in Arp2/3 complex regulation.

Multiscale Model of the Formin Homology 1 Domain Illustrates its Role in Regulation of Actin Polymerization.
B.G. Horan¹, G. Zerze², G.L. Dignon², Y.C. Kim³, D. Vavylonis¹, J. Mittal²;
¹Physics, Lehigh University, Bethlehem, PA, ²Chemical and Biomolecular Engineering, Lehigh University, Bethlehem, PA, ³Naval Research Laboratory, Center for Materials Physics and Technology, Washington, DC

Formins are important regulators of actin polymerization. Formins bind profilin to the polyproline tracks of its believed flexible Formin Homology (FH) 1 domain. The FH2 domains wrap around the barbed end of the actin filament and elongate the filament processively. Profilin-actin complexes on the FH1 domain are modeled to transfer to the barbed end; however, the mechanism is not known. Previous models of the FH1 domain have not captured sequence-specific effects such as the length and distribution of the polyproline tracks and possible variety in mechanosensitivity and response to bound profilin/profilin-actin. To remedy this, we perform simulations of the FH1 domain of well-studied formins: the mouse formins mDia1 and mDia2, the budding yeast formins—Bni1 and Bnr1, and the fission yeast formins—Cdc12, Fus1, and For3. We perform all-atom molecular dynamics simulations of each of these FH1 domains and show that FH1 is a typical intrinsically disordered protein (IDP), with the polyproline tracks forming high propensity poly-L-proline helices. We develop an alpha-carbon coarse-grained model that retains the sequence-specificity of the FH1 domain which is consistent with the IDP notion of FH1, and use this to study the FH1 domain in the context of its biological role. We use the coarse-grained model to investigate the response of FH1 to force and bound profilin. We show how bound profilin/profilin-actin may extend the FH1. We show definitively that multiple profilin-actin complexes can simultaneously bind to the FH1, which may be biologically important given the relatively high concentration of profilin-actin in vivo. We examine the transfer mechanism in further detail. We show how the FH1 may be affected by being on the FH2-bound actin filament barbed end rather than in isolation and examine the geometry of this system with bound profilin-actin.

Force dependence of filopodia adhesion: involvement of myosin II and formins.
N.O. Alieva¹, A.K. Efremov¹, M. Natarajan¹, S. Hu¹, D. Oh¹, Z. Chen¹, H. Ong¹, A. Jégou³, G. Romet-Lemonné³, J.T. Groves⁴, M.P. Sheetz¹, J. Yan¹, A.D. Bershadsky²,²;
¹National University of Singapore, Mechanobiology Institute, Singapore, Singapore, ²National University of Singapore, Center for Biologging Sciences, Singapore, Singapore, ³Institut Jacques Monod, Paris, France, ⁴University of California, Department of Chemistry, Berkeley, CA, ⁵Columbia University, Department of Biological Sciences, New York, NY, ⁶National University of Singapore, Department of Physics, Singapore, Singapore, ⁷Weizmann Institute of Science, Rehovot, Israel

Filopodia are dynamic membrane protrusions driven by polymerization of an actin filament core. This polymerization is mediated by formin molecules at the filopodia tips. Growing filopodia can adhere to the extracellular matrix and experience both external and cell generated pulling forces. The roles of such forces in filopodia growth and adhesion is however insufficiently understood. Here, we induced sustained growth of filopodia by applying pulling force to their tips via attached fibronectin-coated beads trapped by optical tweezers. Strikingly, pharmacological inhibition or knockdown of myosin IIA, which localized to the base region of the filopodia, resulted in cessation of filopodia growth and

Tuesday-36
weakening of filopodia adherence strength. Similar effects were obtained by treating cells with a small molecular formin inhibitor SMIFH2. SMIFH2 caused deterioration of myosin X- VASP- and talin-enriched patches associated with actin filaments at the filopodia tips, followed by quick myosin II dependent retrograde movement of these components. Such dynamics can be explained by SMIFH2-induced detachment of actin filaments from formin molecules observed in in vitro experiments. Collectively our results suggest that myosin IIa generated centripetal force transmitted to the filopodia tips through interactions between formins and actin filaments is required for filopodia adhesion and growth. This force dependent adhesion behavior could play an important role in filopodia-mediated matrix rigidity sensing, durotaxis and tumor invasion.

The interaction of FHOD1 with nesprin-2G activates a cryptic actin binding site and stimulates potent actin bundling activity: implications for nuclear movement.
S. Antoku1, G.G. Gundersen1; 1Pathology Cell Biology, Columbia University, New York, NY

The formin FHOD1 binds to specific spectrin repeats (SR11-13) in the outer nuclear membrane protein nesprin-2G and this interaction is required for formation of TAN (transmembrane actin-associated nuclear) lines and nuclear movement in fibroblasts (Kutscheidt et al, NCB, 2014). To understand the mechanistic basis for this, we tested how the interaction of nesprin-2G’s SR11-13 affected FHOD1’s actin polymerizing and bundling activities. Using purified recombinant proteins, we confirmed that full length (FL) FHOD1 alone did not stimulate actin polymerization by pyrene assays but rather weakly inhibited it. Addition of nesprin-2G SR11-13 activated the inhibitory effect of FL FHOD1 on actin polymerization to a similar degree as that of constitutively active FHOD1 ΔDAD. FHOD1 has reported F-actin bundling activity (Schonichen et al, JCS, 2013) and we confirmed that FHOD1 ΔDAD bundled F-actin and that this activity required both its FH2 domain and a putative second actin binding site (ABS). Low speed pelleting assays to detect actin bundling activity revealed that SR11-13 activated FL FHOD1’s bundling activity (SR11-13 had no activity alone). The level of bundling with FL FHOD1 and SR11-13 was similar to that of FHOD1 ΔDAD, yet SR11-13 further stimulated FHOD1 ΔDAD’s bundling activity to the low nM range making it more potent than that either fascin or α-actinin. TIRF microscopy of fluorescent actin filaments showed that actin bundles were formed by FL FHOD1 only when SR11-13 was present. To understand how SR11-13 stimulated bundling, we tested its effect on the ABS upstream of FHOD1’s FH1 and FH2 domains. Using an N-terminal (NT) FHOD1 construct containing the ABS and adjacent SR11-13 binding site, we found that NT FHOD1 alone did not bind to actin filaments, but did so in the presence of SR11-13. These results show that the nesprin-2G potently activates FHOD1’s actin bundling activity by activating a cryptic actin binding site and suggest that the nucleus plays an active role in strengthening it’s interaction with actin bundles during nuclear movement.

Understanding muscle cell size regulation by the Caenorhabditis elegans formin FHOD-1.
C.V. Yingling1, D. Pruyne1; 1Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY

Formins are best known for their ability to nucleate actin and to remodel actin organization within cells. A mammalian formin FHOD3 has been shown to be required for cardiac muscle to mature past
premyofibrils formation in mice and for sarcomere organization in cardiomyocyte cell culture. Activated FHOD3 induces hypertrophy in neonatal rat cardiomyocytes. However, we do not know how FHOD3 functions. To avoid the pleiotropic effects and embryonic lethality of the mouse model, we will examine a FHOD3-related formin of Caenorhabditis elegans, FHOD-1. FHOD-1 localizes to all muscle types within the worm, including the largest muscle group, the striated body wall muscles (BWM). Previous work has shown that knockout of fhod-1 in the worm will cause thinning of the BWM cells. These fhod-1(-) worms also have disrupted dense bodies, attachment complexes thought to be analogous to mammalian Z-lines, and have a reduction in muscle specific myosin heavy chain 3 (MYO-3) protein expression. We considered four plausible mechanisms of reducing MYO-3 expression in fhod-1(-) worms: 1) reduced transcription, 2) reduced mRNA stability, 3) increased protein degradation or 4) reduced translation. To determine if myo-3 mRNA level was reduced in fhod-1(-) worms, we performed qRT-PCR. Surprisingly, we discovered an increase in myo-3 mRNA levels upon loss of FHOD-1. This increase in myo-3 mRNA in fhod-1(-) worms removes transcription and mRNA stability as an explanation for the reduction in MYO-3 expression. We are currently exploring two alternative mechanisms. One possible mechanism is increased degradation of MYO-3 protein. We will test MYO-3 expression in fhod-1(-) worms after individually inhibiting each of the three known protein degradation pathways in BWM of C. elegans to determine if rescue occurs. The second possible mechanism is reduced translation of myo-3 mRNA. We will test levels of polyribosomes bound to myo-3 mRNA in wild-type and fhod-1(-) worms. Determining how FHOD-1 regulates protein expression might help resolve the role of FHOD3 in the hypertrophy of cardiac muscle.

The Drosophila Formin Fhod Nucleates Actin Filaments.
A.A. Patel¹, Z.A. Oztug Durer²,³, A.P. van Loon¹, M.E. Quinlan²,⁴;
¹Molecular Biology Interdepartmental Doctoral Program, University of California, Los Angeles, Los Angeles, CA, ²Department of Chemistry and Biochemistry, University of California, Los Angeles, Los Angeles, CA, ³Department of Biophysics, Acibadem University School of Medicine, Istanbul, Turkey, ⁴Molecular Biology Institute, University of California, Los Angeles, Los Angeles, CA

Formins are a conserved group of proteins that nucleate and processively elongate actin filaments. Among them, the formin homology domain-containing protein (FHOD) family of formins contributes to contractility of striated muscle and cell motility in several contexts. However, the mechanisms by which they carry out these functions remain poorly understood. Unlike other formins, mammalian FHOD1 and FHOD3 do not accelerate actin assembly in vitro, and have instead been suggested to act as barbed end cappers or bundlers. Here, we show that purified Drosophila Fhod, in contrast with the mammalian homologues, potently accelerates actin assembly by nucleation. We found that Fhod binds tightly to barbed ends, where it slows elongation in the absence of profilin and allows elongation in the presence of profilin. Fhod protects barbed ends from capping protein, but dissociates from barbed ends relatively quickly. Finally, we used cosedimentation assays to determine that Fhod binds the sides of actin filaments and bundles filaments. This work establishes that Fhod shares the capacity of other formins to nucleate and bundle actin filaments, but is notably less effective at processively elongating barbed ends.

Intracellular zinc regulates actin nucleation during mouse oocyte maturation and fertilization via Spire.
Y. Jo³, N. Kim⁴, S. Namgoong⁴;
¹Animal Science, Chungbuk National University, Cheongju, Korea, South

Zinc plays essential roles in mammalian oocyte maturation, fertilization, and early embryogenesis. Previously it has been known that depletion of zinc impairs various stage of oocyte maturation, including cell cycle controls, asymmetric division, and cytokinesis. But the exact mechanistic roles of zinc involved in these process is elusive. Here, we report that zinc is one of the essential cofactors in the actin cytoskeleton remodeling during mouse oocyte maturation, via actin nucleator Spire. Depletion of zinc in oocyte using chemical chelator or knockdown of zinc transporters impair cortical and cytoplasmic actin formation. Spire is colocalized with zinc-containing vesicle via C-terminal FYVE domain containing zinc finger motifs and it is essential for their localization and actin mesh formation in oocytes. Expression of truncation mutants of spire revealed that proper localization and activity of spire require all three major domains of Spire. After fertilization/parthenogenetic activation, oocyte zinc level is decreased by the release of zinc. The subsequent decrease of zinc content after parthenogenetic activation, Spire localization in cortex and vesicle is dramatically changed, indicating that zinc is an essential cofactor for Spire. Collectively, our data revealed the novel roles of zinc in the regulation of actin nucleator spire and controlling asymmetric division during mammalian oocyte maturation.

Epidermal specific knock out of N-WASP expression caused atopic dermatitis like inflammation in mice.
P. Kalailingam¹, H. Tan¹, N. Jain¹, S. Keat¹, J. Chan¹, T. Soon¹, T. Thanabal¹;
¹School of Biological Sciences, Nanyang Technological University, , Singapore, Singapore

Neural-Wiskott Aldrich Syndrome Protein (N-WASP) is a ubiquitously expressed protein which regulates the actin cytoskeleton by activating the actin nucleating activity of the Arp2/3 complex. In order to characterize the role of N-WASP in skin barrier function and their related disease such as atopic dermatitis (AD), we generated conditional N-WASP knockout mice (N-WASPK14KO; N-WASPF/fi; K14-Cre) using K14-cre and N-WASPF/fl mice to ablate expression of N-WASP in keratinocytes. The N-WASPF/fi; K14-Cre (N-WASPK14KO) mice were born following mendelian genetics suggesting that N-WASP expression in keratinocytes is not essential during development. Transepidermal water loss (TEWL) measurement showed a significant increased water loss in N-WASPK14KO mice compared to its control litter mates, N-WASPCtr suggesting a skin barrier defect. The skin barrier defect in N-WASPK14KO mice was confirmed by Lucifer Yellow (LY) penetration assay which revealed greater penetration of the LY in the skin of N-WASPK14KO compared to controls. Bacterial swab and subsequent culture test showed higher number of S. aureus colonization in N-WASPK14KO mice skin compared to control mice skin. The bacterial colonies were confirmed as S. aureus by PCR amplification of Staphylococcal enterotoxin B (SEB). Toluidine blue, Congo red and Immunostaining showed significant increased infiltration of mast cells, eosinophil and T- lymphocytes respectively in the skin of N-WASPK14KO mice compared to control mice. We found significantly higher levels of IL-1α, TNF-α, IL-6
and IL-17 in serum of N-WASP14KO mice compared to control mice. In conclusion, N-WASP knockout in keratinocytes caused atopic dermatitis like inflammation in the skin and activate local and systemic immune response in the mice, suggesting that N-WASP is involved in maintaining the skin barrier and homeostasis in adult mice skin. Thus we have identified N-WASP as one of the critical mediator in atopic dermatitis pathology.

**Identifying Functions of a *Chlamydomonas* Formin in Flagellar Assembly.**

G.L. Witter\(^1,2\), B. Jack\(^3\), T. Kersten\(^4\), S. Dutta\(^3\), P. Avasthi\(^3,5\);

\(^1\)Anatomy and Cell Biology, University of Kansas Medical Center, Kansas City, KS,\(^2\)Department of Dermatology, University of Kansas Medical Center, Kansas City, KS,\(^3\)Biochemistry, Spring Hill College, Mobile, AL,\(^4\)K-INBRE Summer Scholar Program, Kansas City, KS,\(^5\)Department of Ophthalmology, University of Kansas Medical Center, Kansas City, KS

*Chlamydomonas reinhardtii*, a unicellular green alga, is used as a model organism for ciliary/flagellar studies, genetics of centrioles, cell-cell recognition, and cell cycle control. However, little is known about the function of the actin cytoskeleton within this cell. We previously showed that actin plays a role in assembly of the microtubule-based sensory organelle, the cilium. In order to test the role of a subset of the actin network on regulating flagellar length in *Chlamydomonas*, we used a compound, SMIFH2, that inhibits formin, an actin nucleator responsible for making linear filaments. These experiments showed that SMIFH2 has specific shortening effects on flagella. We hypothesized that genetic manipulation of a *Chlamydomonas* formin gene would partially recapitulate the inhibitor phenotype and affect flagellar assembly or maintenance. In contrast to the inhibitor result, we found that the formin mutant had longer flagella and a faster regeneration rate following deflagellation. In a classical experiment to assay the quantity of limiting flagellar precursor protein (the excess protein available for incorporation into flagella without additional protein synthesis), we found that the formin mutant contained a larger precursor pool. Following deflagellation, these mutants also had increased protein synthesis relative to wild-type cells. In pool depleted conditions, new flagellar protein incorporation was initially delayed in the formin mutant but eventually was faster in formin mutants the regenerating flagellum. Together, these data suggest a subset of linear actin filaments play an inhibitory role in the synthesis and incorporation of flagellar proteins. Additional functions for other *Chlamydomonas* formins targeted by SMIFH2 and branched actin may account for the discrepancies between these results and the aggregate effects of actin inhibitors/null mutants on flagellar assembly.

**Screening for function-altering INF2 mutants using a live-cell actin polymerization assay.**

T. Fung\(^1\), R. CHAKRABARTI\(^1\), H.N. Higgs\(^1\);

\(^1\)Department of Biochemistry Cell Biology, Geisel School of Medicine at Dartmouth, Hanover, NH

The inverted formin-2 (INF2) is a vertebrate formin (1249 Amino Acids in length) that can both polymerize and depolymerize actin filaments. In cells, INF2 exists in 2 forms - namely the CAAX form, which localizes to the endoplasmic reticulum (ER); and the non-CAAX form, which is found in the cytoplasm. INF2 stimulation in multiple cell types induces a transient burst of actin polymerization in the cytosol, which peaks within 1 min and depolymerizes by 4 min (Shao et al (2015) PNAS, Ji et al (2015) eLife, Wales et al, (2016) eLife). Recent discoveries showed that mutations near the N-terminus Diaphanous Inhibitory Domain (DID) region correlated with two diseases: focal segmental
glomerulosclerosis (FSGS) and Charcot-Marie Tooth disease (CMTD). Conversely, little is known about how C-terminus mutations affect the function of INF2 biochemically or in mammalian cells. Using genomic sequence and proteomic information from the Broad Institute, UniProt.org, and PhosphoSite.org - we generated a library of INF2 mutations predicted to disrupt post-translational modifications such as ubiquitination (K966N) and phosphorylation (S1192A, T1199A). We screened these mutants for recovery of the ionomycin-induced “actin burst” in INF2-KO U2OS cells by live-cell microscopy. Through our initial screen, we found that these mutations led to subtle but significant differences in actin polymerization and depolymerization. The actin burst for K966N exhibited a lower amplitude (8% decrease) with a shorter recovery time (~40 seconds difference). Both phosphorylation mutants INF2-CAAX induced bursts with slightly lower amplitudes compared to WT (3% for S1192A and 4% for T1199A) but with significantly longer recovery times (~120 seconds delay for both). We also tested the ionomycin-stimulated increase in mitochondrial calcium, which is also INF2-dependent (see poster from Chakrabarti et al), and found 7.7% decrease for K966N compared to WT, mirroring the observations of the actin "burst". Taken together, these results highlight the importance of the C-terminal region of INF2 in its regulation and function. Further studies will probe effects on ER morphology and mitochondria dynamics.

Actin nucleation factors that control autophagy are important for zebrafish organ development.

A. Mathiowetz¹, K.G. Campellone³, D. Daggett¹;

¹Molecular and Cell Biology, University of Connecticut, Storrs, CT

Autophagy is a process of intracellular degradation that is crucial for removing unwanted cytoplasmic material, maintaining cellular homeostasis, and enabling embryonic development. The actin cytoskeleton, which plays key roles in numerous intracellular trafficking pathways, has recently been shown to significantly impact autophagy. In mammalian cells, the homologous actin nucleation factors JMY and WHAMM promote autophagosome biogenesis, but the importance of these proteins in animal development is not known. To address this question, we used the model vertebrate organism Danio rerio (zebrafish) to examine the functions of JMY and WHAMM. We found that the zebrafish orthologs of JMY and WHAMM contain motifs known to be important for binding actin, the Arp2/3 complex, and autophagosomal membranes. Consistent with mammalian JMY activities, zebrafish JMY nucleated actin in the presence and absence of the Arp2/3 complex in vitro, but it lacked the microtubule binding ability of human WHAMM. Unexpectedly, zebrafish JMY appeared to be a more potent Arp2/3 activator than mammalian JMY. In vivo, zebrafish embryos treated with morpholinos for depleting JMY exhibited changes in body morphology, alterations in heart and pronephros development, and pericardial edema. Treatment with a combination of morpholinos to JMY and WHAMM caused more pronounced morphological defects than JMY knockdown alone. However, these phenotypes were not as severe as those found in embryos treated with a morpholino to Atg5, a core component of the autophagy machinery. These results indicate that JMY and WHAMM are important for organogenesis during embryonic development and suggest that actin nucleation plays a key role in this process.

Actin filament elongation factors formin and Ena/VASP trigger the transition from lamellipodia- to filopodia-like networks.
C. Suarez¹, J.D. Winkelman¹, A. Harker², P.M. McCall³,⁴, A.N. Morganthaler¹, M.L. Garde³,⁴,⁵, D.R. Kovar¹,²; ¹Department of Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, ²Department of Biochemistry and Molecular Biology, The University of Chicago, Chicago, IL, ³James Franck Institute, The University of Chicago, Chicago, IL, ⁴Department of Physics, The University of Chicago, Chicago, IL, ⁵Institute for Biophysical Dynamics, The University of Chicago, Chicago, IL

Cells simultaneously assemble and maintain different actin filament (F-actin) networks that are involved in diverse processes such as cell motility and cell division. Filopodia are finger-like membrane protrusions composed of long F-actin bundles that have been proposed to sense extracellular chemical and mechanical signals to steer the cell. Two actin elongation factors, formin and Ena/VASP, have been found at filopodia tips and induce specific architectures. It has been hypothesized that filopodia can be generated from F-actin networks that consist of densely packed, branched actin filaments that are kept short by capping protein.

How can filopodia emerge from this high density of capped filaments, and do different assembly factors facilitate the formation of diverse filopodia?
We propose that, in the presence of capping protein, filopodia formation is triggered by the combined action of the actin bundling protein fascin and the actin elongation factors formin mDia2 or Ena/VASP. By combining micropatterning and bead motility assays with three-color Total Internal Reflection Fluorescence (TIRF) microscopy, we reconstituted the formation of filopodia-like F-actin networks from densely-branched networks in vitro. We show that in the presence of saturating concentrations of capping protein, filopodia-like network formation is inhibited. In contrast, it is rescued by inclusion of the processive actin filament barbed-end elongator formin mDia2, and to lesser extent by Ena/VASP. Interestingly, formin-generated networks are longer and free of capping protein, unlike the short Ena/VASP-generated networks. In addition, the F-actin bundler fascin facilitates filopodia-like network formation by inhibiting Arp2/3 complex-mediated branching up to 50 percent. Finally, we found that saturating concentrations of Ena/VASP increase the dissociation rate of formin mDia2 from F-actin barbed ends.

Our reconstituted in vitro system reveals that the combination of the F-actin bundler fascin with the actin elongation factors formin or Ena/VASP is sufficient to trigger a transition from a dense branched network of capped F-actin to filopodia-like networks. Additionally, formin and Ena/VASP generate specific protrusion morphologies resembling those that have been observed in vivo.

Characterization of Formin-2 Functions using in vitro Approaches.
P. Dutta¹, S. Maiti², A. Ghose¹;
¹Department of Biology, Indian Institute of Science Education and Research Pune, Pune, India, ²Biological Sciences, Indian Institute of Science Education and Research Kolkata, Kolkata, India

The cytoskeleton plays an indispensable role in the cellular morphogenesis, endocytosis, cell division and other cellular processes. Orchestration of actin and microtubules is central to the dynamicity of the cell cytoskeleton. Formins are cytoskeleton modulators and play an essential role in the development process of cell cytoskeleton by modulating both microfilaments and microtubules. Formin-
2 (Fmn2) is characterised as a cytoskeleton regulator involved in organising the actin filaments. Fmn2 has an essential role in spindle positioning and migration in oocytes. Fmn2 interacts with FilaminA to regulate endocytosis and with p21 to control cell cycle. Recently our lab has shown that Fmn2 is required for spinal commissural connectivity in chick neurons. Fmn2 belongs to typical formin family characterized by the presence of known FH1FH2 domains in their C-terminal end. In order to understand Fmn2 function and its regulation, we have undertaken a detailed characterization of chick Fmn2 using in vitro reconstitution assays. Chick Fmn2 is capable of potently binding F-actin. Using fluorimetric assays, we show that chick Fmn2 is able to nucleate, elongate actin filaments and also replace CapZ from the filament tip. Co-sedimentation assays revealed that Fmn2 can cross-link and bundle F-actin. The latter was also confirmed by TIRF microscopy. Our data suggest that Fmn2 also binds to microtubule and we are currently conducting detailed structure-function analysis to uncover the domains mediating the actin microtubule cross talk of Fmn2. These studies offer important insights into Fmn2 function, especially the co-regulation of actin and microtubule dynamics. Detailed characterization of these activities is likely to reveal key modalities of Fmn2 regulations and its ability to coordinate the microtubule and actin cytoskeletons.

Adenomatous polyposis coli (APC) nucleates actin assembly to drive cell migration and microtubule-induced focal adhesion turnover.

M.A. Juanes1, H. Bouguenina2, J.A. Eskin1, R. Jaiswal1, A. Badache2, B.L. Goode1;

1Department of Biology, Brandeis University, Waltham, MA, 2Institut Paoli-Calmettes, CRCM, Inserm, Institut Paoli-Calmettes, CNRS, Marseille, France

Adenomatous polyposis coli (APC) is a tumor suppressor protein (310 kDa) that functions in Wnt signaling and in cytoskeleton rearrangements that govern cell migration, cell protrusions and adhesion. APC is also the ‘gatekeeper’ gene in human colorectal tumorigenesis, with C-terminal truncations of APC leading to >80% of all colorectal cancers. The C-terminal ‘Basic’ domain of APC binds to microtubules and actin, and potently nucleates actin assembly in vitro. APC also governs microtubule organization and dynamics in vivo. The lack of clean separation-of-function mutants in APC has made challenging to disentangle APC’s effects on actin versus MTs, and to rigorously assess the in vivo importance of its specific interactions and activities. With the goal of uncoupling APC’s effects on actin nucleation from its direct interactions with MTs, we mapped the sequences in APC required for actin nucleation, and then generated the APC-m4 mutant, which alters only two residues but abolishes actin nucleation activity without altering in vitro interactions with MTs. Cells expressing full-length APC carrying the m4 mutation (APC-m4) complemented in vivo cellular functions in microtubule organization, microtubule dynamics, and mitochondrial distribution caused by RNAi depletion of endogenous APC, but failed to support directed cell migration. APC-WT and APC-m4 proteins both localized to focal adhesions, but expression of APC-m4 led to diminished actin assembly at focal adhesions and severe defects in microtubule-induced focal adhesion disassembly/turnover. Using the APC-m4 mutant, we have demonstrated the in vivo importance of the actin assembly-promoting activity of APC and discovered that it is critical for directed cell migration. Our observations further suggest that these functions stem from a requirement for APC-mediated actin assembly at FAs - in a role that is required for MT-induced FA disassembly. To our knowledge, this is the first evidence of an actin assembly requirement in the MT-induced FA turnover process, and given the dual interactions of APC with MTs and actin, suggests that APC may directly coordinate MT and actin dynamics in stimulating FA turnover, which is a critical step in directed cell migration.

A novel interaction between NMIIB and Survivin is essential for proper cell division.
A. Babkoff\(^1\), E. Cohen-Kfir\(^1\), D. Ronen\(^1\), S. Ravid\(^1\);
\(^1\)Biochemistry molecular biology, The Hebrew University of Jerusalem, Jerusalem, Israel

Cell division is necessary for proper growth and development of many organisms. It ends with the physical separation of the two daughter cells, a process known as cytokinesis. The primary motor protein responsible for cytokinesis is non-muscle myosin II (NMII), and together with F-actin it assembles the cleavage furrow forming the contractile ring. The site of the contractile ring assembly and the timing of its constriction are closely coordinated with chromosome segregation to allow accurate partitioning of the genome and formation of the two daughter cells. The chromosomal passenger complex (CPC) plays an important role in coordinating and regulating these processes through its functions in central spindle formation, regulation of furrow ingestion, and abscission. The CPC is composed of Aurora B kinase, Borealin, INCENP, and Survivin. When one of the CPC proteins is perturbed, the other components do not localize properly during cell division, leading to disruption in cell division. The mechanism by which CPC localizes to the cleave site and regulates the formation of the contractile ring to eventually achieve cytokinesis is unknown. The CPC member, Survivin is believed to play a dual role in cell cycle progression and apoptosis. We recently found that Survivin and NMII form a complex in vivo through direct interactions. This interaction is NMII isomorph specific and is regulated by Survivin phosphorylation. Survivin inhibits NMIIB filament assembly, which may indicate that it prevents the premature formation of the contractile ring. Identification of Survivin binding site to NMIIB provides a molecular explanation for this inhibition. During telophase and cytokinesis, NMII and Survivin co-localize to the cleavage furrow and midbody. These results may indicate that Survivin and NMIIB interaction is essential for cell division.

Graded activation of ROCK and MLCK tunes regional stress fiber formation and mechanics via preferential myosin light chain phosphorylation.
E. Kassianidou\(^1,2\), J.H. Hughes\(^1,2\), S. Kumar\(^1,3\);
\(^1\)Bioengineering, University of California, Berkeley, Berkeley, CA, \(^2\)UC Berkeley - UCSF Graduate Program in Bioengineering, Berkeley, CA, \(^3\)Chemical and Biomolecular Engineering, University of Berkeley, Berkeley, CA

Stress fibers (SFs) are prominent force-generating cytoskeletal structures chiefly comprised of actin and non-muscle myosin II (NMMII). NMMII motor activity is strongly promoted by phosphorylation of the NMMII light chains (MLCs) by MLCK and Rho-associated kinase (ROCK). MLCs can be phosphorylated once (p-MLC) or twice (pp-MLC), with each phosphorylation state distinctly influencing myosin ATPase activity. Prior work suggests MLCK and ROCK regulate SF formation in the cell periphery and cell center respectively, and both MLC phosphorylation states have been observed throughout the cell. However, it is unclear how MLCK and ROCK differ in their regulation of MLC phosphorylation state, how these kinases regulate these two pools of SFs, and how these parameters influence SF mechanics. Here, we address these questions by combining inducible genetic expression of MLCK or ROCK with mechanical measurements of single SFs in live cells and phosho-specific immunoanalysis. Immunoblots
reveal that constitutive activation (CA) of MLCK preferentially increases whole-cell levels of p-MLC while CA of ROCK increases pp-MLC. Quantitative immunofluorescence analysis demonstrates that MLCK preferentially increases recruitment of p-MLC to peripheral SFs while ROCK recruits pp-MLC to central SFs. To relate kinase activity to SF mechanical properties, we used ablation to sever single SFs in live cells and tracked the retraction of the severed ends as tension dissipated. We found MLCK increased the effective viscosity and total stored elastic energy in peripheral SFs but not central SFs, while ROCK preferentially increased these same parameters in central SFs. To directly link MLC phosphorylation state and stress fiber mechanics, we overexpressed phosphomimetic mutants of p-MLC and pp-MLC and found that phosphomimetic p-MLC influenced only peripheral SF viscoelastic parameters while phosphomimetic pp-MLC influenced only central SF viscoelastic parameters, phenocopying our ablation findings. Finally, by varying the concentration of the small-molecule inducer in the culture medium, we could establish gradations in kinase expression and concomitant p- and pp-MLC levels, thereby enabling quantification of these relationships. Application of this strategy revealed surprising and previously unappreciated nonlinearities between MLC phosphorylation state and SF viscoelastic properties. This work supports a model in which MLCK regulates peripheral stress fiber viscoelasticity via monophosphorylation of MLC while ROCK regulates central stress fiber viscoelasticity via di-phosphorylation of MLC.

Cdc42 GEF Gef1 coordinates actomyosin ring constriction and septum ingression during cytokinesis.
B. Wei1, P. Mlynarczyk1, U. Onwubiko1, J. Habiyaremye1, A. Clack1, S. Abel2, M. Das1;
1Biochemistry Cellular and Molecular Biology, University of Tennessee, Knoxville, TN, 2Chemical and Biomolecular Engineering, University of Tennessee, Knoxville, TN

Cytokinesis is a temporally organized multi-step process leading to the physical separation of daughter cells during division. In fission yeast, cytokinesis involves the assembly of an actomyosin ring that constricts concurrently with septum ingression and furrow formation. The septum provides the force required to overcome internal turgor pressure in the cell. It is not clear how a cell spatiotemporally coordinates simultaneous ring constriction and septum ingression. We have reported that the conserved GTPase Cdc42 is activated in a unique spatiotemporal manner during cytokinesis depending on the localization of its activators, Gef1 and Scd1. Gef1 specifically promotes the recruitment of the septum-synthesizing enzyme Bgs1 at the ring to allow timely onset of ring constriction and septum ingression. It is not clear how Gef1 promotes the recruitment of Bgs1 to the division site. Previous reports suggest that Bgs1 localization at the ring depends on the F-BAR protein Cdc15. Here we show that mutants with reduced recruitment of Cdc15 at the assembled ring and also lacking gef1 display defects in ring constriction. In addition, these mutants also display uneven distribution of Cdc15 at the ring. Interestingly, these mutants do not show any defect in ring assembly, suggesting that the constriction defects observed here are due to impaired events after ring assembly. Cells with uneven Cdc15 distribution along the ring display abnormally long constriction times. Regions of the ring with reduced Cdc15 show delayed constriction rates and non-concentric furrowing. To understand how Gef1 promotes Cdc15 distribution and timely Bgs1 recruitment along the ring, we developed a computational model to describe how proteins are evenly organized in an actomyosin ring. Our model predicts that protein-protein interaction along with robust protein recruitment and recycling along the ring leads to even protein distribution at the ring. To test if Gef1 promotes protein-protein interactions, we investigated the distribution of other proteins along the ring in a Gef1-dependent manner. We find that
loss of gef1 leads to defects in the distribution of the type II myosin Myp2, but not that of the ring assembly myosin, Myo2. Previous reports have shown that Myp2 is recruited to the ring after ring assembly and is required for normal ring constriction. Based on these findings, we posit that Gef1 at the assembled actomyosin ring coordinates Bgs1-dependent septum ingression and Myp2-dependent ring constriction, leading to concentric furrow formation. Thus the Cdc42 GEF Gef1 allows the actomyosin ring to act as a landmark for the proper organization of proteins at the division site to ensure efficient septum ingression, ring constriction, and furrow formation.

Compartmentalized regulation of myosin light chain phosphatase and myosin light chain kinase during cell spreading.
N.E. Snell\textsuperscript{1}, M. Markwardt\textsuperscript{1}, K. Seckinger\textsuperscript{1}, M. Rizzo\textsuperscript{1};
\textsuperscript{1}Physiology, University of Maryland Baltimore, Baltimore, MD

Non-muscle myosin II (NMMII) is critical for cell migration; phosphorylation of the regulatory light chain (RLC) controls myosin motors binding to actin filaments and drives cell contraction. Myosin light chain kinase (MLCK) and myosin light chain phosphatase (MLCP) are the primary regulators of RLC phosphorylation. However, how the activities of these two regulatory proteins coordinate to promote cellular movement are not well understood. To investigate the distribution of MLCP activity in live cells, we developed a FRET-based MLCP biosensor. REFS2 fibroblasts transfected with the MLCP sensor were introduced to nitric oxide (NO), which induced MLCP activity. Chemical generation of NO inhibited cell spreading on a fibronectin matrix and was associated with MLCP activation. Similarly, modifying the potential MLCP phosphorylation sites to Alanine at (T694A) and (T852A) also increased activity. To determine the distribution of MLCK and MLCP, cells were co-transfected with CFP/YFP kinase FRET sensor and OFP/RFP phosphatase FRET sensor. Multi-parametric measurements determined the localization of active MLCP and MLCP during spreading. Differential regulation of MLCK and MLCP was observed along the moving membrane, and enhanced MLCK activity and decreased MLCP activity was observed adjacent to the leading edge. Additionally, presence of ROK inhibitor Y27632 reduced MLCK activity and enhanced MLCP activity during migration. These results suggest the importance of compartmentalized MLCP and MLCK activity during cell movement.

Actomyosin contractility maintains the integrity of the Drosophila testis niche during gonadogenesis.
J. Sui\textsuperscript{1}, L. Wingert \textsuperscript{1}, S. DiNardo\textsuperscript{1,2};
\textsuperscript{1}Cell and Developmental Biology, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, \textsuperscript{2}Institute for Regenerative Medicine, University of Pennsylvania, Philadelphia, PA

Proper formation of niches is essential to maintain the balance of self-renewal and differentiation within associated stem cells. We use the Drosophila testis as a model to study these interactions. In this organ, the niche makes intimate contacts with the germline stem cells it regulates. Thus, the efficiency of signaling depends on proper morphogenesis of the niche; however, how the niche achieves its final architecture remains unknown. Using live imaging techniques, we have identified two phases during niche formation: 1. Assembly, in which specified cells migrate and coalesce at one end of the organ, and 2. Compaction, during which the assembled niche cells condense further, finalizing their associations.
with germ cells. Here, we show that actomyosin contractility is implicated to maintain the integrity of the niche along its germ cell interfaces during compaction. Live imaging showed that compaction was correlated with the enrichment of non-muscle myosin II and increase of f-actin protrusive activity along niche-stem cell interfaces. This suggests that forces are acting during compaction. Therefore, we explored the relative magnitude and direction of these forces. We used a laser to cut niche-stem cell interfaces and measure the retraction velocity as a proxy for tension. We found that these interfaces were under greater tension later during compaction than at the onset of this process when germ cells and niche cells first associate. Furthermore, retraction velocities were decreased in the presence of a Rho Kinase inhibitor, suggesting that actomyosin contractility was implicated in producing tension. We additionally observed a change in the direction of the net forces comparing early versus late compaction. After an early cut, the interface deformed such that the germ cell encroached into niche cell space. This did not occur upon later cuts. The data suggests that germ cells apply a force orthogonal to the niche during compaction, and normally the niche cells offer resistance to that force. Later in morphogenesis, forces are re-directed, as tension is aligned with niche-stem cell interfaces. Our findings show that the behavior of stem cells and their relationship with the niche are integral to niche morphogenesis.

Profilin Directly Enhances Microtubule Growth Through Residues Mutated in Amyotrophic Lateral Sclerosis.
J.L. Henty-Ridilla¹, M.A. Juanes², B.L. Goode²;
¹Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, ²Cell Biology, Brandeis University, Waltham, MA

Profilin is one of the most abundant and central actin regulatory proteins in eukaryotic cells. Profilin also decorates the sides of microtubules and indirectly influences cellular microtubule dynamics through interactions with Formins. Here, we investigated whether Profilin has direct regulatory effects on microtubule dynamics. We show that human Profilin-1 binds to microtubules in vitro and enhances the growth rate of microtubules several-fold. These microtubule effects are conserved in budding yeast and Drosophila Profilin homologs, and are unaffected by mutations in its canonical actin monomer— or poly-L-proline—binding sites. Instead, microtubule regulation depends on several residues mutated in patients with amyotrophic lateral sclerosis (ALS). The enhanced microtubule dynamics elicited by Profilin are attenuated by increasing concentrations of actin monomers. This suggests a competitive relationship between microtubules and actin for Profilin binding and this agrees with the close proximity of the known actin and microtubule binding surfaces. Consistent with these biochemical results, a two-fold increase in expression of wildtype Profilin accelerates the growth rate of microtubules in cells, and cells expressing similar levels of each of the ALS-associated Profilin mutants did not. These results demonstrate Profilin directly interacts with and enhances the growth rate of microtubules in vitro and in cells, and indicate that Profilin coordinates cellular actin and microtubule dynamics. Further, cells harboring ALS-linked Profilin mutations may ultimately leads to the motor neuron degeneration through defective microtubule regulation.

**Composition of LAT clusters regulates their movement within actomyosin networks.**  
J.A. Ditlev1,2, A.R. Vega3, D.V. Koester3,4, X. Su1,5, R.D. Vale2,5, S. Mayor3,4, K. Jaqaman5, M.K. Rosen1,2;  
1Department of Biophysics and Howard Hughes Medical Institute, UT Southwestern Medical Center, Dallas, TX, 2Howard Hughes Medical Institute Summer Institute, Marine Biological Laboratory, Woods Hole, MA, 3Department of Biophysics, UT Southwestern Medical Center, Dallas, TX, 4National Centre for Biological Sciences, Bangalore, India, 5Department of Cellular and Molecular Pharmacology and Howard Hughes Medical Institute, University of California San Francisco, San Francisco, CA

In activated T cells, phase separated LAT clusters move from the edge to the center of the immune synapse. Recent studies have used super-resolution microscopy to describe two networks of actin within the immune synapse; a region of actin retrograde flow that exists near the synapse edge and a region of formin-generated actin bundles that exists adjacent to the region of retrograde flow, near the center of the synapse. LAT clusters move through these two regions at velocities that are tightly correlated with actin movement, suggesting that cluster movement is directly linked with actin movement. However, the molecular mechanism that regulates cluster movement through the different actin cytoskeletal networks within activated T cells was unknown. Using Jurkat T cells that fluorescently expressed components of LAT clusters, we observed that the molecular composition of LAT clusters in activated Jurkat T cells changes as clusters move from the edge to the center of the synapse. We hypothesized that this composition change may alter the ability of clusters to interact with the surrounding actin cytoskeletal network. To test our hypothesis, we reconstituted LAT phase separated clusters within two types of active actomyosin networks on supported lipid bilayers. Within a steady-state actomyosin network, in which LAT clusters of varying compositions formed amid a constantly moving actin network, we observed that cluster composition regulated the mechanism by which clusters were actively moved by the actomyosin network. Within a contractile actomyosin network, in which LAT clusters of varying compositions were formed within an existing actin network prior to Myosin II-induced actin network contraction, cluster movement was tightly correlated with actin movement depending on the composition of LAT clusters. Using our reconstituted system, we discovered a molecular clutch that links LAT cluster movement with actin filament movement in active actomyosin networks. The biochemical results from our reconstituted system explain how the movement of LAT clusters is correlated with the movement of both actin retrograde flow and contractile actomyosin bundles within different regions of an activated Jurkat T cell.

**Optimal adhesion stability is required for proper sarcomere assembly in cardiomyocytes.**  
A.C. Neininger1, N. Taneja1, D.T. Burnette1;  
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Hypertrophic and dilated cardiomyopathies affect 1 in 500 and 1 in 250 individuals in the US, respectively. ~70% of the causative mutations in patients are in genes that encode either adhesion or contractile proteins. A balance of adhesion and contraction is required in healthy cardiomyocytes (i.e., heart muscle cells), loss of which leads to detrimental phenotypes and disease states. Treating these diseases will require reconstructing the delicate balance between adhesion and contraction found in healthy cardiomyocytes. Unfortunately, how the adhesive and contractile systems assemble in cardiomyocytes is not well understood. Classic work has shown that inhibiting contraction (i.e., beating)
of cultured primary cardiomyocytes results in a loss of adhesion. This indicated that there is feedback between the adhesive and contractile systems. To characterize this potential relationship, we studied iPSC-derived human cardiomyocytes (hCM) in culture during adhesion and sarcomere assembly. To investigate the role of adhesion stability in hCM contractility, we modulated adhesion stability with several different techniques. Inhibition of focal adhesion kinase (FAK, an integral component of focal adhesion turnover) led to stabilized adhesions in hCM. Surprisingly, FAK inhibition also caused precocious sarcomere formation. Stabilization of adhesions by plating on increased fibronectin concentrations also caused precocious sarcomere formation, and plating on decreased fibronectin concentrations reduced sarcomere formation. However, precocious sarcomere formation resulting from increased adhesion area led to aberrant beating characteristics and sarcomere disorganization. siRNA mediated knockdown of FAK led to decreased adhesion stability, and disrupted sarcomere formation. Similarly, inhibition of contraction rapidly breaks down sarcomeres. To quantify these observed changes, we performed computer-assisted analysis of the borders of sarcomeres (i.e. Z-lines) to quantify metrics of sarcomere assembly over hundreds of hCM. These techniques ensure quick, unbiased, and quantitative measurements and specifically detect minute changes in sarcomere structure. We have shown that decreasing adhesion in turn decreases sarcomere assembly, and similarly, that increasing adhesion leads to precocious sarcomere formation in a disorganized manner. These results suggest there is an optimal adhesion amount for proper sarcomere assembly and homeostasis. Understanding this relationship helps us better understand the mechanisms underlying cardiomyopathy pathology.

How is apical constriction triggered? Possible roles for afadin and zyxin.
M.M. Slabodnick1, T.D. Cupp1, A. Chen1, S. Tintori1, B. Goldstein1;
1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Apical constriction is a commonly used mechanism to change a cell's shape and initiate morphogenesis in broad range of animal systems, including the vertebrate neural tube. Apical constriction occurs as a result of actomyosin contractions at the apical surface, which shrink the exterior face of the cell as the cells move to the interior of the embryo. This project seeks to understand the mechanisms used by cells and tissues during development to spatially and temporally regulate the forces that generate shape changes using Caenorhabditis elegans gastrulation as a model for studying the mechanisms of apical constriction. Gastrulation in C. elegans involves two endodermal precursor cells (E cells) that shrink their apical surfaces and move from the embryo's surface to the interior at the 26-28 cell stage. Surprisingly, data suggests that both actomyosin contractions and strong apical tension precede shrinking of the apical surface. This suggests that a temporally regulated link allows for the coordination of the contracting apical actomyosin networks with the apical cell-cell junctions to trigger apical constriction. We pursued both a proteomic as well as a bioinformatic approach to identify proteins that could act as a link between α-catenin in the adherens junction and the actin cytoskeleton. We identified genes of interest that show enrichment in the E cell lineage prior to gastrulation and are evaluating whether or not they are required for normal development. These approaches have identified two major candidates that could function in a clutch mechanism – afd-1/afadin and zyx-1/zyxin. Both candidates display gastrulation defects when knocked down by dsRNA injection and have known functions consistent with the idea that they could form a link between adherens junctions and the actin cytoskeleton. So far we have determined that afd-1 is required for normal gastrulation and that the protein is expressed and colocalizes with the cadherin-catenin complex. Also, knockdown of zyx-1 appears to result in defective coupling of actomyosin contractions to cell junctions during apical constriction. I am currently working to characterize the mechanisms through which afadin and zyxin are functioning in vivo. Both afadin and
zyxin are broadly conserved genes and these data could apply to mechanisms that regulate apical constriction in other systems.

The pre-metazoan origin of animal cell contractility.  
T. Brunet¹, N. King¹;  
¹Molecular and Cell Biology, University of California Berkeley/HHMI, Berkeley, CA

Actomyosin-mediated cell contractility has been fundamental to the evolution of animal complexity. During development, morphogenesis is mediated by embryonic cell contractility and movements of adult organisms rely on the specialized contractility of muscle cells. Even though embryonic and adult cell contractility have been documented in all major animal lineages (sponges, ctenophores, cnidarians, bilaterians) and thus likely date back to the last common animal ancestor, their pre-metazoan evolutionary origins remain unclear. Genomic data indicate that choanoflagellates genomes encode homologs of the main metazoan contractility proteins: actin, myosin, their upstream regulators (myosin kinases, calcium sensors, voltage-gated calcium channels), and even transcription factors that specify animal muscle cells (Mef2, Myocardin and SRF). Immunostainings have confirmed the presence of actomyosin at the basal pole of the cell (which shows contractile activity during filopodia-mediated settlement), pharmacological assays and live imaging have shown that its activity is necessary for proper settlement, and traction force microscopy allows quantification of contractile forces. By comparing the cellular modules and transcriptional circuits involved in choanoflagellate contractility to their animal counterparts, we infer the presence in choanozoan ancestors of an ancient mechanosensory-effector arc controlling contractile behavior that paved the way for the later evolution of animal contractile cells, including muscle cells.

Septins as modifiers of actin dynamics.  
T. Kogan¹, K. Nakos², E. Spiliotis², S.B. Padrick¹;  
¹Biochemistry, Drexel University, Philadelphia, PA, ²Biology, Drexel University, Philadelphia, PA

Controlled dynamic rearrangements of the actin cytoskeleton underlie essential changes to cell shape, steps of cell division and cell motility. The septins, a group of GTP-binding filament forming proteins, constitute a relatively new class of cytoskeletal proteins and were initially discovered as participants in yeast cell division. Septins are known to interact with the actin cytoskeleton, but neither the detailed mechanism of septin interactions with actin nor their effect on actin dynamics are well understood. A number of septin families exist in vertebrates and are thought to interact with each other to form discrete hetero-oligomeric complexes, which can then assemble into filaments. One complex is well established, the Sept2/6/7 hexamer, which is two subassemblies of Sept7 bound to a Sept6 family member, bound to a Sept2 family member, held together by Sept2-Sept2 interactions, and is supported by a crystal structure. The Sept3 family is thought to add at the ends of this complex to produce an octamer. Increased expression of the Sept9 member of the Sept3 family is associated with a number of invasive cancer phenotypes, suggesting that the hexameric and octameric assemblies may have distinct functions. Given this observation, and the necessary role of actin dynamics in altered cell motility, we
asked whether septins directly alter actin dynamics in vitro. We find that both the Sept2/6/7 complex and Sept9 have effects in Arp2/3 complex mediated actin polymerization assays. Intriguingly, actin polymerization in the presence of Sept9 is accelerated, while in the presence of the Sept2/6/7 complex polymerization is delayed. From this we conclude that distinct Septin assemblies likely have distinct functional roles in modifying cellular actin dynamics.

BMW is an exceptionally potent actin assembly factor from a human parasite.
M. Winterhoff¹, S. Brühmann¹, M. Kollmar², R. Schnabel³, U. Curth¹, J. Faix¹;
¹Institut of Biophysical Chemistry, Hannover Medical School, Hannover, Germany, ²Department of NMR-based Structural Biology, Max-Planck-Institute for Biophysical Chemistry, Göttingen, Germany, ³Institute for Genetics, Technical University Braunschweig, Braunschweig, Germany

Assembly, organization and turnover of filamentous actin structures are essential for cell function. The initial and rate-limiting step in actin filament formation is the assembly of actin nuclei onto which additional monomers are subsequently added by filament elongators. As yet three types of actin nucleators have been established: the Arp2/3 complex, formins and tandem-monomer-binding nucleators. Here were characterized a novel and powerful tandem nucleator from a parasitic nematode causing lymphatic filariasis in man. *Brugia malayi* WH2-domain containing protein (BMW) harbors four WH2 domains preceded by proline-rich stretches at its N-terminus suggesting that it could recruit four actin monomers to form a polymerization nucleus. In vitro BMW nucleates actin polymerization at low nanomolar concentrations in a dose-dependent manner and does not require profilin for activity. A short N-terminal fragment encompassing the WH2 domains is sufficient for nucleation, but the nucleation activity is markedly enhanced in longer constructs suggesting synergy with other functional domains for full activity. In line with this notion, but in contrast to other tandem nucleators, BMW contains multiple F-actin binding sites which are required to induce the formation of massive bundles with mixed polarity in vitro as assessed by TIRF imaging. The bundles increase by growth on both ends and by fusion with neighboring bundles. Consistently, ectopic expression of BMW in commonly used cell types also leads to formation of massive bundles composed of hundreds of filaments and is associated with drastic depletion of the cellular G-actin pool arguing that most actin is consumed by BMW. Multi-color TIRF imaging at low BMW concentrations further revealed that the protein primarily nucleates actin at filament barbed ends and is subsequently either released to the filament sides or back into solution. Surprisingly, however, BMW can also associate with the pointed ends of the filaments. Finally, we explored the requirement of the WH2 domains for nucleation and bundling by analyses of deletion mutants in vitro and in vivo. Unexpectedly, nucleation and bundle assembly is markedly enhanced in constructs lacking the first two WH2 domains and is still seen with constructs lacking the first three WH2 domains in biochemical assays and transfected cells. Since BMW is a monomer as assessed by analytical ultracentrifugation, we conclude that BMW must utilize a novel nucleation mechanism, which will be discussed.
Sialic acids are negatively charged nine carbon atom sugar present in N-glycan, O glycan and gangliosides. GNE (UDP-GlcNAc 2-epimerase/ ManNAc kinase) is the key regulatory enzyme for biosynthesis of sialic acid that catalyzes epimerization of UDP-GlcNAc to ManNAc followed by phosphorylation to ManNAc-P. Mutations in GNE lead to rare genetic disorders: sialuria characterised by excretion of excess sialic acid in urine due to loss of feedback control and GNE related myopathy characterised by muscle weakness and atrophy due to hyposialylation. The pathomechanism of disease is poorly understood as GNE has been found to affect other cellular functions beside sialic acid synthesis such as apoptosis and cell adhesion. GNE interacts with α-actinin 1 and 2 and affects integrin signalling leading to focal adhesion formation. In the present study, we aim to decipher role of GNE in actin dynamics to regulate cytoskeletal organization for muscle cell integrity. For this purpose, L6 rat skeletal muscle cell line was knocked out for GNE gene either at exon 2 or exon 9 using pSEPT vector and rAAV mediated homology recombination technology. However, GNE knockout resulted in 50% cell death that could not be rescued after sialic acid supplementation. Alternately, the study was carried out in HEK cell based model overexpressing pathologically relevant GNE mutations (D176V-epimerase mutant and V572L-kinase mutant) that showed hyposialylation and reduced GNE enzymatic activity. Reduced G- and F-actin levels were observed in GNE mutant cells compared to wild GNE or vector control by immunoblotting and phallolidin staining. However GNE neither directly binds actin nor affect its in vitro polymerization activity rather RhoA and Cofilin levels were reduced in GNE mutant cells that may contribute to reduced G- and F-actin levels. Our study indicates that mutation in GNE affects actin levels that may contribute to cytoskeletal disruption and inhibit structural integrity of the cell. Molecules for Upregulation of actin levels may offer therapeutic tools for diseases associated with deficiency of GNE.

RACK1 (Receptor for Activated C Kinase 1) is critical for fundamental cellular activities and has a central role in the activation and response of immune cells. Mast cell activation via the high affinity IgE receptor (FceRI) is accompanied by a reorganization of the actin cytoskeleton and ultimately results in degranulation and release of inflammatory mediators. However, the role of RACK1 in mast cell activation has not been previously investigated. Using proteomic analysis of lipid raft fractions, we identified, for the first time, the presence of RACK1 in RBL-2H3 mast cells. By immunostaining, in non-stimulated mast cells, RACK1 was distributed in a punctate manner throughout the cytoplasm both in vivo and in vitro. Following RBL-2H3 mast cell stimulation via FceRI for 15 s and 1 min, the majority of RACK1 was localized in regions adjacent to the plasma membrane. To knockdown RACK1, RBL-2H3 mast cells were transduced with lentiviral particles encoding shRNAs against RACK1. The transduced cells
showed an approximately 54% reduction in RACK1. To analyze if actin distribution is affected by RACK1, the ShRNA control and RACK1 knockdown mast cells were stimulated or not via FcεRI, stained with phalloidin-Alexa 488, and analyzed by confocal microscopy. The non-stimulated ShRNA control mast cells were fusiform in shape and the cortical actin formed a continuous layer adjacent to the plasma membrane. In contrast, non-stimulated RACK1 knockdown mast cells were rounded or ovoid and the cortical F-actin was fragmented with spaces in the subcortical areas devoid of actin. Following stimulation via FcεRI, cortical F-actin was dramatically reduced in RACK1 knockdown mast cells in comparison with ShRNA control cells. RACK1 knockdown resulted in a significant increase in basal and FcεRI-stimulated β-hexosaminidase release. The increased basal degranulation may be related to the fact that CD63+ cytoplasmic granules were localized in the cortical F-actin-free regions in RACK1 knockdown mast cells, thus facilitating release at the plasma membrane. Furthermore, single cell calcium imaging analysis showed that thapsigargin and FcεRI-stimulated Ca2+ entry in RACK1 knockdown mast cells was decreased relative to ShRNA control cells. Additionally, in the absence of extracellular Ca2+, RACK1 knockdown mast cells showed a defective Ca2+ store depletion when stimulated via FcεRI. Thus, the present investigation indicates that RACK1 is a critical regulator of actin dynamics in mast cells, a novel negative regulator of mast cell degranulation, and may have a significant impact on the regulation of calcium signaling.

1Division of Molecular Cell Biology, Technische Universität Braunschweig, Braunschweig, Germany,  
2Department of Cell Biology, Helmholtz Centre for Infection Research, Braunschweig, Germany,  
3Department of Physics, Max-Delbrück-Centrum für Molekulare Medizin , Berlin, Germany,  
4Randall Division of Cell and Molecular Biophysics, King's College London, London, United Kingdom

Lamellipodia constitute actin networks at the cell periphery built by Arp2/3 complex and accessory proteins and are driving efficient migration on plane substrates in various cell types and conditions. Lamellipodin (Lpd) localizes to the very edge of lamellipodia. Lpd was identified as a ligand of Ena/VASP proteins, which promote actin filament elongation. In addition, Lpd binds to the WAVE regulatory complex, the latter of which mediates Arp2/3 complex activation in lamellipodia. Lpd is considered to be important for lamellipo-dia formation, positively regulates cell migration and has been implicated in promoting cancer cell invasion in 3D. However, a precise understanding of Lpd functions in protrusion is so far lacking. Here, we describe the first characterization of B16-F1 cell lines, in which detectable Lpd protein levels are eliminated by CRISPR/Cas9 technology. Interest ingly, formation of lamellipodia was not inhibited upon deletion of Lpd, although defects in their dynamics were observed: Video microscopy combined with quantifications of various protrusion parameters employing a method involving semi-automatic, dynamic cell-edge detection followed by MATLAB analysis revealed that Lpd knockout B16-F1 cells display a decreased average rate of protrusion and an increase of retraction speed as well as of cell numbers exhibiting fluctuating protrusions. In addition, average rates of random cell migration were also moderately reduced in Lpd knockout clones. These phenotypes, surprisingly, were independent of lamellipodial actin filament densities, Arp2/3-complex distributions or rates of actin network polymerization, all of which remained unchanged in Lpd knockout cells as compared to controls. Current efforts to uncover the molecular mechanisms underlying observed phenotypes in Lpd-deficient B16-F1 cell lines include determination of localization and average residency times at lamellipodia tips of key components driving the formation of these structures. In conclusion, this study provides the first
systematic, software-aided analysis of cell edge morphodynamics of cells in the absence and presence of Lpd, laying the foundation for clarifying its function in cell edge protrusion.

Mesenchymal cell migration is frequently accompanied by protrusion of thin leaflets of plasma membrane called lamellipodia or membrane ruffles. We are interested in the mechanistic dissection of these actin networks formed downstream of the key Rho-family GTPases Rac and Cdc42. We recently showed that Cdc42 operates through FMNL2 and FMNL3 formins to generate a subpopulation of lamellipodial actin filaments essential for homogenous protrusion and appropriate force development. However, FMNL2/3 functioned independently from Arp2/3 complex-dependent filament branching, also revealing that the latter alone is not sufficient for productive lamellipodial protrusion. Moreover, although Arp2/3 complex is essential for the generation of these structures, it remains unclear how tuning of its activity by its lamellipodial activator WAVE complex, operating downstream of the Rho-GTPase Rac, affects critical protrusion parameters. To address this, we have recently developed mammalian, non-haematopoietic cell lines genetically deficient for distinct subunits of the pentameric WAVE complex using CRISPR/Cas9. We have used highly motile B16-F1 melanoma cells, constituting an excellent, well-studied and widely used model system for lamellipodia protrusion and lamellipodia-dependent cell migration. Clonal cell lines genetically disrupted for the Specifically Rac-associated protein 1 (Sra-1) and its isogene PIR121 are completely devoid of lamellipodia and membrane ruffles, and display severely diminished cell migration, as expected from previous RNAi studies. Moreover, re-expression of wildtype Sra-1 but not of a Rac binding-deficient mutant fully restores lamellipodia formation, confirming lamellipodia deficiency to be solely caused by disruption of functional WAVE complex downstream of Rac. In contrast to Sra-1/PIR121 double knockout, genetic disruption of the NCK associated protein 1 (Nap1), so far considered to be an essential WAVE complex subunit in the non-hematopoietic system, causes much more variable results, with clones ranging from being almost devoid of lamellipodia to one clone displaying cells with lamellipodia at a frequency of 70% (11 Nap1 KO clones in total). Importantly, the ability to form lamellipodia in these clones correlates with spontaneous, compensatory expression of the hematopoietic Nap1 parologue Hem1. Moreover, the level of spontaneous Hem1 expression defines the density of Arp2/3-complex as well as F-actin in the lamellipodia of distinct cell lines, thus allowing for the first time to quantitatively assess how the extent of WAVE complex-mediated Arp2/3 complex activation at the protruding edge of lamellipodia contributes to rates of actin network polymerization and protrusion as well as lamellipodial force development.

Building and burning bridges: Adaptor protein Bbc1 regulates endocytic actin patch assembly by disrupting interactions of Wsp1/Vrp1 with Myo1.
C.D. MacQuarrie1, R.T. Carroll2, M. Mangione2, K.L. Gould2, V. Sirotkin1;
1Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY,
2Department of Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

Arp2/3 complex-mediated branched actin nucleation is important across species for cell motility and endocytosis. Branched actin assembly is stimulated by Nucleation Promoting Factors (NPFs), such as Wiskott-Aldrich Syndrome protein (WASP). WASp works in complex with WASp Interacting Protein (WIP), which may enhance its NPF activity. An important unresolved question is how the actin assembly machinery is positioned to efficiently drive endocytic invagination and internalization. We investigate mechanisms of branched actin assembly in a favorable model system, endocytic actin patches in fission yeast S. pombe. We have determined that the fission yeast WIP homolog verprolin Vrp1 acts as a transient bridge between myosin-1 Myo1 and WASp homolog Wsp1, helping these two proteins stay in actin patches longer. Here we investigate the role of an adaptor protein Bbc1, which is often classified as a member of the WASP-Myosin-1 module but whose physiological role remains unclear. We knocked out the bbc1 gene through homologous recombination (bbc1Δ), combined bbc1Δ with actin patch markers labeled with fluorescent proteins, and examined the effects of deleting bbc1 on actin patch dynamics by quantitative spinning disk confocal microscopy. We found that Bbc1 interacts with the Myo1 SH3 domain in vivo, depends on the Myo1 SH3 domain for localization to patches, and competes with Vrp1 for binding the Myo1 SH3 domain. Deletion of bbc1 appears to lengthen the transient interaction of Wsp1-Vrp1 with Myo1. Normally Myo1 and Wsp1-Vrp1 exhibit distinct localization: Myo1 remains at the plasma membrane while Wsp1-Vrp1 internalize with the endocytic vesicle. In contrast, in bbc1Δ cells a portion of Wsp1-Vrp1 remains at the membrane with Myo1, splitting Wsp1-Vrp1 puncta. The splitting depends on an interaction between Myo1 and Wsp1-Vrp1 because splitting is reduced partially or completely when bbc1Δ is combined with either vrp1 deletion or deletion of the Myo1 SH3 domain, respectively. Strikingly, bbc1Δ cells feature endocytic invaginations that are twice as long, which we propose is due to the increased population of Wsp1 and Vrp1 at the base of invagination. Additionally, Bbc1 acts as an inhibitor of actin assembly, but this function is redundant with the adaptor protein Sla1. Our data provide a novel mechanism for regulation and positioning of the actin assembly machinery at endocytic sites. We propose that Bbc1 disrupts the transient Myo1-Vrp1-Wsp1 bridge. In the absence of Bbc1 a greater fraction of Wsp1-Vrp1 remains at the membrane, focusing new branches towards the membrane thus providing an increased number of tracks for Myo1 to increase its pull on the membrane, which results in increased tubule size.

2Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN,
3Department of Biology, Indiana University - Purdue University Indianapolis, Indianapolis, IN

The highly homologous beta (ACTB) and gamma (ACTG1) cytoplasmic actins are ubiquitously expressed in all cell types and differ by only 4 functionally similar amino acids within the N-terminus. Despite the
remarkable conservation between the ACTB and ACTG1 sequences, previous \textit{in-vitro} and \textit{in-vivo} data suggest that cytoplasmic actins support unique functions. Mice homozygous for severely hypomorphic or null Actb alleles are early embryonic lethal. In contrast, Actg1 null mice survive to term but display significant perinatal lethality, stunted growth, and decreased survival into adulthood. Ablation of ACTB in primary mouse embryonic fibroblasts (MEFs) resulted in severe growth impairment not observed in ACTG1 null MEFs. To determine if the striking phenotypic differences between ACTB and ACTG1 null models were due to the 4 N-terminal amino acid variances, we used transcription activator-like effector nuclease (TALENs) and a single stranded donor oligo sequence to edit the endogenous mouse Actb locus. We altered the ACTB nucleotides that coded for the 4 beta-actin amino acids to instead code for the 4 gamma-actin amino acids by editing the wobble base in each codon. The resulting mice express a chimeric Actb/Actg1 (\(\beta\gamma_{\text{chimera}}\)) mRNA transcript expressed under control of the endogenous ACTB regulatory elements and translated into gamma-actin protein. Crosses of heterozygous mice yielded wildtype (WT), heterozygous and homozygous \(\beta\gamma_{\text{chimera}}\) mice born at Mendelian ratios that live to at least 3 months of age. Additionally, primary MEFs generated from heterozygous and homozygous \(\beta\gamma_{\text{chimera}}\) mice displayed growth rates not different from WT MEFs. Furthermore, qRT-PCR data from primary MEFs, brain and lung tissue demonstrate transcript synthesis at both the endogenous Actg1 and the \(\beta\gamma_{\text{chimera}}\) loci, which corresponded with a 2-fold increase in gamma-actin protein expression and no beta-actin protein expression as assessed by Western blot. Total actin levels remained constant across all three genotypes. The surprising viability of \(\beta\gamma_{\text{chimera}}\) mice and primary MEFs is in stark contrast to what we and others have previously published. Our data suggest that cells and tissues can sense the specific absence of beta-actin protein while regulating total actin expression to maintain a constant cellular protein level. The dispensability of beta-actin protein in cells and mice further suggests that the severe cell and organismal phenotypes observed with gene knockout are due to factors beyond simple loss of beta-actin protein expression.

\textbf{Vav2-RhoG–mediated cytoskeleton and nuclear skeleton remodeling.}

I. Prabakaran\textsuperscript{1}, G. Koo\textsuperscript{3}, S. Xu\textsuperscript{1}, M.A. Guvako\textsuperscript{a};
\textsuperscript{1}Surgery, University of Pennsylvania, Philadelphia, PA

The oncoprotein Vav2 is a target of tyrosine kinases that are often overexpressed in cancer. As a member of the Dbl family of the guanine nucleotide exchange factors (GEFs), Vav2 activates the Rho GTPases (Rac1, Cdc42, RhoA, and RhoG); the molecular switches regulating cytoskeleton dynamics, cell shape, growth, adhesion, migration as well as gene expression. By mass spectrometry (MS) and immunoprecipitation, we have previously shown the association of Vav2 with tyrosine kinase-type receptors: Human epidermal growth factor receptor 2 and 4 (HER2 and HER4) and insulin-like growth factor I receptor (IGF-IR) in human MCF-7 breast cancer cells. In the presence of HER2/4 and IGF-IR signaling, Vav2 localized to the plasma membrane, and its overexpression caused massive lamellipodial protrusions fringed by F-actin. Upon inhibition of IGF-IR’s kinase, Vav2 overexpression induced prominent stress fibers, traversing the cell body and interconnecting focal adhesions. This distinct phenotype was accompanied by the nuclear deformation and decrease in the nuclear matrix protein lamin A/C. The specific domains of the Vav2 protein responsible for the regulation of the cyto- and nuclear skeleton were examined through the mutational analysis of the Vav2 protein. The expression of oncogenic (delta 1-183) Vav2 and a partially activated Y172FVav2 increased the number of cells with the misshapen nuclei, whereas the catalytically inactive mutant (L217A Vav2) and the SH2 domain mutants (W673RVav2 and G693RVav2) significantly reduced the number of cells with the structural defects in the nuclei. Analysis of Vav2 mutants uncovered the importance of (i) Vav2 interactions with HER tyrosine

\textsuperscript{Tuesday-56}
kinases via the SH2 domain and (ii) Vav2’s GEF activity in cyto- and nuclear skeleton remodeling. Through MS/MS spectra search with 1% of false discovery search, we identified the small GTPase RhoG (Ras homology growth-related) protein in the Vav2 interactome. Although RhoG has been reported to interact with Vav2, its cellular functions remain poorly characterized. We posited that Vav2 --RhoG regulated cyto- and nuclear skeleton. To begin to test the hypothesis, we examined the organization of F-actin and DNA by immunofluorescence microscopy and lamin A/C expression by fluorescence-activated cell sorting (FACS) in the control and RhoG knockdown breast cancer cells. Silencing of RhoG reduced stress fibers buildup and partially protected the cell nuclei from distortion and loss of lamin A/C that would otherwise be caused by Vav2 overexpression. These analyses uncovered the role of Vav2 and RhoG in the cyto- and nuclear skeleton remodeling. Altered nuclear organization by oncprotein Vav2 may affect genome integrity in cancer and it warrants further investigation.

MRTF/SRF transcription promotes cell-in-cell invasion for entosis through Ezrin-dependent bleb-dynamics.
L. Soto Hinojosa¹, M. Holst¹, C. Baarlink¹, R. Grosse¹;
¹Institute of Pharmacology, University of Marburg, Marburg, Germany

Entosis is a nonapoptotic cell death process involving homotypic cell-in-cell invasion that occurs in human tumors or malignant fluids and has been associated with tumor suppressive as well as promoting effects. We previously demonstrated the importance of formin-mediated polarized actin dynamics and the essential role of nonapoptotic plama membrane blebbing in this cellular motile process. Although the contractile actin cortex involved in bleb-driven motility is well characterized, a role for transcriptional regulation has not been addressed. Serving as a paradigm for actin-controlled transcription, we explored the impact of the actin-regulated MRTF/SRF transcriptional pathway for sustained blebbing and subsequent entotic invasion. Our findings reveal a remarkably tight association between cortical blebbing and rapid MRTF nucleocytoplasmic shuttling resulting for SRF transcriptional activity. Specifically, we show that SRF-dependent up-regulation of the metastasis-associated ERM protein Ezrin is critical for bleb dynamics to promote cell-in-cell invasion. Our results highlight the essential role of the MRTF/SRF transcriptional pathway for bleb-associated invasive motility.

The Role of Actin Trails in Mediating Bulk Axonal Actin Transport.
N. Chakrabarty¹, P. Dubey², A. Ganguly³, Y. Tang⁴, K. Ladt⁵, P. Jung¹⁶, S. Roy²⁷;
¹Department of Physics and Astronomy, Ohio University, Athens, OH, ²Department of Pathology and Laboratory Medicine, University of Wisconsin-Madison, Madison, WI, ³Department of Pathology, University of California, San Diego, La Jolla, CA, ⁴Department of Molecular and Cellular Physiology, Stanford University, School of Medicine, Stanford, CA, ⁵Department of Neurosciences, University of California, San Diego, La Jolla, CA, ⁶Quantitative Biology Institute, Ohio University, Athens, OH, ⁷Department of Neuroscience, University of Wisconsin-Madison, Madison, WI

Classic pulse-chase radiolabeling studies have shown that actin – a critical cytoskeletal protein – is conveyed in axons via slow axonal transport; but the mechanistic basis for this movement is unknown. Recently, using filamentous actin (F-actin) probes and low-light imaging, we found that axonal actin was surprisingly dynamic, with local assembly/dis-assembly events (“hotspots”) and polymers elongating.
along the long-axis of the axon-shaft (“actin trails”). Though the frequency of anterogradely-elongating polymers was greater, it’s unclear how hotspots and trails can lead to axonal transport. To understand axonal actin organization at a molecular level, we generated a biophysical model starting with first principles of monomer/F-actin assembly; simulating axonal actin dynamics including hotspots and trails. Interestingly, our model predicted a slow, biased transit of the actin population, which we also confirmed experimentally. Our data suggest that actin is conveyed in axons by an unprecedented mechanism involving local assembly and biased polymerization – kinetics that ultimately lead to its slow transport. We posit that other dynamic cellular structures might use similar mechanisms for conveyance.

Nanotopography biases cell migration, cytoskeletal dynamics, and focal adhesion distribution.
W. Losert1;
1Physics, University of Maryland, College Park, MD

Many biological and physiological processes depend upon directed migration of cells, which is typically mediated by chemical or physical gradients or by signal relay. Here we show that cells can be guided in a single preferred direction based solely on local asymmetries in nanotopography on subcellular scales. These asymmetries can be repeated, and thereby provide directional guidance, over arbitrarily large areas. The direction and strength of the guidance is sensitive to the details of the nanotopography, suggesting that this phenomenon plays a context-dependent role in vivo. We demonstrate that asymmetric nanotopography guides the direction of internal actin polymerization waves, and that cells move in the same direction as these waves. The conservation of the asymmetric shape of many natural scaffolds suggests that actin-wave-based guidance is important in biology and physiology. Furthermore, nanoridges/grooves impact the focal adhesion distribution and cytoskeletal orientation in epithelial cells. Both the focal adhesion and the cytoskeleton behaviors can be tuned by changes in nanotopographies. Overall, the excitable systems character of the cellular scaffolding, controlled via nanotopography, provides a simple, universal mechanism for guiding a range of migratory behaviors in many living systems.

Exploring actin dynamics of thin filaments in Caenorhabditis elegans striated muscle.
S. Sundaramurthy1, S. Ono2, D. Pruyne1;
1Department of Cell and Developmental Biology, Upstate Medical University, Syracuse, NY,
2Department of Pathology and Department of Cell Biology, Emory University, Atlanta, GA

Actin is the major component of thin filaments, which form part of the core structure of muscle sarcomeres. Actin and various other sarcomeric proteins have been shown to undergo dynamic turnover without affecting the overall structure of the muscles in different model systems. The actin filaments, in particular, have been found to be dynamic in both immature and mature muscle cells. This dynamic nature of actin might help in the maintenance of thin filaments. It was observed in chick cardiomyocytes that injected rhodamine-labeled actin was incorporated at both ends of filaments with greater amounts incorporated at the pointed ends (Littlefield et al; 2001). This leads us to believe that the actin dynamics at the filament ends play a major role in maintaining the length of the thin filaments.
Caenorhabditis elegans is a powerful system to study for studying the protein interactions in sarcomeres. The actin dynamics in the thin filaments of Body Wall Muscles (BWMs) in C. elegans has not been characterized. We are using a GFP-actin expressing worm strain to perform Fluorescence Recovery After Photobleaching (FRAP) experiments. By staining F-actin with phalloidin we have confirmed that GFP-actin localized similar to wild-type actin in the BWMs. We performed FRAP experiments on immobilized live worms and observed 40-50% recovery of total GFP-actin within 25 minutes. This is the first experimental evidence that actin filaments are dynamic in the BWMs of C. elegans. In order to assist in resolving actin recovery with respect to barbed and pointed ends, further FRAP analysis will be done in worms co-expressing Z-line associated α-actinin fused to m-Cherry with GFP-actin. With this, we should be able to quantify the actin dynamics at the barbed and pointed ends of the thin filaments. Capping proteins and tropomodulin help in the stabilization of barbed and pointed ends of the thin filaments respectively, whereas the barbed end regulators that aid the incorporation of G-actin from the G-actin pool are not entirely clear. Formins are a conserved family of proteins that nucleate and elongate actin filaments in vitro. We observed the formins FHOD-1 and CYK-1 localized near/at the Z-lines in sarcomeres. The mutants of these two formins had reduced BWM width. We hypothesize that formins play a role in the regulation of thin filament dynamics. We will further continue our analysis of actin dynamics with the worms bearing mutations in fhod-1 and cyk-1 genes.

Characterization of the cytoskeleton of *Porphyra umbilicalis* and comparison to other red algae based on analysis of the completed *Porphyra* genome.

H.V. Goodson¹, S.H. Brawley²;
¹Chemistry Biochemistry and Biological Sciences, University of Notre Dame, Notre Dame, IN, ²School of Marine Sciences, University of Maine, Orono, ME

Recent assembly of the nuclear genome (87.7 Mb) of the red alga *Porphyra umbilicalis* (Bangiophyceae) made it possible to characterize the cytoskeleton of this economically important and evolutionarily significant species and to gain insight into the cytoskeletons of red algae more broadly (Brawley et al. 2017. *PNAS* www.pnas.org/cgi/doi/10.1073/pnas.1703088114). The red algae are a founding lineage of the Archaeplastida. Multicellular red algae are known from 1.6 billion year old fossils, and the oldest taxonomically-resolved fossil of a multicellular eukaryote is *Bangiomorpha* (1.2 billion years old, Bangiophyceae). Both red algal nuclear genes and a red algal chloroplast are found in diatoms, haptophytes, apicomplexans, and many dinoflagellates due to the evolution of these groups through ancient secondary endosymbioses involving red algae. Using bioinformatic tools including BLAST and PSI-BLAST, we searched for key filament, motor, and regulatory proteins, and found that the complement of cytoskeletal components in *Porphyra* is significantly reduced relative to other multicellular organisms. For example, while the actin and tubulin filament proteins are present, as expected, a number of key regulatory proteins are absent, and the number of motors is especially reduced. In particular, the actin motor myosin is entirely absent from *Porphyra* and other sequenced members of the most species-rich classes of red algae (Bangiophyceae, Florideophyceae; BF). Only a small set of kinesins and no dynein motors of the canonical microtubule-based motors are present. These observations raise questions about how *Porphyra* cells accomplish intracellular transport. We have extended our cytoskeletal analyses to other red algae with sequenced genomes and find that the only universal motor proteins are a small number of kinesins. Some species in a sister clade (SCRP) of mesophilic red algal classes and the extremophiles *Galdieria* (Cyanidiophyceae) have a single myosin that resembles the myosin-27 of apicomplexans. Another surprising observation is the lack of the actin-
nucleating complex ARP2/3, which raises questions about how *Porphyra* neutral spores accomplish amoeboid movement. Formins are present, and may support this movement. The array of nuclear actin-related proteins is also reduced, suggesting that *Porphyra* might have a reduced ability to regulate chromatin-remodeling as compared to other eukaryotic lineages. Overall, we suggest that the reduced cytoskeletal capabilities and complexity of *Porphyra* and other red algae may explain apparent limitations to cell size, the ability to form complex tissues, and to achieve large individual stature in comparison to other multicellular organisms.

**Mechanosensory role of alpha-actinin 4 in pancreatic cancer cell migration.**  
D.G. Thomas¹, N. Good², E.S. Schiffhauer¹, A. Surcel¹, Q. Zhu², D.N. Robinson³;  
¹Cell Biology, Johns Hopkins School of Medicine, Baltimore, MD, ²Pathology, Johns Hopkins School of Medicine, Baltimore, MD

Alpha-actinin 4, a cytoskeletal actin bundling protein, is upregulated and implicated in the metastasis of a variety of cancers, including pancreatic ductal adenocarcinoma (PDAC). The alpha-actinin family consists of four members, alpha-actinin 1 through 4. In dissemination assays using 3-dimensional tissue spheroids consisting of a heterogeneous mixture of alpha-actinin 4 overexpressing cells and wild-type, overexpression of alpha-actinin 4 increased dissemination compared to wild type cells. Cellular behavior of the two isoforms is similar in randomly migrating cells and dual expression of mCherry-ACTN1 and GFP-ACTN4 show similar localization patterns at the edges of lamellapodia and protrusions in migrating cells. Alpha-actinin 4 alters cell mechanics as determined by micropipette aspiration experiments. Additionally, upon applied mechanical stress, alpha-actinin 1 and 4 exhibit distinct behaviors in cells, notably alpha actinin 4 displays robust accumulation at sites of cortical dilation, while alpha-actinin 1 does not mechanorespond. We hypothesize that this response is mediated both in part by the catch-bond behavior of alpha actinin 4 as well as differential actin binding affinities between the two isoforms. The actin binding domains of alpha-actinin 1 have a >100x higher affinity towards actin than alpha-ctinin 4 (0.36 μM and 34 μM, respectively). Purified alpha-actinin 1 and alpha-actinin 4 proteins exhibit similar behaviors in actin bundling assays, producing thick and ordered actin bundles. However, mutation of the alpha-actinin 4 lysine residue at position 255 to glutamic acid (K255E) results in a 5-fold increase in actin binding, but leads to a loss of localization to leading edge protrusions, as well as a loss of accumulation at sites of dilational stress. The actin bundles formed with the K255E mutant are thinner and create erratic meshed networks. These data suggest that the dynamic turnover necessary for proper actin bundle formation is driven by both actin affinity as well as the catch-bond behavior of alpha-actinin 4.

**Determining Concentration-Dependent Effects of Thymosin β4 in Living Cells through Quantitative Protein Delivery.**  
K. Skruber¹, E.A. Vitriol¹;  
¹Anatomy and Cell Biology, University of Florida, Gainesville, FL

The ability of actin to contribute to essential cellular functions such as motility, cell division, and vesicle trafficking is dependent on the precise control of its polymerization from monomers (G-actin) into filaments (F-actin) and the depolymerization of filaments back into the monomer pool. To support the dynamic nature of the actin cytoskeleton, the cell keeps a large reserve of actin monomers through G-
actin binding proteins such as Thymosin β4 (Tβ4). Tβ4 sequesters actin monomers and prevents their polymerization. However, in addition to its main function in inhibiting actin assembly, Tβ4 can also localize monomers to specific types of actin networks by regulating their release from a non-polymerizable sequestered state. The majority of our understanding of Tβ4 is from in vitro biochemical assays, which can be difficult to directly translate to the more complex environment of a living cell. Using electroporation, we are able to introduce known quantities of purified protein into cells, thus potentially bridging the gap between bulk solution assays and cellular experiments. With electroporation, we can introduce purified protein as large as 50 kDa across a wide range of concentrations. Also, millions of cells can be electroporated simultaneously with high cell viability and nearly 100% expression. The goal of this project is to determine the in vivo role of Tβ4 in regulating the G-actin pool and the assembly of F-actin networks. We have introduced fluorescently-labeled, purified Tβ4 into cells in defined amounts and measured its effects on both actin monomers and filaments, on the organization of F-actin throughout the cell, and on the localization of Tβ4 and actin monomers. In addition to establishing the concentration-dependent relationship between Tβ4 expression and actin dynamics, this study provides a template for quantitative delivery of protein into living cells as a means for determining its cellular role.

Inhibitable kinesin motors to study intracellular trafficking.
M.F. Engelke1, B. Waas1, B.L. Allen1, K.J. Verhey1;
1Cell Developmental Biology, University of Michigan Medical School, Ann Arbor, MI

The kinesin-2 motor KIF3A/KIF3B/KAP is the essential driver of intraflagellar trafficking (IFT) in mammalian cells and interference with its function results in the absence of cilia. In contrast, KIF17 appears to be an accessory IFT motor, as knockout of KIF17 alone has little effect in mice, but results in synthetic effects when combined with other knockouts. The lack of fast and specifically acting kinesin inhibition methods currently precludes the direct analysis of kinesin-2 function in cilia. Here we adapt a chemical-genetic kinesin inhibition approach that we originally developed for kinesin-1 (Engelke et al., 2016, Nat. Commun.) and demonstrate that this approach yields functional kinesin-2 motors that can be abruptly inhibited by small, cell-permeable molecules. To do this we pursued two strategies: I) We inserted the six amino acid tetracysteine tag into surface loops of the motor domain such that binding of biarsenic dyes conformationally distorts and thereby inhibits motility. II) We fused DmrB dimerization domains to the motor heads such that addition of B/B homodimerizer cross-links the motor domains and inhibits processive motor stepping. Using cellular assays, we show that the engineered kinesin-2 motors are able to transport artificial cargo similarly to the wild type motor, but cargo transport is efficiently inhibited by the addition of inhibitor. Future studies will enable us to deploy the inhibitable kinesin-2 motors and for the first time abruptly inhibit KIF3A/KIF3B/KAP and monitor its function in the genesis, maintenance, and resorption of primary cilia. For KIF17 this approach will allow us to determine the direct involvement of KIF17 in IFT, before compensatory mechanisms can attenuate the resulting phenotype.
Regulated autoinhibition of kinesin-1 is essential to polarized dendritic transport.
M.T. Kelliher1, Y. Yue2, A. Ng1, D. Kamiyama3, B. Huang4, K.J. Verhey2, J. Wildonger1;
1Biochemistry, University of Wisconsin - Madison, Madison, WI, 2Cell and Developmental Biology, University of Michigan, Ann Arbor, MI, 3Cellular Biology, University of Georgia, Athens, GA, 4Department of Pharmaceutical Chemistry, University of California - San Francisco, San Francisco, CA

Neuronal polarity relies on the selective localization of cargo to axons or dendrites by molecular motors. Kinesin-1 has a critical role in transportation of cargo into axons, but is also known to be active in dendrites. This raises the question of how kinesin-1 activity is regulated to maintain the polarized distribution of cargo within neurons. Our in vivo structure-function analysis of endogenous kinesin-1 in Drosophila reveals a novel role for autoinhibition in polarized dendritic transport. Mutations that disrupt kinesin-1 autoinhibition result in the mislocalization of Golgi outposts (GO) to axons. Our findings show that disruption of autoinhibition is distinct from mutations that inhibit ATP hydrolysis; axonal mislocalization of GO is not found when kinesin-1 enzymatic activity is impaired. Autoinhibition also functions to control kinesin-1 localization within the neuron. Uninhibited kinesin-1 accumulates in axons and is depleted from dendrites, resulting in dendrite growth defects. Confirming an essential role for kinesin-1 in dendrite development, dendritic morphology is also altered when kinesin-1 levels are depleted through RNAi. Genetic interaction tests reveal that a balance of kinesin-1 inhibition and dynein activity is necessary to localize GO to dendrites and keep them from entering axons. Lowering both kinesin-1 and dynein levels is not sufficient to drive GO into axons. In contrast, relieving kinesin-1 autoinhibition when dynein levels are reduced is sufficient to disrupt the polarized transport of outposts. We propose a mechanism in which dynein is required to carry outposts into dendrites, yet kinesin-1 activity must be precisely regulated by autoinhibition to achieve the selective dendritic localization of outposts. Finally, we have evidence that localization of other dendritic cargo may rely on the tight regulation of kinesin-1 autoinhibition. This suggests that autoinhibition as a mechanism of regulating kinesin-1 activity may be broadly important for compartment-specific localization of cargo in neurons.

A. Goldstein1, D. Goldman1, E. Valk2, M. Loog2, L.J. Holt3, L. Gheber1;
1Department of chemistry and Ilse Katz Institute for Nanoscale Science and Technology, Ben-Gurion University of the Negev, Beer Sheva, Israel, 2Institute of Technology, University of Tartu, Tartu, Estonia, 3Molecular Pharmacology Institute for Systems Genetics, New York University, New York, NY

Kinesin-5 mitotic motors play essential roles in mitotic spindle assembly and dynamics by cross-linking and sliding apart antiparallel microtubules emanating from the spindle pole bodies (SPBs). Recently, we found that localization to the spindle of S. cerevisiae kinesin-5 Cin8 is regulated by phosphorylation at three Cdk1 sites in its catalytic motor domain. We also determined that each of these Cdk1 sites contribute to phospho-regulation of Cin8 in a unique manner. The mechanism of this phospho-regulation remains unclear. It has been previously suggested that phospho-regulation may occur by two modes; (1) contest-specific which constrains the phospho-regulation events to specific sites and will not recapitulate at a different site, or (2) plastic in which phospho-regulation is spatially flexible within a specific domain and may occur at distant sites. Here we tested the plasticity of phospho-regulation of
Cin8, and examined whether novel synthetic Cdk1 sites created by a single amino acid replacement can mimic the known phospho-regulation or create new phenotypes. For this purpose, we systematically generated Cin8 mutants carrying a novel Cdk1 site as a sole source for Cdk1 phospho-regulation and examined them by in vitro phosphorylation assay, quantitative and qualitative in vivo microscopy and in vivo yeast viability assay. The majority of the sites resulted in phosphorylation independent phenotypes. We found that out of 29 novel sites that we have generated, only one site in the motor domain, adjacent to a native Cdk1 site, recapitulated the phospho-regulation of the adjacent native site, although several sites were created nearby. This result indicates that phospho-regulation of Cin8 by Cdk1 at this site is rigid and undergoes phospho-regulation in highly context-specific manner. Two additional sites resulted in novel phospho-regulation of Cin8; however they resulted in a less optimized phospho-regulation. Interestingly multiple-sequence-alignment revealed that one of these sites is present in other organisms, suggesting that phospho-regulation at this site is flexible throughout evolution and may occur according to the functional requirements in these organisms.

Macromolecular crowding modulates intracellular transport by teams of kinesin-1 motors.
G. Nettesheim1, G. Jaffe1, S.J. King2, G.T. Shubeita1,3;
1Physics, The University of Texas at Austin, Austin, TX, 2Burnett School of Biomedical Sciences, University of Central Florida, Orlando, FL, 3Physics, New York University Abu Dhabi, Abu Dhabi, United Arab Emirates

The cytosol is crowded with a high concentration of macromolecules. Crowding can alter protein conformation, binding rates, and reaction kinetics, yet it is not known how crowding affects intracellular cargo transport by molecular motor proteins. We report on the consequences of crowding on cargo transport by kinesin-1 motors both in Drosophila embryos and in vitro. Surprisingly, we find that crowding significantly slows transport by teams of motors, while having no effect on single motor velocity. By applying controlled forces on single motors using an optical trap we find that this emergent property of kinesin teams results from the individual’s increased sensitivity to hindering load in a crowded medium. The consequences of this single motor property shed light on the long observed variability of cargo transport velocity in different cellular contexts. Based on the data, we further propose a model by which entropic forces in the crowded medium lead to the motor’s altered detachment characteristics, and suggest that crowding can be used as an additional control parameter in the quest for a better understanding of kinesin’s mechanochemical cycle.

Aplip1 (Drosophila JIP1) regulates myonuclear positioning and muscle stability.
A.L. Auld1, S.A. Roberts2, C.B. Murphy3, J.M. Camuglia1, E.S. Folker1;
1Biology, Boston College, Chestnut Hill, MA

During muscle development myonuclei undergo a complex set of movements that result in evenly spaced nuclei throughout the muscle cell. In Drosophila two separate pools of Kinesin and Dynein govern this process. Although these two pools of motors work in synchrony, how these two pools are specified is not known. Here, we investigate the role of Aplip1 (a JIP1 homolog), a known regulator of both Kinesin and Dynein, in myonuclear positioning. Aplip1 localizes to the myotendinous junction where it can extend from the muscle pole. Additionally, Aplip1 has independent roles in myonuclear
positioning and muscle stability. In Aplip1 mutant embryos there was an increase in the percentage of embryos that had both missing and collapsed muscles. Via a separate mechanism, we demonstrate that Aplip1 is required to position and dynamically move nuclei within muscle. Through genetic interaction experiments, we saw that Aplip1 interacted with the Dynein anchor, Raps, and Kinesin to correctly position nuclei within muscle cells. We propose that Aplip1 is important for normal myonuclear movement via the regulation of Dynein at the cell cortex and the regulation of Kinesin activity at the nuclear envelope.

**BORC regulates the axonal transport of synaptic vesicle precursors by activating ARL-8.**

S. Niwa\(^1\), L. Tao\(^2\), S.Y. Lu\(^3\), G. Liew\(^3\), W. Feng\(^4\), M.V. Nachury\(^3\), K. Shen\(^3\);

\(^1\)Frontier Research Institute for Interdisciplinary Sciences and Graduate School of Life Sciences, Tohoku University, Sendai, Japan, \(^2\)Department of Biology, Stanford University, Stanford, CA, \(^3\)Department of Molecular and Cellular Physiology, Stanford University, Stanford, CA, \(^4\)Chinese Academy of Sciences, Institute of Biophysics, Beijing, China

Axonal transport of synaptic vesicle precursors (SVPs) is essential for synapse development and function. The conserved ARF-like small GTPase ARL-8 is localized to SVPs and directly activates UNC-104/KIF1A, the axonal-transport kinesin for SVPs in C. elegans. It is not clear how ARL-8 is activated in this process. Here we show that part of the BLOC-1 related complex (BORC), previously shown to regulate lysosomal transport, is required to recruit and activate ARL-8 on SVPs. We found mutations in six BORC subunits--blos-1/BLOS1, blos-2/BLOS2, snpn-1/ Snapin, sam-4/Myr lysin, blos-7/Lyspersin and blos-9/MEF2BNB cause defects in axonal transport of SVPs, leading to ectopic accumulation of synaptic vesicles in the proximal axon. This phenotype is suppressed by constitutively active arl-8 or unc-104 mutants. Furthermore, SAM-4/Myr lysin, a subunit of BORC, promotes the GDP to GTP exchange of ARL-8 in vitro and recruits ARL-8 onto SVPs in vivo. Thus, BORC regulates the axonal transport of synaptic materials and synapse formation by controlling the nucleotide state of ARL-8. Interestingly, the other two subunits of BORC essential for lysosomal transport, kxd-1/KXD1 and blos-8/Diakedin, are not required for the SVP transport, suggesting distinct subunit requirements for lysosomal and SVP trafficking.

The kinesins are a large superfamily of ATP-dependent motor proteins that can walk along microtubules to transport cargo. However, the kinesin-4 motor KIF7 appears to lack the ability to undergo processive motility. Thus, the motility and enzymatic properties of the COS2/KIF7/KIF27 subfamily of kinesin-4 motors remain poorly understood. In this study, we demonstrate that whereas mammalian KIF7 and its Drosophila homolog Coastal2 (COS2) show no motility at the single molecule level, the mammalian parologue KIF27 is a slow processive motor. To test whether these kinesin-4 motors can drive processive motility when working in teams, we carried out microtubule gliding assays in vitro and peroxisome transport assays in living cells. In both assays, KIF27 showed slow motility whereas KIF7 failed to
transport cargo, consistent with their motility in single molecule assays. Both KIF7 and KIF27 showed defective mechanochemical coupling, existing in a strongly microtubule-bound state regardless of nucleotide condition. The mechanistic basis of immotile KIF7 behavior was determined to arise from an inability to release ADP in response to microtubule binding. The mechanistic basis of slow processive KIF27 behavior was determined to arise from its slow ATPase rate and high affinity for both ATP and microtubules. Our results demonstrate that sequence changes to the core kinesin motor domain can result in dramatic differences in kinetic and motility properties across the kinesin-4 family of motors.

Analysis of plus end directed motor proteins Cin8 and Kip3 reveals their unique role in maintaining the integrity of the chromosome specifically during meiosis.

P. Mittal\(^1\), S.K. Ghosh\(^1\);
\(^1\)Department of Bioscience and Bioengineering, Indian Institute of Technology, Bombay, Mumbai, India

Kinesin motors provide the molecular forces that are required at the kinetochore-microtubule interface and thereby control the process of chromosome segregation. Despite elucidation of their functions in mitosis, their roles in meiosis are poorly explored. Given the fact that at least in budding yeast, there are temporal and mechanistic differences between mitosis and meiosis in kinetochore maturation, establishment of kinetochore-microtubule attachment and orientation of the sister kinetochores with respect to the spindle poles, we found a temporal variation in the distribution pattern of Cin8, Kip1 and Kip3 from prophase I to metaphase I between centromeres and SPBs suggesting their distinct roles in the early meiotic events. Consistent to this we observed an erroneous homolog pairing during meiosis I in the \(cin8\Delta\) as compared to \(kip1\Delta\) or \(kip3\Delta\) and consequently a defect in the homolog bi-orientation on meiosis I spindle in the former mutant but not in the latter two. These defects may account for very poor spore viability in \(cin8\Delta\) but not in \(kip1\Delta\) or \(kip3\Delta\). Further we checked the mitotic role of Cin8 and Kip3 in the maintenance of kinetochore integrity during meiosis and interestingly we found that especially in meiosis Cin8 is predominantly required for the stable localization of outer kinetochore protein Ndc80 as compared to Kip3 and as a result reduction in the localization of Ndc80 at the centromere leads to the destabilization of the inner kinetochore protein, Ndc10 in case of \(cin8\Delta\) but not in case of \(kip3\Delta\). Owing to the compromised localization of Ndc80 at the centromere and functional redundancy among the motors we studied meiosis in \(cin8\Delta\;kip3\Delta\) double mutant and we observed a drastic reduction in the spore viability. Further analysis revealed that both Cin8 and Kip3 act at the downstream of the FEAR pathway. As a result, the way essentiality of the FEAR components changes between mitosis and meiosis similarly it does in case of \(cin8\Delta\;kip3\Delta\) double mutant. Examining the meiosis undergoing \(cin8\Delta\;kip3\Delta\) cells, an unusual aneuploidy was detected in the meiosis II cells which surprisingly later proved to be an outcome of the chromosome breakage verified by different experimental techniques. Albeit the mechanism behind the loss of chromosome integrity is still under investigation, overall our study indicates that the kinesin motors may influence the kinetochore-microtubule interface and thus the gross chromosome segregation significantly in meiosis perhaps more than they do so in mitosis.

VLDL Secretion from Hepatocytes is Controlled by Phosphatidic Acid.
M. Kumar1, P. Rai1, P. Barak1,2, S.S. Kamat3, R. Mallik3;

Lipid droplets (LDs) are catabolized in hepatocytes to provide lipids for assembling VLDL particles, which are then secreted to peripheral tissues. This requires extensive physical interactions between LDs and endoplasmic reticulum (ER). We found that this interaction requires LDs to be transported towards the smooth ER by motor proteins, resulting in lipid and protein exchange between these two organelles. How do metabolic signals control the activity of motors on LDs to facilitate catabolism of lipids? Here, using targeted lipidomics, in-vitro reconstitution, organelle motility and biochemical assays, we have attempted to solve this puzzle. We found that insulin via phospholipase D activity increases the phosphatidic acid level on LDs in fed state of an animal. This recruits the small GTPase Arf1 and the kinesin motor to LDs, which are transported to the ER followed by LD catabolism. Phosphatidic acid levels on LDs are reduced after fasting. This removes Arf1 and kinesin from LDs to reduce ER-LD physical contacts, and in turn decreases lipid availability for VLDL lipidation. This mechanism appears to control triglyceride secretion from the liver across feeding/fasting cycle and ensures that serum triglyceride levels are maintained approximately constant.

The unique N-terminal extension of the oncogenic KIF14 kinesin motor domain is an F-actin bundler elongater, and nucleator.
J. Hellinga1, I. Kalhari2, B.H. Kwok2, J. Allingham1;
1Graduate Studies, Queen’s University, Kingston, ON, 2CHEMICAL BIOLOGY OF CELL DIVISION, Research for Immunology and Cancer, University of Montreal, Montreal, QC

Introduction: Kinesins are widely known as regulators of microtubule dynamics and as microtubule-based transporters of vesicles and chromosomes in eukaryotes. The KIF14 kinesin is unique in that it possesses a ~350 amino acid N-terminal extension of its motor domain (named the NTE domain) that helps it associate with, and trigger assembly of actin filaments and actin filament bundles1. These abilities help explain the importance of KIF14 in mitosis and cytokinesis, which are microtubule and actin-based functions, respectively. They could also have an important correlation with the overabundance of KIF14 in many aggressive cancers2,3. Our dissection of the human KIF14 NTE into its separate functional subdomains has begun to establish the mechanistic basis of actin polymer assembly by this motor.
Results: Assessment of the ability of different length NTE protein constructs to stimulate F-actin assembly in vitro revealed that the C-terminal region of the NTE was essential for this activity; even though shorter NTE constructs lacking this region could still bind F-actin. TIRF microscopy showed that F-actin assembly involves a combination of actin nucleation and elongation from both ends of these actin nuclei. Further NTE dissection identified actin-binding site(s) between residues 133-260, and showed that the actin filament bundling motif(s) resides within this region. Analytical size-exclusion chromatography of the truncated NTE proteins demonstrated that the C-terminal-inclusive constructs are multimeric, while C-terminally truncated proteins are monomers. This implies a necessity for a...
higher-order arrangement of KIF14 to stimulate F-actin formation. We also provide evidence to suggest that this higher-order NTE assembly involves association of NTE regions that are largely disordered, and possibly dynamic, in the absence of actin.

Conclusion: The structural details of the KIF14 NTE-actin interaction are still under investigation and are occurring in parallel with studies of its motor domain with microtubules. This work will inform on how KIF14 influences actin dynamics at the midzone during cytokinesis, perhaps as a mediator of contractile ring formation, and could help identify a strategy to inhibit KIF14 activities for the benefit of cancer sufferers.

Eukaryotic cells transport organelles and other cargos along microtubules to control their distribution within the cell and deliver them to distant locations. While we understand how molecular motors can transport cargos along individual microtubules, the cell’s microtubules are usually arranged in a complex 3D network. While traversing this network, cargos need to navigate intersections where microtubules cross at a wide variety of separation distances and angles. To gain insight into how cargos navigate these intersections, we have used a recently established 3D construction technique based on holographic optical trapping to build single 3D microtubule intersections in vitro with relevant nanoscale precision. We then used these fully suspended microtubule structures to perform motility assays on kinesin-1 coated cargos. We find that some intersection geometries influence cargos to pass along their current microtubule, while other geometries influence them to switch to the intersecting one. To understand how, we use a 3D Brownian dynamics simulation of cargo transport to investigate the mechanisms which give rise to the observed switching probabilities across separation distances and angles. Using these stochastic simulations, we find that switching probability is often determined by a competition between a stronger motor team on the primary microtubule and the intersecting microtubule sterically hindering that team’s progress. This understanding of the basic mechanisms of switching at single intersections in 3D helps lay a foundation for understanding how the cell may regulate switching to control how cargos navigate the MT network and ultimately their spatial organization.
The mitotic spindle is microtubule (MT)-based machine that segregates a replicated set of chromosomes during cell division. Many chemotherapeutics target the spindle by altering or disrupting microtubules, the polymer that forms the spindle. While these drugs are efficacious, microtubules are a major component of all cells and their disruption can have deleterious effects on cell types that rely on MTs for function, such as neurons. In addition to tubulin, MT-dependent motors that function during mitosis are logical targets for drug development. Eg5 (Kinesin-5) and Kif15 (Kinesin-12), in particular, is an attractive pair of motor proteins to pharmacologically target since they work in concert to drive centrosome separation and promote spindle bipolarity. Kinesin 5 inhibitors (K5Is) have been extensively studied since their discovery, with many advancing to both Phase 1 and 2 clinical trials. Despite the initial excitement for K5Is due to their promising results in cell and mouse tumor models, they have largely failed in the clinic. Since Kif15 over expression has been shown to overcome K5I treatment in tissue culture cells, a potential explanation for K5I clinical failure may be due to the cell’s ability to utilize a Kif15 dependent spindle assembly pathway. Recently, our laboratory discovered that the emergence of K5I resistance, a phenomenon commonly observed in tissue culture cells, depends on the expression of Kif15. This result underscores the hypothesis that a combinatorial drug approach to target spindle assembly, by inhibiting both Eg5 and Kif15, will cripple rapidly dividing cancer cells. Therefore, we set out to perform a small molecule screen on a focused group of known kinase inhibitors, with the goal of identifying lead chemical scaffolds that inhibit Kif15. Using an in-vitro ATPase assay, the Published Kinase Inhibitor Set (distributed by GSK) was screened in duplicate and two compounds, both containing oxindole cores, significantly inhibited Kif15’s MT stimulated ATPase activity. The activities of both compounds were confirmed in a MT gliding assay as well as a second ATPase assay. Concentration response curves were performed in triplicate and IC50s were calculated for each. VU0482674 became our lead compound, exhibiting an IC50 of 800nM. Similarly, VU0482674’s IC50 in the MT gliding assay was calculated to be 734nM. Furthermore, treatment with VU0482674 on K5I resistant cells (KIRCs), whose ability to form bipolar spindles relies on Kif15, results in nearly 100% monopolar spindles. VU0482674 has no effect on mitotic progression in normal RPE-1 cells, suggesting that the compound primarily inhibits Kif15 during cell division. Structure Activity Relationship (SAR) analysis of VU0482674 is currently underway.
Members of the kinesin motor superfamily are subject to post-translational modifications, which are hypothesized to tune kinesin motors for specific cellular functions. The kinesin-5 motor Eg5 (Kif11) forms homotetramers that function to crosslink and slide anti-parallel microtubules during spindle formation. Eg5 is subject to a number of post-translational modifications. Here we focused on understanding the role of acetylation at lysine 146, a residue in the α2 helix of the Eg5 motor domain. Acetylation at this site disrupts the formation of a salt bridge with aspartate 91. We have assessed the activity of an acetylation mimic mutant Eg5 (K146Q) at the single molecule and cellular levels. Time resolved kinetics assays indicate that Eg5 K146Q displays enhanced coupling of switch 1 and the neck linker. In single molecule optical trapping assays, Eg5 K146Q dimers are more likely than wild type (WT) dimers to stall rather than dissociate from the microtubule under load. Based on these results, acetylated Eg5 motors would be predicted to stall microtubule sliding during spindle formation, acting as a brake and slowing spindle pole separation. To test this prediction, mCherry (mCh) tagged Eg5 WT and K146Q motors were expressed at low levels in HeLa cells. Both WT and K146Q mCh-Eg5 localized to the mitotic spindle, with similar distributions along the spindle length. To compare the functional activity of WT and K146Q Eg5, cells expressing GFP-tubulin and equivalent levels of mCh-Eg5 WT or mCh-Eg5 K146Q were treated with the Eg5 inhibitor monastrol, resulting in mitotic arrest and the formation of monopolar spindles. Bipolar spindle formation following monastrol washout was then imaged and measured. While spindle lengths at the completion of pole separation were similar in cells expressing mCh-Eg5 WT or K146Q (11.02 ± 0.29 μm WT, 10.87 ± 0.26 μm K146Q, mean ± SEM), pole separation occurred at a significantly slower velocity in cells expressing mCh-Eg5 K146Q (0.84 ± 0.07 μm/min) than in cells expressing mCh-Eg5 WT (1.35 ± 0.15 μm/min). This velocity difference is consistent with Eg5 acetylated at K146 stalling rather than dissociating from the microtubule, and acting as a brake during pole separation.

**Membrane-mediated Motor Reorganization in Microtubule-based Transport.**

R. Jiang¹, S. Park², G. Chen², S. Majd³, W.O. Hancock¹,²;

¹Intercollege Program in Physiology, The Pennsylvania State University, University Park, PA, ²Department of Biomedical Engineering, The Pennsylvania State University, University Park, PA, ³Department of Biomedical Engineering, University of Houston, Houston, TX

Transport of membranous organelles, such as mitochondria and endosomes, are of vital importance for the survival and proper operation of cells. These organelles are transported by kinesin and dynein motors that walk towards the plus-end and minus-end of microtubules, respectively. Despite considerable understanding in the chemomechanical cycle of single motors, how multiple motors coordinate with each other when connected through a membrane is not well understood. During transport, membrane-bound motors are expected to slip in the plane of the membrane, which should diminish their transport abilities, but also are expected to diffuse and accumulate on the microtubule, which should increase the number of active motors pulling the cargo. To visualize these processes, we set up a 2D system in which kinesin-1 motors are transporting microtubules while linked to a lipid bilayer supported on a glass surface. At high motor density, kinesin-1 quickly accumulated to the microtubule upon its landing and the accumulation process reached steady-state in seconds. At steady-state, motor intensity along a microtubule increased from the minus- to the plus-end. These phenomena indicated that the fluid lipid bilayer allows motors to freely diffuse and reorganize along the...
microtubules during vesicle transport. This reorganization of motors may serve as a strategy that cells use to maintain vesicle transport in the highly-crowded cytoplasm.

Understanding the roles of kinesin-1 during axon degeneration.
Y. LiEW, A. Prokop;
1Faculty of Biology, Medicine and Health, University of Manchester, Manchester, United Kingdom

Axons are the longest cellular processes in animals which often have to be maintained for an organism’s lifetime, despite the fact that their delicate structure renders axons vulnerable to degeneration. Mutations of the MT-based motor protein kinesin-1 have prominent links to axon degeneration, but the underlying pathomechanisms remain unclear. Normally, axons contain parallel bundles of microtubules (MTs) which form their structural backbones and tracks for long distance transport, whereas kinesin-1 mutant axons show swellings with disorganised MT bundles. We propose that these disorganised MTs are not a consequence but a potential cause of axon degeneration. We test this hypothesis in Drosophila primary neurons which we have developed into a powerful model for studying axonal cytoskeletal machinery (Prokop et al., 2013, J. Cell Sci. 126, 2331ff.). In fly axons, kinesin-1 depletion leads to reduced axon growth and areas of disorganised MTs, which we propose as a potential model for axon swellings. Using point mutations in kinesin-1 or genetic depletion of specific interaction partners, we assessed the contribution of three sub-functions of kinesin-1 towards MT regulation: (1) MT sliding, (2) cargo transport or (3) mitochondrial dynamics. We found that impaired cargo or mitochondrial transport, but not MT sliding cause MT disorganisation. Furthermore, we found that kinesin-3 contributes to those two functions, and that it strongly interacts with kinesin-1 during MT disorganisation, suggesting that the observed phenomenon might link to a wider pool of axonal transport motors.

We will discuss our latest investigation results into the underlying pathomechanisms, focussing on mitochondrial ROS and functional inhibition of other classes of MT regulators, such as MT stabilisers or severers. We believe that an understanding of the roles of motor proteins in MT regulation will provide fundamental new understanding of axon biology, and that Drosophila is the most useful tool to achieve this goal.

Transport Properties of Molecular Motor Ensemble with Bi-Directional Motors : A Computational Approach.
R. Srivastava, S. Bhaban, J. Melborne, S. Rajaganapathy, M.V. Salapaka;
1Electrical Engineering, University of Minnesota, Twin Cities, Minneapolis, MN

Intracellular transportation involves multiple molecular proteins working together in coordination. These proteins are of different types, i.e. they have different chemical as well as physical properties. Understanding transport properties of these molecules individually as well as of their ensembles help understand the underlying mechanism of genesis of neurodegenerative diseases. Analytical approaches and Monte-Carlo simulations used to study how motor-proteins coordinate the transportation of a cargo are either simplistic in nature and require high computational power, while being unable to capture the rare events. To overcome these challenges, semi-analytical approaches have proven to be quite effective for studying biologically relevant quantities while enabling us to observe the occurrence
of rare events. So far, semi-analytical approaches have been developed for studying the transportation of a shared cargo by a team of unidirectional motors. Here, the movement of cargo is restricted to only one direction on microtubule lattice. Further work has been done to extend this approach to the case when some of the motors are mutated while still being restricted to one directional motion of cargo. These approaches, while being less computationally intensive compared to Monte-Carlo simulations, produce comparable results to any other techniques available for simulating single species, unidirectional transportation. They also give insights about some of the rare events occurring which other techniques fail to capture. This provides the motivation to extend the existing semi-analytical framework for bi-directional intracellular transportation, where transport is enabled by a team of multiple kinesin and dynein motors.

We develop a more generalized approach which enables us to study the transportation of cargo by an ensemble of motors travelling in opposite directions on the mitorubule. This enables us to study biologically relevant quantities such as average run-length and average velocity of the cargo molecule while taking into account bi-directional motion of ensemble. Added direction of motion and forces gives rise to the change in behavior of ensemble and makes the extension of the single species, unidirectional case to a two species, bi-directional case a non-trivial task. We begin by defining the transition probabilities of change in absolute configurations of ensemble. We determine an equivalence class of various absolute configuration by using the relative configurations defined by the relative distances of the motors. We prove that the number of such relative configurations are finite. We further calculate these quantities for an ensemble of motors consisting of Kinesin and Dynein and some of the key results are presented.

Myosin 18A-alpha targets the Rac GEF Beta-PIX to the dendritic spines of cerebellar Purkinje neurons and is required for normal spine morphology.

C.J. Alexander¹, M. Barzik², J.A. Hammer III¹;
¹National Heart Lung and Blood Institute, National Institutes of Health, Bethesda, MD, ²National Institute on Deafness and Communication Disorders, National Institutes of Health, Bethesda, MD

Dendritic spines are signaling microcompartments that serve as the primary site of synapse formation in neurons, and that house the machinery underlying memory formation. Actin plays a vital role in the generation and maintenance of spines, and changes in spine actin organization underlie memory formation (Hotulainen and Hoogenraad, 2010). Not surprisingly, therefore, non-muscle myosin 2 (NM2) also plays a critical role in spine structure and function (Ryu et al., 2006). Myosin 18A (M18A) is a NM2-like myosin expressed from flies to man that co-assembles with NM2 to make mixed filaments (Billington et al., 2015). Importantly, M18A is alternatively spliced to create many versions that contain unique N- and C-terminal extensions harboring both recognizable (e.g. PDZ domains, SH3 domain binding sites) and uncharacterized protein: protein interaction domains. For example, M18A-alpha possesses a 300-residue N-terminal extension that contains a PDZ domain, a binding site for F-actin, and a binding site for the Rac GEF Beta-Pix, which has been shown to play a key role in controlling spine actin assembly (Zhang et al., 2005; Saneyoshi et al., 2008). Current thinking is that M18A’s primary biological function is to present these protein: protein interaction domains on the surface of mixed NM2 bipolar filaments to dramatically increase their functional diversity. Here we show that endogenous and exogenous GFP-tagged M18A-alpha are concentrated along with NM2 in the dendritic spines of
cerebellar Purkinje neurons, and that M18A-alpha’s N-terminal extension drives its spine localization. miRNA-mediated knockdown of M18A-alpha results in significant defects in the number of primary dendrites, spine number and spine length, all of which are rescued with an RNAi-immune version of M18A-alpha. Intriguingly, preliminary data shows that Beta-PIX co-localizes with M18A-alpha in spines, and that it’s spine localization is lost upon M18A-alpha knockdown. Taken together, these data suggest that M18A-alpha and Beta-Pix form a complex in spines that plays a role in establishing normal cell polarity upon initial neurite outgrowth and normal spine morphology.

Genomic knockout of Myosin-X in mouse results in semi-lethality and decreased filopodia.
E.G. Heimsath, Jr.1, R.E. Cheney1, Y. Yim2, J.A. Hammer III2, M. Mustapha3;
1Cell Biology and Physiology, UNC School of Medicine, Chapel Hill, NC, 2Cell Biology and Physiology Center, National Institutes of Health - NHLBI, Bethesda, MD, 3Otolaryngology, Stanford University, Stanford, CA

Myosin-X (Myo10) is an unconventional myosin best known for its striking localization to the tips of filopodia and spindle assembly and positioning. Despite the broad expression of Myo10 in vertebrate cells and tissues, its functions at the organismal level remain largely unknown. We report here the generation of KO-first (Myo10tm1a/tm1a), Floxed (Myo10tm1c/tm1c), and KO mice (Myo10tm1d/tm1d) that target full-length and headless Myo10. Complete knockout of Myo10 (both Myo10tm1a/tm1a and Myo10tm1d/tm1d) results in semi-lethality and a 60% incidence of exencephaly, a severe defect in neural tube closure that is incompatible with survival after birth. Myo10 KO embryos that were not exencephalic were able to develop into adults, but exhibited several defects. 100% of Myo10 KO mice exhibited a white belly spot, ~50% had webbed digits, and virtually all had a small kink near the tip of the tail. 100% of Myo10 KO mice exhibited persistent hyperplastic primary vitreous (PHPV) containing the hyaloid vasculature, a fetal vasculature that perfuses the developing eye and that normally regresses as the adult retinal vasculature forms. Myo10 KO mice that survived birth could breed with one another to produce litters of KO embryos, demonstrating that Myo10 is not strictly essential for adult survival, meiosis, or mitosis. Heterozygous KO mice appeared normal, demonstrating that one copy of Myo10 is sufficient for normal development. Homozygous KO-first mice exhibited the same phenotype as homozygous KO mice. An independent mouse mutant containing a spontaneous deletion in full-length and headless Myo10 (Myo10tm1/m1) exhibited the same core phenotype, conclusively demonstrating that complete loss of Myo10 results in a high frequency of embryos with exencephaly and adults with a white belly spot, persistent hyaloid vasculature, and a high incidence of webbed digits. During retinal angiogenesis, the tip endothelial cells of the vascular fronts exhibited 60% fewer filopodia in Myo10 KO compared to controls, demonstrating that Myo10 is required to form normal numbers of filopodia in vivo. The generation of Myo10 KO-first, Floxed, and KO mice provides key tools for the field and reveals the organismal phenotype resulting from complete loss of Myo10. It also reveals that Myo10 has important functions in mammalian development in neural tube closure, pigmentation, and regression of the hyaloid blood vessels.

The proteolysis of Myo10, by Calpain, under low calcium conditions is activated by its FERM domain Acyl-CoA Binding Protein Motif.

M.M. Tovar; K. Goussset
1Biology, California State University, Fresno, Fresno, CA

Myosin-X (Myo10) is a ubiquitously expressed motor protein involved in the formation of filopodia and tunneling nanotubes (TNTs), as well as in the invasiveness of cancer and the spread of pathogens. Its structure is unique, containing a Motor Head domain, 3 IQ motifs, an α-helix, a coiled coil, 3 PEST domains, 3 PH domains, a MYTH4 domain, and a FERM domain. Under physiological conditions, full length Myo10 (FLMyo10) is expressed at low levels and proteolyzed into three distinct bands by gel electrophoresis. We hypothesized that Myo10 overexpression may overwhelm the proteolytic machinery thereby allowing more FLMyo10 to reach the plasma membrane where it induces TNT formation.

Previously, Berg et al. hinted at a role for calpain in Myo10 proteolysis. Wang et al. suggested that calpain binds to PEST sites, in a Ca2+ dependent manner, and cleaves its target proteins at their IQ motifs. Proteolysis can be inhibited by Calmodulin (CaM) binding to the IQ motif. Myo10 possesses each of these domains, and the calmodulin-like protein, CALML3 can bind to Myo10, increasing both FLMyo10 expression and the number and length of filopodia.

Here, we show that KCI a disrupter of CaM complex formation, and the calmodulin inhibitor J8, decrease FLMyo10 *in cellulo*. Surprisingly, calpain inhibitors have no effect on Myo10 proteolysis, and Ca2+ chelators increased proteolysis. Interestingly, Myo10 contains an Acyl-CoA Binding Protein (ACBP) motif, a potent activator of Calpain-2 (CAPN2) under low Ca2+ requirements. Thus, we examined whether Myo10 ACBP motif could bind with CAPN2 and serve as an activator of Myo10 proteolysis under physiological Ca2+ conditions. Our *in silico* docking experiments show that Myo10 ACBP motif is predicted to bind to a specific pocket of CAPN2. Furthermore, binding to this pocket is disrupted by the loss of the calpain small subunit (CAPNS1), and completely lost upon the formation of a complex with calpastatin (endogenous calpain inhibitor).

Next, we used UCSF Dock Blaster drug discovery tools to find compounds that could disrupt the ACBP/calpain binding. One of these compounds in CAD cells lowered the proteolysis of Myo10 by 40% and a cell line with a CAPNS1 deletion, expressing long, thin filopodia-like structures, displays a striking absence of the Myo10 proteolytic bands.

Overall, the Myo10 ACBP motif, under low Ca2+ levels, specifically targets Myo10 for proteolysis. This proteolysis is disrupted by increased Ca2+ through the activation and binding of CaM and CALML3 to the IQ domains, and/or by the loss of the CAPNS1 small subunit. This work shows that calpain can be activated under physiological Ca2+ levels enhancing our understanding of how calpain targets its substrates and could lead to a novel method of TNT induction.

Mitochondria distribution to filopodia by the actin-based motor Myo19.

B.I. Shneyer; M. Usaj; N. Wiesel-Motiuk; R. Regev; A. Henn
1Biology, Technion-Israel Institute of Technology, Haifa, Israel

Eukaryotic cells are exposed to many environmental cues and stress conditions which have profound effects on mitochondria dynamics. The role of the actin cytoskeleton in relation to mitochondria...
function and dynamics is only now beginning to emerge, revealing new functions for actin-based motors. Here, we focus on the recently discovered actin-based motor, Myo19, which is associated with the mitochondria and on its effects on mitochondrial biology. We show that Myo19 localizes with mitochondria to filopodia tips in response to glucose starvation, ROS and EGF. However, how Myo19 localizes to mitochondria, how its enzymology allows the translocation of mitochondria to filopodia, and what is the function of mitochondria at these filopodia is not known. First, we reveal that Myo19 is integrated to the outer mitochondrial membrane (OMM) through a previously unidentified binding motif in its tail domain, ensuring a highly stable interaction between Myo19 and the OMM. Point mutations within the 30 amino acids of this motif inhibit localization of Myo19 to the OMM. Secondly, using time-lapse fluorescent microscopy we show that Myo19 undergoes both anterograde and retrograde movements in filopodia, which are coupled to their extension and retraction, respectively. Thirdly, by studying the enzymology of Myo19 we provide a detailed reaction mechanism of its ATPase cycle. Both the slow ADP isomerization and ADP release prolong the time Myo19 spend in the strong actin binding state and hence contribute to its relatively high duty ratio. However, the predicted duty ratio based on our measured rate and equilibrium constants is lower than required to support motility as a monomer. Thus, we predict that an ensemble of Myo19 motors is required to efficiently propel mitochondria movement on actin filaments. Finally, we provide a model explaining how Myo19 translocation may be regulated by the local ATP/ADP ratio. Interestingly, local mitochondria concentration in neurons is correlated with increased branching of actin-based protrusions of the dendritic spines. Thus, we suggest that Myo19 acts as an ATP sensor, and translocates mitochondria to regions that demand high local levels of ATP for processes such as actin polymerization.

**Uncovering a Myosin XI-Mediated Transport Mechanism Conserved between Physcomitrella patens and Arabidopsis thaliana.**

R. Orr¹, F. Furt¹, M. Munson², L. Vidali¹;
¹Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA; ²Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

The diverse morphologies observed across plants and animals require a coordinated asymmetry of intracellular components organized by the cytoskeleton. Tip growth of filamentous protonemata in the moss Physcomitrella patens presents an experimentally robust platform to investigate polarized growth driven by the molecular motor myosin XI (homologous to myosin V). This machinery continuously elongates the cell by trafficking secretory vesicles without actively transporting large organelles as observed in flowering plants. Therefore, by coupling vesicles to myosin XI, an unidentified moss myosin XI-cargo complex may function as an essential and conserved component of growth. Here we exploited P. patens’ only two functionally redundant myosin XIs, compared to the 13-member A. thaliana myosin XI family, to elucidate putative cargo-binding interfaces. We hypothesized that A. thaliana myosin XI isoforms of higher sequence identity and similar subcellular (apical) localization to moss myosin XIs will functionally complement growth in P. patens myosin XI-RNAi knockdown background. Although A. thaliana and P. patens diverged approximately 450 million years ago, their myosin XI proteins share approximately 60-70% identity within the cargo-binding domain. We generated chimeric myosin XIs through fusions of the P. patens head domain with three isoforms of the cargo-binding tail domain of A. thaliana (K,E, and F). Chimeric myosin XIs K and E reconstituted polarized growth in moss in an RNAi complementation assay, whereas isoform F failed to complement. Following this result, we attempted to identify the heretofore unknown myosin XI vesicle receptor through an extensive yeast two-hybrid
screen. This approach identified a RabE subfamily member (Sec4 in yeast, Rab8 in human) as a putative binding partner. Preliminary data with in-house directed yeast two-hybrid and bimolecular binding assays with purified myosin XI and RabE suggests a direct interaction. These results support the notion of sequence-level functional conservation of myosin XI transport across the plant kingdom.

Drosophila myosin 7a in Phagocytosis and Eye Development.
A.S. Hong1; J.R. Sellers1;
1NHLBI, National Institutes of Health, Bethesda, MD

Drosophila myosin 7a (Dm7a) is an unconventional myosin required for the maintenance of the Johnston’s organ (the auditory center in Drosophila) and the morphology of the bristle structures on the thorax. Both of these structures are formed by bundled arrays of actin. Here we show that Dm7a is involved in the process of engulfment of bacteria particles in the Drosophila larval hemocytes. Using the UAS/GAL4 system, we express GFP-Dm7a in the larval hemocytes where it localizes to the cortical regions of the cell and induces the formation of filopodia that are also enriched in Dm7a. We imaged the phagocytosis of fluorescently-tagged bacteria by hemocytes expressing GFP-Dm7a. When a bacterium contacts the cell surface of a hemocyte, the latter sends out a filopodium which wraps around the bacterium followed by engulfment. Occasionally an extended filopodia was seen to contact a bacterium and transport it back to the cell surface. Phagocytosis assays revealed that hemocytes from Dm7a mutant flies are defective in their ability to engulf bacteria compared to wildtype hemocytes, although bacteria do bind to their cell surface. Additionally, a lethality assay whereby larvae were challenged with bacteria show that 21% of wildtype larvae eclosed into adult flies, but less than 10% of Dm7a mutant larvae eclosed under these conditions. These results suggest a role for Dm7a in phagocytosis and in the defense mechanism of the fly. Additionally, immunostaining of adult eyes with Dm7a showed its localization in the pigment cells. In electron microscopy sections of the adult eyes of Dm7a mutants the pigment granules around the primary pigment cells and at the base of the rhabdomeres of the photoreceptor cells were absent. We are investigating the functions of Dm7a in the development of the eye.

The mechanome of asymmetric cell division.
T.T. Pham1,2, J. Helenius3, N. Lee2, E. Lund2, D. Mueller3, C. Cabernard2;
1Biozentrum, University of Basel, Basel, Switzerland, 2Department of Biology, University of Washington, Seattle, WA, 3D-BSSE, ETH Zürich, Basel, Switzerland

Asymmetric cell division (ACD) generates cellular diversity and is an important process during development. Stem cells in particular utilize ACD in order to self-renew the stem cell yet generate differentiating siblings. Some stem cells undergo both physical and molecular ACD and it is unknown how biophysical parameters, such as cortical tension, stiffness or osmotic pressure affect the formation of sibling cell size asymmetry. We use Drosophila neural stem cells (neuroblasts) to study the contribution of biophysical parameters on ACD. We are combining fluorescence microscopy with atomic force microscopy (AFM), particle image velocimetry (PIV) and genetically encoded stiffness sensors to measure the dynamics of the actomyosin network and cortical stiffness of cultured neuroblasts. The
combination of these measurements allow us to propose a model, explaining how dynamic changes in physical parameters contribute to the establishment of sibling cell size differences during mitosis.

The cytokinetic localization of Sid2p and Mob1p of the fission yeast Hippo like pathway requires both formin and type V myosin.

Z.J. Morris¹;

¹Department of Biological Sciences, University of Toledo, Toledo, OH

The Hippo tumor suppressor pathway is an evolutionarily conserved signaling pathway that regulates cell proliferation from yeast to human. At its core, the Hippo pathway is a kinase cascade consisting of two kinases Mst1 and LATS1, in addition to their respective activators Salvador and MOB1. The actin cytoskeleton has been identified as a key regulator of the Hippo pathway but the molecular mechanism remains unclear. Here we examined whether actin binding proteins regulate the localization of the Hippo pathway proteins in fission yeast. Schizosaccharomyces pombe possesses a Hippo like pathway, Septation Initiation Network (SIN), which includes Sid2p and Mob1p, the homologues of LATS1 and MOB1 respectively. Our study focused on five actin binding proteins, For3p, Myo51p, Myo52p, Adf1p (cofilin), and Fim1p. We counted the number of Mob1p and Sid2p molecules in either the spindle pole bodies (SPBs, the yeast equivalent of centrosomes), or the contractile ring during cell division with quantitative fluorescence microscopy. On the SPBs, the number of both Mob1p and Sid2p gradually increase starting at metaphase until reaching ~1200 at +76 minutes after the separation of SPB. On the contractile ring, these two molecules start to accumulate during anaphase B, ~33 minutes after the separation of SPBs. Their numbers reach a peak of ~1600 when the contractile ring initiates constricts. Because the ratio of these two molecules in either the SPBs or the contractile ring remain 1:1 throughout cell division, we only counted only the number of Mob1p molecules in five mutants for3Δ, myo51Δ, myo52Δ, adf1-M3A, and fim1Δ. Only the deletion of either For3p or Myo51p resulted in ~20% decrease in the number of Mob1p molecules in the contractile ring. In contrast, the numbers of Mob1p molecules in the SPBs were not affected by any of the five mutations. For3p is a formin required for assembly of the actin cables in fission yeast and Myo51p is a type V myosin essential for the intracellular transportation along the actin cables. To determine whether Mob1p is transported to the contractile ring by Myo51p along the cables, we quantified the number of Mob1p molecules in the contractile ring in a myo51 mutant that is missing its cargo binding domain. We found that the number of Mob1p-GFP molecules in the contractile ring decrease by ~30% in this myo51 truncation mutant. In conclusion, we discovered that in fission yeast the actin cytoskeleton regulates the localization of the Hippo pathway proteins Sid2p and Mob1p through myosin V mediated intracellular transportation along bundled actin filaments assembled by formins. Our study provides a potential mechanism for the regulation of the Hippo pathway by the actin cytoskeleton in other organisms including humans.

Dissecting the Molecular and Cellular Basis of Familial Cardiomyopathies.

S.R. Clippinger¹, P.E. Cloonan¹, L. Greenberg¹, V. Rogers³, M.J. Greenberg¹;

¹Biochemistry and Molecular Biophysics, Washington University School of Medicine, St. Louis, MO

Familial cardiomyopathies, affecting up to 1 in 500 individuals, are the leading cause of sudden death in young people. The most common forms, dilated and hypertrophic cardiomyopathies, are characterized
by pathological remodeling of the heart tissue and increased fibrosis, which can lead to heart failure and arrhythmias. In dilated cardiomyopathy (DCM), the ventricular wall thins while in hypertrophic cardiomyopathy (HCM), it thickens. Both diseases are caused by mutations in the proteins that regulate heart contraction, a prominent one being troponin-T. Interestingly, mutations within the same protein can lead to either dilation or hypertrophy and different prognoses depending on the site of the mutation. To understand how molecular changes lead to differing disease phenotypes, we have studied the contractile effects of two mutations in troponin-T, R92Q and delta K210, that cause HCM and DCM, respectively, in patients. Using purified recombinant proteins, we see that R92Q causes hypercontractility in the in vitro gliding assay while delta K210 causes hypocontractility. Using transient kinetic and steady state biochemical measurements, we show that these effects are due to alterations in the positioning of tropomyosin along the actin filament during muscle activation. Moreover, we show that these molecular-based changes lead to alterations in the contractility of stem-cell derived cardiomyocytes that have undergone genome editing to introduce the disease-causing mutations. Taken together, our results reveal new insights into the disease pathogenesis.

HSPB1 protein increases actomyosin ATPase activity of myofibrils fraction.
Y. Kato1, K. Yoshito1, K. Yoshino2, A. Takeuchi2, M. Yamanoue1, Y. Shirai1, S. Ueda1;
1Department of Agrobioscience, Kobe University, Kobe, Japan, 2Biosignal Research Center, Kobe University, Kobe, Japan, 3Analytical Laboratory, Kobe Pharmaceutical University, Kobe, Japan

HSPB1 is one of the small heat shock proteins (HSPBs). HSPB1 is predominantly expressed in skeletal muscle, and forms a complex between HSPBs according to cellular stress response. HSPB1 protein is suggested to various functions of skeletal muscle in stressed or unstressed condition. Although HSPB1 has been suggested to be involved in various functions of skeletal muscle under stress or unstressed conditions, its detailed molecular mechanism is not clear. Therefore, we performed a covalent immunoprecipitation (Co-IP) assay with anti-HSPB1 antibody against the lysate of skeletal muscle and searched for HSPB1 binding protein. As a result of the nanoLC/MS/MS analysis, we identified MLC1/3 protein which is one kind of myosin light chain of myofibrils as candidate of novel HSPB1 binding protein. In this study, in order to elucidate the role of the interaction between HSPB1 and MLC1/3, we analyzed the influence of HSPB1 protein to actomyosin ATPase in myofibrils activity by molybdenum blue colorimetric method. Adding purified recombinant HSPB1 protein to myofibrils fraction prepared from mouse hind limb muscle, a significant increase of actomyosin ATPase activity was confirmed depending on the concentration of HSPB1. The highest value of actomyosin ATPase activity was observed when HSPB1 protein was added to myofibrils fraction in a molar ratio of 1: 1 to myosin heavy chain (MHC). On the other hands, the increase in actomyosin ATPase activity was not confirmed by addition of HSPB1 (S135F) which is a point mutation related to Charcot-Marie-Tooth disease. Furthermore, in immunofluorescence staining using paraffin section of mouse gastrocnemius muscle, HSPB1 proteins were co-localized with MLC1/3 and MHC proteins near A-bands in sarcomere of myofibrils. These results suggested that HSPB1 regulates muscle contraction between actin and myosin bands in muscle cells.

Normal cardiac physiology of mice with one allele of mouse α-cardiac myosin replaced with human β-cardiac myosin.
F. Haque1,2, M. Sarikhani3, S. Mukherjee4, L.A. Leinwand4, N.R. Sundaresan5, J.A. Spudich5, J.A. Mercer1; 1Centre for Cardiac Biology and Disease, Institute for Stem Cell Biology and Regenerative Medicine, Bangalore, India, 2National Centre for Biological Sciences, TIFR, Bangalore, India, 3Department of Microbiology and Cell Biology, Indian Institute of Science, Bangalore, India, 4Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, 5Biochemistry, Stanford University, Stanford, CA

Switching of cardiac myosin heavy chain (MyHC) expression between α and β isoforms is important in development and disease. It also differs substantially in direction and timing between species. Homozygous null mice lacking α-MyHC die in utero, while heterozygotes are haploinsufficient with cardiac dysfunction (1). To determine the effect of human β-MyHC on this haploinsufficient phenotype, we have replaced the entire coding and intronic regions of the mouse Myh6 gene with those of the human MYH7 gene. Heterozygotes express human β-MyHC at about 50% of the total myosin. Mice homozygous for this replacement exhibit embryonic lethality, but heterozygotes are surprisingly indistinguishable from homozygous wild-type controls in baseline echocardiographic and histological measurements, thus rescuing the cardiac deficits caused by hemizygosity for Myh6. The heterozygotes showed a significant hypertrophic response to isoproterenol, suggesting that these mice can be a good model system to study the effects of cardiomyopathy-causing mutations in human MYH7.

Dictyostelium Myosin Heavy Chain Kinase D Phosphorylates Myosin II and Localizes to Leading Edge Structures.
E. Lehman1, R. Muthukkumar 1, P. Steimle1; 1Biology, University of North Carolina at Greensboro, Greensboro, NC

The assembly of myosin II bipolar filaments results from interactions between the heavy chain “tails” of myosin II monomers and leads to the formation of filaments that can contract actin filaments and drive cell shape change. In Dictyostelium cells, myosin II filament assembly is inhibited by phosphorylation of the tail region of the myosin II heavy chain (MHC) and is catalyzed by at least three MHC kinases (MHCKs -A, -B, and -C) that share homologous alpha-kinase catalytic and WD-repeat domains. In the current study, we examined the cellular and enzymatic properties of fourth Dictyostelium heavy chain kinase, MHCK-D. We found that overexpression of MHCK-D resulted in a severe reduction in Dictyostelium growth in suspension culture that was accompanied by a marked increase in the number of multinucleated cells. Further studies revealed that overexpressing MHCK-D leads to a nearly complete loss of myosin II bipolar filaments associated with the cytoskeletal fraction of the cell. These results are significant since they demonstrate that MHCK-D can indeed function as an effector of myosin II filament turnover in the cell. Complementary studies of cells lacking MHCK-D expression revealed that MHCK-D, which is only expressed during Dictyostelium multicellular development, is required for normal disassembly of myosin II filaments. Truncation analysis revealed that the WD-repeat domain of MHCK-D is required for the overexpression phenotype and indicates that the WD-repeat domain of MHCK-D plays a similar substrate-targeting function as the WD-repeat domains of the other MHCKs. Studies of GFP-MHCK-D localization in live cells revealed that the kinase translocates from a mainly cytosolic
distribution to cortical patches when aggregation-competent cells are stimulated with cyclic-AMP. In migrating cells, the kinase localizes to leading edge structures, suggesting that MHCK-D plays a role in the turnover of myosin II filaments specifically at the front of the cell, and indicates that localization is an important means by which the kinase’s function is regulated. Studies examining the catalytic activity of affinity-purified Flag-tagged MHCK-D showed that the kinase exhibits robust activity toward a peptide substrate MH-1 and toward myosin II filaments, providing further direct evidence of MHCK-D’s role in controlling myosin II filament turnover. The kinase activity of MHCK-D also appears to be activated by autophosphorylation. Truncation analysis revealed that the WD-repeat domain is required for phosphorylation of myosin II, but not for phosphorylation of MH-1 peptide, indicating a substrate-targeting role for the WD-repeat domain.

Actin and microtubule crosstalk mediates persistent polarized growth.
S. Wu\(^1\), M. Bezanilla\(^1\);
\(^1\)Biological Science, Dartmouth College, Hanover, NH

A dynamic actin cytoskeleton is essential for polarized growth in mosses. Without actin, cells swell at their apexes and growth is severely inhibited. During growth, wild type cells have an accumulation of actin just below the cell tip. While this apical actin accumulation is persistent over long time periods, imaging with high temporal resolution reveals that this population of actin filaments is highly dynamic constantly turning over. In the absence of microtubules, the apical actin accumulation loses the longer temporal persistence and instead stochastically forms and reforms in various regions of the cell, often leading to cell expansion at other sites.

In wild type cells, cytoplasmic microtubules are focused with their plus ends just below the apical actin accumulation. We find that in a mutant lacking all five myosin VIII genes (Δmyo8), the microtubule focus is lost and the actin accumulation loses the long-term persistence similar to loss of all microtubules. Interestingly directional persistence is impaired in this mutant. We also find that myosin VIII localizes at the junction between the focused microtubule plus ends and the apical actin accumulation. This suggests that myosin VIII is the physical link between microtubules and actin. These data so far suggest that microtubules are required for the formation and maintaining of actin structures. When microtubules are disrupted, burst of actin filaments randomly form in the cytoplasm, associated with strong accumulation of actin nucleator For2A. This suggests that proper distribution of For2A depends on intact microtubule network, and For2A greatly influenced actin structure formations. Interestingly, in Δmyo8 mutant cells, we observed waves of actin bundles moving along the cell cortex. We found that For2A localization in the cytoplasm is only slightly altered compared to cells with disrupted microtubules, suggesting there are other factors contributing to the actin phenotypes we observed in Δmyo8 mutant. Interestingly, we found that the population of For2A at the cell cortex is hyperactive, producing more actin filaments compared to wild-type cells. These hyperactive For2A potentially results in more actin bundle formation at the cell cortex.

In conclusion, we found that myosin VIII mediated actin-microtubule crosstalk is important for maintaining persistent directional growth in moss protonemal cells. We also found For2A to be another player coordinating the functions of the two cytoskeletons. In addition, myosin VIII modulates For2A activity at the cell cortex in some fashion. We don’t know how myosin VIII modulates For2A activity at this point, but this observation will provide us a window to investigate the interplay among these molecules.

**Functional relationship of MyTH-FERM myosin and VASP during filopodia initiation.**

A.L. Arthur¹, K.J. Petersen², G. Lluxton³, A. Houdusse⁴, M.A. Titus²;

¹Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN, ²Biochemistry, Molecular Biology, and Biophysics, University of Minnesota, Minneapolis, MN, ³Structural Motility, Institut Curie, Paris, France, France

Cells use filopodia, slender actin-filled membrane protrusions, to sense the environment, aid directed migration and serve as the first points of contact for cell-cell interactions. Filopodia initiation requires re-organization of the cortical dendritic actin network into actin bundles oriented perpendicular to the membrane, but how proteins assemble into initiation sites and reorganize the cortical actin network during this process is not well understood. The conserved mechanism of filopodia formation in metazoan and amoebozoan cells, such as Dictyostelium, requires a MyTH-FERM myosin and VASP, however, it is not known how these two proteins are recruited to the membrane, whether they cooperate during filopodia initiation and what role the myosin motor activity plays in initiation. The Dictyostelium filopodial MyTH-FERM myosin, DdMyo7, is localized to the cell cortex prior to filopodia initiation in wild type cells but not in a vasp null mutant, revealing a role for the actin regulator VASP in DdMyo7 localization. Using a bypass approach, lipid anchored DdMyo7 was found to localize to the cortex in vasp null cells, but did not significantly promote filopodia formation. The role of the DdMyo7 motor activity in filopodia initiation was investigated by introducing mutations in the catalytic domain of DdMyo7 that confer either weak or strong actin binding by disrupting ATP hydrolysis or ATP binding, respectively. Neither DdMyo7 mutant was capable of supporting filopodia formation, revealing that full ATP hydrolysis activity is required for its function. The strong actin binding rigor mutant DdMyo7 is enriched at the cell cortex but, in contrast, the weak actin binding mutant (i.e. non-hydrolyzer) has significantly reduced cortical localization. Introduction of mutations in conserved sites in the DdMyo7 tail required for autoinhibition rescues localization by the hydrolysis mutant. Altogether, the data support a model whereby DdMyo7 is recruited to the cortex by VASP, then actin binding releases motor auto-inhibition by the tail, allowing DdMyo7 and VASP to organize the actin network into parallel bundles to initiate filopodia. This work was supported by a GIA from the AHA and a grant from the Minnesota Medical Foundation.

**UNC-45A oligomerizes at the neck.**

K.Z. Chen¹, M. Bazzaro², A. Mooneyham²;

¹Biology, University of Maryland, Baltimore County, Baltimore, MD, ²OBGYN, University of Minnesota, Twin Cities, Minneapolis, MN

UNC-45A is a highly conserved member of the UCS protein family (UNC-45/CRO1/She4p). Each the product of a unique gene, vertebrates have two isoforms, UNC-45A which is detectable as at least RNA in all cells, and UNC-45B which is expressed in muscle cells only. We and others have recently shown that UNC-45A is required for a variety of NMII-mediated functions in mammalian cells, including motility, adhesion, exocytosis, and cytokinesis (1-4). Mechanistically, we have recently proposed a model whereby UNC-45A acts like a negative regulator of Rho activity upstream of ROCK (5).
Studies conducted in C. elegans have revealed that UNC-45 has four domains, an N-terminal domain known to bind to Hsp90, a C-terminal domain, whose functions and binding partners are still unknown, a neck domain that is required for UNC-45A oligomerization, and a C-terminal domain which binds to non-muscle myosin II (NMII). We set forth to determine whether the mammalian form of UNC-45, UNC-45A, oligomerizes in vivo and in vitro. Moreover, we sought to determine the region of UNC-45A required for oligomerization. Cell lysates from cancer cells were treated with increasing concentrations of the cross-linking agent disuccinimidyl suberate (DSS). We confirmed the presence of UNC-45A oligomers by Western blot analysis. Our data shows that endogenously expressed UNC-45A does indeed form high molecular weight oligomers in human cancer cells. Additionally, full-length, deleted N-terminal, deleted central or deleted C-terminal recombinant proteins were treated with DSS. Our Western blot analysis shows that none of the deletions abrogated the ability of UNC-45A to form oligomers suggesting that the neck domain may be required for oligomerization.

Microtubules Nucleation and Organization 2

XMAP215 is a microtubule nucleation factor that functions synergistically with the gamma-tubulin ring complex.
A. Thawani1, R.S. Kadzik2, S. Petry1,2;
1Department of Chemical and Biological Engineering, Princeton University, Princeton, NJ, 2Department of Molecular Biology, Princeton University, Princeton, NJ

Microtubules form a variety of cytoskeletal structures vital to the function of the cell, including the mitotic spindle. The first step in building these structures is the generation of microtubules, yet little is known about how microtubules are nucleated in the cell. For several decades, γ-tubulin has been accepted as the universal microtubule nucleator of the cell. Although there is evidence that the γ-tubulin ring complex (γ-TuRC) might not be the sole microtubule nucleator, identification of other nucleation factors has proven difficult. We developed novel tools to visualize and quantify individual microtubule nucleation events in meiotic Xenopus egg extracts. Using these assays, we discovered that XMAP215, the well-characterized microtubule polymerase, is essential for nucleation of microtubules. XMAP215 promotes microtubule nucleation in a concentration-dependent manner and requires γ-TuRC for this function. We demonstrate that distinct domains of XMAP215 are required for its polymerization and nucleation activity, and that TOG domains of XMAP215 are essential for mediating its microtubule

Tuesday-81
nucleation activity as well as binding to γ-TuRC. Finally, we reconstituted microtubule nucleation in vitro using purified γ-TuRC and XMAP215. While XMAP215 and γ-TuRC possess minimal nucleation activity individually, together these factors synergize to stimulate microtubule nucleation. In sum, XMAP215 is a novel MT nucleation factor that cooperates with γ-TuRC to generate the microtubule cytoskeleton of the cell.

Characterization of a plant-specific microtubule-nucleating protein MACET.
S. Schmidt¹, A. Smertenko¹;
¹Institute of Biological Chemistry, Washington State University, Pullman, WA

In plants, rigid oligosaccharide cell walls impose restrictions on the mechanism of cytokinesis. Whereas animal cells constrict along the division plane and abscise, plant cells initiate a partition at the center of the cell that then expands centrifugally. The animal cytokinetic microtubule array, the midbody, is static and stationary; in contrast, the plant cytokinetic array, the phragmoplast, is dynamic and mobile. The phragmoplast delivers vesicles containing cell wall material to the partition site. The vesicles coalesce into a continuous cell plate which, guided by the phragmoplast, eventually fuses with the mother cell plasma membrane. During cell plate construction, the phragmoplast can expand directionally through the cytoplasm for hundreds of microns, as is the case in highly anisotropic vascular cells in the xylem and phloem. Although most known phragmoplast proteins are also essential for midbody functions, the distinct mechanisms of these two microtubule arrays necessitates that phragmoplast expansion involves plant-specific regulators of microtubule dynamics. Identification of novel regulators will advance our understanding of plant cytokinesis and enable better modeling of this unique process. Here we have identified a land plant-specific microtubule-associated protein MACERATOR1 (MACET1), which directly binds microtubules through two novel microtubule-binding domains located at the N- and C-termini. In vitro turbidimetric and co-sedimentation assays reveal that MACET1 promotes microtubule polymerization. Interestingly, MACET1 induces formation of asters similar to known microtubule-nucleating proteins and reduces average microtubule length in vitro. Microtubule nucleation assays in vitro demonstrated that MACET1 facilitates de novo nucleation of microtubules. Time-lapse imaging of individual microtubules in vitro showed that MACET1 inhibits rescue following depolymerization, but does not affect polymerization or depolymerization rates. MACET1 expresses only in mitotic cells and delineates the site of the future cell plate position in prophase, and localizes to the phragmoplast distal zone during cytokinesis, which is the zone where microtubules are thought to be nucleated. MACET1-GFP also localizes to microtubule-nucleation sites during interphase in transiently transfected cells. Mutant analysis revealed the importance of MACET1 for root growth rate, implicating MACET1 in regulation of cell division. Our data demonstrate that MACET1 plays a role in cytokinesis by promoting microtubule nucleation and restricting their elongation.

Spectraplakin Shot anchors a perinuclear MTOC in Drosophila polyploid cells.
T. Sun¹, Y. Song¹, X. Liang¹, J.C. Pastor-Pareja¹;
¹School of Life Sciences, Tsinghua University, Beijing, China

Microtubule-organizing centers (MTOCs) are subcellular sites capable of growing and arraying microtubules. Apart from centrosomes in dividing cells, non-centrosomal MTOCs (ncMTOCs) are
widespread in nature. It is not known how uncoupling of the centrosome cycle from the cell cycle is achieved in polyploid cells, arising from repeated genome replication without cell division. In a screening for genes affecting Collagen secretion in Drosophila, we found absence of the spectraplakin Shot caused defective Collagen release by fat body adipocytes, a polyploid cell type in the larva. In trying to understand Shot function, we discovered that in adipocytes and other polyploid cell types the nuclear envelope organizes a dense perinuclear microtubule cortex and therefore functions as a ncMTOC. This perinuclear microtubule organizing center (pnMTOC) is responsible for nuclear size, nuclear position and organelle distribution. Anchoring of microtubules to the nuclear membrane requires Shot, as loss of Shot causes collapse of the perinuclear microtubule cortex into a single centrosome-like microtubule organizing center (clMTOC) with profound effects in cellular organization. The ectopic clMTOC does not seem to form through failure of centrosome inactivation during diploid-to-polyploid transition, since conditional knock down of Shot after polyploidization still evokes the phenotype. To better understand this phenomenon, we conducted a second screening for cytoskeleton-related genes required for the formation of the clMTOC. Through this screening, we found several genes involved in formation of the pnMTOC, including nespin Msp-300 and microtubule severing enzyme Katanin. We also found that microtubule minus-end binding protein Patronin, which normally localizes to the pnMTOC, is required for nucleation of the ectopic centrosome-like structure. We finally show that formation of both the pnMTOC and the ectopic clMTOC is dependent on cell cycle progression, and that the clMTOC can direct growth of a membrane cone akin to a monopolar mitotic furrow, to which both the actin and microtubule cytoskeletons contribute.

Adapting proximity labeling techniques to identify novel non-centrosomal MITOC proteins in C. elegans.
A.D. Sanchez¹, T. Branon², A. Ting¹, J.L. Feldman¹;
¹Biology, Stanford University, Stanford, CA, ²Chemistry, Massachusetts Institute of Technology, Cambridge, MA

Microtubules orchestrate critical processes such as intracellular transport and mechanical support. Microtubules have inherent structural polarity, with a dynamically growing plus end and a comparatively stable minus end which associates with microtubule organizing centers (MTOCs). MTOCs play a critical role in nucleating, stabilizing, and/or anchoring microtubules. The centrosome is the primary MITOC during cell division, but in differentiated cells, MITOC function is often reassigned to new sites called non-centrosomal MTOCs (ncMTOCs). Although centrosome composition has been studied thoroughly, ncMTOC composition is relatively poorly understood. Additionally, compared to proteins that associate with plus ends or the entire length of microtubules, the number of minus end proteins that have been identified is relatively small, suggesting that our understanding of the protein composition of ncMTOCs is far from complete. We aim to define a more complete picture of ncMTOC protein composition by identifying proteins proximal to the ncMTOC-specific microtubule minus end protein PTRN-1/Patronin. The technique BioID (proximity-dependent protein biotinylation labeling) offers the unique advantage of screening for proximal proteins in an in vivo context by fusing a promiscuous mutant biotin ligase (BirA*) to a bait protein and identifying proximal proteins that were biotinylated. As a model, C. elegans has been very useful for studying ncMTOCs in many tissues, with the intestine being the best characterized. We are adapting BioID for use in the C. elegans intestine by testing several recently-identified fast acting BirA mutants for biotinylation activity in vivo. Expression of BirA(11mut) in the intestine resulted in significantly increased cytoplasmic biotinylation, indicating that endogenous biotin is sufficient for
BirA(11mut) activity. To enrich BirA(11mut) at the ncMTOC, we fused BirA(11mut) to PTRN-1. These fusion proteins properly localized to the ncMTOC and enriched biotinylation to the ncMTOC. We are currently optimizing biotinylation activity, and testing other BirA mutants. We will use these tools in conjunction with mass spectrometry to identify novel proteins that compose the ncMTOC. Additionally, we will probe the localization of candidate proteins and use reverse genetic tools to determine the role of the candidate proteins for ncMTOC function. Overall, adapting BioID to C. elegans will provide an additional screening tool in a living multicellular animal for the discovery of novel proximity proteins in vivo.

Non-random γ-TuNA-dependent spatial patterning of microtubule nucleation at the Golgi.
A.A. Sanders¹, K. Chang¹, X. Zhu¹, R.J. Thoppil¹, W.R. Holmes², I. Kaverina¹;
¹Cell and Developmental Biology, Vanderbilt University, Nashville, TN, ²Physics and Astronomy, Vanderbilt University, Nashville, TN

Non-centrosomal microtubule (MT) nucleation at the Golgi generates MT network asymmetry in motile vertebrate cells. Investigating Golgi-derived MT (GDMT) distribution, we find that MT asymmetry arises from non-random nucleation sites at the Golgi (hotspots). Using computational simulations, we propose two plausible mechanistic models of GDMT nucleation leading to this phenotype. In the “Cooperativity” model, formation of a single GDMT promotes further nucleation at the same site. In the “Heterogeneous Golgi” model, MT nucleation is dramatically upregulated at discrete and sparse locations within the Golgi. While computationally both models are equally probable, GDMT nucleation leans toward simultaneous rather than sequential, supporting Heterogeneous --Golgi model. Investigating the molecular mechanism underlying hotspot formation, we have found that hotspots are significantly smaller than a Golgi subdomain positive for scaffolding protein AKAP450, which is thought to recruit GDMT nucleation factors. We have further probed potential roles of known GDMT-promoting molecules, including γ-TuRC-mediated nucleation activator (γ-TuNA) domain-containing proteins and MT stabilizers CLASPs. While both γ-TuNA inhibition and lack of CLASPs resulted in drastically decreased GDMT nucleation, computational modeling revealed only γ-TuNA inhibition suppressed hotspot formation. We conclude that clustered GDMT nucleation is a result of γ-TuNA-dependent local activation of γ-TuRC at the Golgi.

Non-centrosomal microtubules and not the centrosome control endothelial cell polarity and sprouting angiogenesis.
M. Martin¹, A. Veloso², J. Wu¹, F. Dequiedt², E. Katrukha¹, A. Akhmanova¹;
¹Cell Biology, Utrecht University, Utrecht, Netherlands, ²GIGA-Molecular Biology in Diseases, University of Liège, Liege, Belgium

Microtubules regulate cell polarity during diverse processes such as directional migration. In dividing mammalian cells, microtubules are traditionally believed to be organized into a radial, centrosomally-anchored network where the relative positioning of the centrosome and the nucleus has been long considered to play a pivotal role in setting up asymmetry. Here, by using sprouting angiogenesis as a paradigm of a polarised physiological process, we deciphered the contribution of centrosomal and non-centrosomal microtubules to controlling cell asymmetry. In strong contradiction with the crucial role
attributed to the centrosome in setting up polarity, we showed that the loss of centrosomes had no effect on the ability of endothelial cells to polarize and move in 2D and 3D environments. In contrast, by silencing the microtubule minus-end-stabilizing protein CAMSAP2, we uncovered a key function for non-centrosomal microtubules in establishing endothelial cell polarity during the process of sprouting angiogenesis. Non-centrosomal microtubules controlled Golgi positioning and trafficking, 2D directional migration and formation of large persistent protrusions in 3D. Moreover, by interfering with CAMSAP2 recruitment to the Golgi apparatus, we showed that although Golgi-tethered microtubules are important for regulating polarity, other non-centrosomal microtubules could also contribute to polarized cell sprouting in 3D. Importantly CAMSAP2 was also required for persistent endothelial cell sprouting during in vivo zebrafish vessel development. In the absence of CAMSAP2, cell polarization in 3D could be partly rescued by centrosome depletion, indicating that the centrosome acts as an inhibitor of cell polarity. We propose that CAMSAP2-protected non-centrosomal microtubules are needed for breaking the symmetry imposed by the radial centrosome-anchored microtubule array to enable microtubule enrichment in a single cell protrusion.

1Biology, Indiana University, Bloomington, IN, 2Molecular and Cellular Pharmacology, University of Miami, Miami, FL, 3Nikon Instruments Inc., Melville, NY, 4Infectious Diseases, University of Miyazaki, Miyazaki, Japan

The organization of a microtubule-based cytoskeleton is dictated by microtubule nucleators or organizing centers. Toxoplasma gondii, an important human parasite, has an array of 22 regularly spaced cortical microtubules stemming from a hypothesized organizing center, the apical polar ring. We have examined the functions of the apical polar ring by characterizing two of its components, a putative microtubule-associated motor, KinesinA, and a second protein, apical polar ring protein 1 (APR1). Parasites that lack both of these proteins are capable of generating 22 cortical microtubules with wild-type like arrangements, indicating that these proteins do not template and are not “rulers” dictating the spacing between the microtubules. However, the apical polar ring is fragmented in live ΔkinesinAΔapr1 parasites and is undetectable by electron microscopy after detergent extraction. Other cytoskeletal structures such as the conoid, preconoidal rings, intra-conoid microtubules and cortical microtubules are not affected, highlighting the modularity of these substructures within the same framework. Mechanical instability of the apical polar ring is associated with detachment of microtubules from the apical end of the parasite, and linked to an overall diminished ability of the obligate intracellular parasite to move and invade host cells, as well as decreased secretion of effectors important for these processes. Together, the findings demonstrate the importance of the structural integrity of the apical polar ring and the microtubule array in the Toxoplasma lytic cycle, which is responsible for massive tissue destruction in acute toxoplasmosis. Efforts are currently underway to identify the protein(s) responsible for nucleating and templating the 22 cortical microtubules by biochemical and proteomic methods, as well as to reconstitute activity of the putative organizing center in vitro.

A novel perinuclear non-centrosomal MTOC in Drosophila fat body cells maintains nuclear positioning through pericentriolar material proteins and the LINC complex.

Y. Zheng1, R.A. Buchwalter1, T.L. Megraw1, J.V. Chen1, L. Kao1;
1Department of Biomedical Sciences, Florida State University, Tallahassee, FL

Many differentiated cell types establish non-centrosomal microtubule organizing centers (MTOCs) to achieve critical cellular, developmental, and physiological functions. Here we identified a novel non-centrosomal MTOC localized in the perinuclear region of Drosophila fat body, a differentiated cell type with uniform nuclear spacing. The fat body MTOC generates radial perinuclear microtubules. We show that nuclear spacing and MTOC assembly is mediated by pericentriolar material (PCM) proteins and LINC complex proteins. This fat body perinuclear MTOC is composed of at least ten PCM proteins with perinuclear localization, but lacks non-PCM centriolar proteins. Two PCM proteins, centrosomin (Cnn) and Sas-4 cooperate in the assembly of perinuclear microtubules ring and the recruitment of other PCM proteins including the microtubule anchor Ninein to the perinuclear region, as revealed by cnn sas-4 double mutant. The perinuclear assembly of the MTOC in fat body cells requires the LINC complex proteins, including SUN domain protein Koi, which we found critical for proper nuclear positioning in fat body cells. In koi mutant, the perinuclear localization of Cnn, Nin and microtubules are impaired, which may account for the uneven nuclear spacing in the fat body cells of koi mutant. Thus, our study uncovers a novel non-centrosomal perinuclear MTOC in Drosophila fat body cells that is required for proper nuclear positioning through PCM proteins and the LINC complex.

Microtubules are a major component of the cytoskeleton and mediate important cellular functions including organelle positioning, intracellular trafficking and mitotic spindle formation. In most proliferating cells, microtubules are nucleated radially from a classical microtubule organizing center, the centrosome. By contrast, a variety of differentiated cells nucleates and organizes microtubules from other sites than the centrosome, such as the Golgi, the plasma membrane or the nucleus. In 1985, Bornens and colleagues described the relocalization of pericentriolar material at the nuclear envelope (NE) of muscle nuclei. Since then, the mechanism and the proteins involved in this event remained unknown. We performed a siRNA screen against 300 NE proteins in differentiating muscle cells and follow relocalization of pericentrin, a major centrosomal protein, and microtubule nucleation.
Interestingly, we found the LInker of Nucleoskeleton and Cytoskeleton (LINC) complex to be involved in these processes. Myotubes depleted of different LINC components showed mislocalization of pericentrin to the cytoplasm and failed to nucleate microtubules from the NE. Using the proximity-dependent biotin identification (BioID) method, we found several centrosomal proteins, including Akap450, Pcm1, and Pericentrin, whose association with Nesprin-1α is increased in differentiated myotubes. We show that Nesprin-1α recruits Akap450 to the NE independently of kinesin and that Akap450, but not other centrosomal proteins, is required for MT nucleation from the NE. Furthermore, we demonstrate that this mechanism is disrupted in congenital muscular dystrophy myotubes from a patient carrying a nonsense mutation within the SYNE1 gene (23560 G>T) encoding Nesprin-1. Finally, using computer simulations and cell culture systems, we provide evidence for a role of MT nucleation from the NE on nuclear spreading in myotubes. Our data thus reveals a novel function for Nesprin-1α/Nesprin-1 in nuclear positioning through recruitment of Akap450-mediated MT nucleation activity to the NE.

Distinct roles of pericentriolar proteins in acentriolar MTOC of mouse meiotic spindle formation.
I. Lee1, Y. Jo3, S. Namgoong1, N. Kim1;
1Animal Science, Chungbuk National University, Cheongju, Korea, South

Mammalian oocytes lack a centriole that acts as a microtubule organization center (MTOC) in most somatic cells. During oocyte maturation, MTOCs undergo remodeling processes including decondensation, fragmentation, and self-organization. However, the underlying mechanisms of MTOC remodeling in mouse oocytes are not well-understood. We showed that two pericentriolar proteins, Cep192 and Cep152, play crucial roles during MTOC remodeling in mouse oocytes. Cep192 is present in MTOCs at all stages of oocyte maturation, and its depletion induces ablation of MTOC, delay in spindle formation, and abnormal chromosomal alignment in spindles. In the case of Cep152, its localization on MTOC is limited at the germinal vesicle (GV)-stage and then disappears from the MTOC after germinal vesicle breakdown (GVBD)-stage. Cep152 exclusion from MTOC is involved in the fragmentation of MTOC, and it is regulated by CDK1 activity. Together, our results demonstrate the different roles of Cep192 and Cep152 in MTOC remodeling, and a novel regulatory mechanism during meiotic spindle formation in mouse oocytes. *Supported by Grant from Next Generation Biogreen 21 Program (PJ011206), Rural Developmental Adminstration, Republic of Korea.

Golgi-derived microtubules in pancreatic β-cells are regulated by glucose through cAMP and EPAC2.
K.P. Trogden1, G. Gu2, I. Kaverina1;
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Insulin release from pancreatic β-cells is tightly regulated. In response to evenly sustained high glucose only a small fraction of insulin granules are released. Previous work from our lab has shown that microtubules (MTs) act to negatively regulate insulin release and in response to high glucose are destabilized to help with the release of granules. The formation of MTs in cells occurs primarily through templated nucleation, which uses the γ-tubulin ring complex as a template and can occur at the
centrosome, from the side of previously formed MTs (augmin-dependent), or at the Golgi. Successful MT formation also requires stabilization of newly-forming MT seeds, a process that is known to require CLASP2 for Golgi-derived microtubules (GDMTs). Previous work has shown that GDMT nucleation in pancreatic β-cells is increased upon a high glucose stimulus. Now, we have addressed the function of these newly formed GDMTs. Our data indicate that they likely play a role in trafficking of newly synthesized proinsulin through the membrane networks from the ER to the Golgi and further into nascent secretory granules, and might affect proinsulin to insulin processing, potentially affecting glucose-stimulated insulin release (GSIS). We were also interested in what processes in the cell cause the increase in GDMTs in response to high glucose. Here we show that GDMT nucleation increases in two waves in response to high glucose in an isolated β-cell line, MIN6, which mirror the well-described two waves of GSIS. The first wave doubles to amount of GDMTs and occurs rapidly, peaking by 5 minutes. This increase proceeds the expansion of the Golgi that occurs during glucose stimulation, indicating it involves a change in regulation and not an increase in available sites for nucleation. We decided to further explore what is causing this increase during the first wave. We have found that the cAMP pathway, which is also involved in GSIS, controls the increase in GDMT nucleation. Addition of a cAMP analog in low glucose leads to a doubling of GDMT nucleation. Out of the two major cAMP effectors, EPAC2, a paralog of the more ubiquitously expressed EPAC1, rather than protein kinase A (PKA) cause this increase. Interestingly, EPACs interact with the light chain, LC2 and LC1, of MAP1A and MAP1B, respectively, which are known to bind and stabilize MTs. We propose that EPAC2 in β-cells is acting though LC1 or LC2 to stabilize newly nucleated GDMTs. When activated upon glucose stimulation, EPAC2 stabilizes these newly formed GDMTs allowing them to grow out from the template, therefore increasing the number of GDMTs in high glucose. To better understand this process, we are currently testing this hypothesis.

Comparison of migration rates and microtubule nucleation in MDA-MB-231 and MCF-7 breast cancer cells.
B. Bell1, L. Zahn1, C. Grady1, S. Lundin-Schiller1;
1Biology, Austin Peay State University, Clarksville, TN

Golgi derived microtubule (MT) arrays have been shown to be essential for directionally persistent cell migration and vesicle transport in some cells. This mechanism works through the recruitment of a number of proteins, including a MT precursor γ-tubulin ring complex (γ-TuRC), to the cis-side of the Golgi. This study seeks to determine if Golgi derived MT arrays are an important defining characteristic of highly invasive breast cancer cells. Two breast cancer cells lines, MDA-MD-231 and MCF-7, were compared for migration rates in scratch assays and co-localization of Golgi proteins with MT and MT recruitment proteins using both microscopic co-localization and co-immunoprecipitation (co-IP). In scratch assays, MDA-MB-231 cells display a significantly different (P < .05) mean (n=9) migration rate of 18 x 103 μm2/hr compared to MCF-7 cells with a mean (n=9) migration rate of 4.7 x 103 μm2/hr. In microscopic co-localization experiments, the overlap of immunofluorescence of components required for microtubule formation were compared using calculated Mander’s Co-localization Coefficient values. Co-localization of a cis-Golgi membrane protein (GM130) and the microtubule subunit, α-tubulin, has a higher incidence (p <0.0001) after microtubule disruption in MDA-MB-231 cells (0.82±0.11, n=5) than in MCF7 cells (0.08±0.06, n=5). Co-localization of GM130 with γ-tubulin, a component of the γ-TuRC, was also considered. This co-localization was compared between cell lines and between cells with and without an environment conducive to migration, through the treatment of cells with epidermal growth
factor (EGF). These components more readily co-localize (p<0.0001) within MDA-MB-231 cells in a migratory environment (0.47±0.23, n=10) than in either cell type without treatment (MDA: 0.06±0.04, n=10; MCF7: 0.03±0.02, n=10) or MCF7 cells treated with EGF (0.10±0.06, n=10). These findings suggest a marked increase in Golgi derived microtubule activity in breast cancer cells that are highly invasive. However, preliminary experiments to co-IP GM130 and γ-tubulin have not supported the hypothesis. Experiments are ongoing to more precisely characterize any co-immunoprecipitation of relevant proteins.

*Septin-microtubule interplay enables initiation of branching morphogenesis.*

D.K. Bogorodskaya¹, J.P. Wiegartner¹, L. Ligon¹; ¹Biological Sciences, Rensselaer Polytechnic Institute, Troy, NY

Many organs, such as kidney, lungs and mammary gland, are formed by a process of branching morphogenesis which begins with the formation of cytoplasmic extensions from the basal surface of polarized cells in an epithelial sheet. We have shown that the microtubule (MT) cytoskeleton is necessary for the formation of these extensions, and now we have established that septins also play a key role in extension formation as well. Septins have previously been shown to play an essential role in a variety of morphogenic changes and are also necessary for epithelial cells to switch to a motile phenotype. Septins can interact directly with MTs and indirectly with the MT network via MAPs. Here, we sought to determine if the interaction between septins and the MT cytoskeleton plays a role in this earliest stage of branching morphogenesis -- the formation of primary extensions from single epithelial cells. We induced morphogenesis in spheroids of polarized epithelial cells grown in 3D culture with hepatocyte growth factor (HGF), which resulted in the formation of cytoplasmic protrusions extending from the basal surface of single cells. These early stage extensions are filled with prominent MT bundles, and disruption of the MT cytoskeleton inhibits extension formation. Septins are also recruited to the base of the protrusions, where they colocalize with the MT bundles. Additionally, septins colocalize with MT bundles in the body of mature extensions. Septin disruption before morphogenesis leads to a decrease in extension formation. When septin inhibitors were added after morphogenesis was initiated, we observed extensions containing disorganized, curved and splayed MTs as opposed to tight bundles of parallel MTs. We hypothesize that septins interact with MT bundles and this interaction may provide the mechanical stiffening and cytoskeletal reorganization necessary for the initiation and stabilization of HGF-induced extensions in morphogenesis.

*Effects of Microtubule Stabilizers in Neurodevelopment and Injury.*

Y. Song¹², J.J. Pineda², T.J. Mitchison¹²; ¹Harvard Program in Therapeutic Science, Harvard Medical School, Boston, MA, ²Systems Biology, Harvard Medical School, Boston, MA

Microtubules (MTs) are structural components vital for important neuronal functions such as neurite outgrowth and maintenance, as well as for axonal trafficking and synaptic remodeling. Neuronal MTs
are particularly stable compared with those in other cell types and often exist for years before they get degraded and recycled. They are mostly synthesized in the somatodendritic compartment and have to be transported along axons as much as a meter or more in humans to reach the terminals where synaptic proteins are delivered and synaptic transmission occurs. A significant portion of neuronal MTs stay polymerized when challenged with MT destabilizers in test tubes and various non-neuronal cell lines, suggesting that baseline MT stability is high in neurons. Such stability increases during development and maturation, but decreases with axonal injury and neurodegeneration. This leads to an intriguing question: can stabilizing MTs facilitate neurite outgrowth during early development or restore axonal integrity and function upon injury? To address these questions, we have characterized a group of MT stabilizing drugs (Epothilone D, Epothilone B, Ixabepilone, Taxol and Synstab) regarding their binding affinity to MTs in vitro using biochemical assays and fluorescent live imaging; and evaluated their effects on neurite growth during normal differentiation and regrowth after axotomy. Dose and time dependent drug treatments were performed on ReNcell VM cells (an immortalized human neural progenitor cell line), and differentiated VM cells that exhibit neuronal morphology and electrophysiology, followed by high-content live-cell imaging and automated imaging analysis. We found that these drugs showed bimodal effects on initial neurite extension and regeneration after injury. To understand the molecular mechanisms underlying regulation of MT stability by these drugs and their biological effects, we have used multiplex proteomics to study dose-dependent changes in signaling pathway components and MAPs over time. These results may provide useful information for understanding not only neuronal MT dynamics and stability in health and disease, but also for determining the therapeutic value of MT stabilizers in axonal injury and neurodegeneration where loss of neuronal MT integrity may exacerbate disease pathology.

The microtubule plus-end-tracking protein TACC3 promotes persistent axon outgrowth and mediates responses to axon guidance signals during development.
B. Erdogan¹, G. Cammarata¹, E. Lee¹, B. Pratt¹, L.A. Lowery¹;
¹Biology, Boston College, Chestnut Hill, MA

Precise neuronal connection requires proper axon guidance. Microtubules (MTs) of the growth cone are the driving force to navigate the growing ends of axons. Pioneering microtubules and their plus-end tracking proteins (+TIPs) play integrative roles during this navigation. Recently, we introduced the protein TACC3 as a member of the +TIP family regulating microtubule dynamics in Xenopus laevis growth cones and show that manipulation of TACC3 levels affects axon outgrowth by regulating axon outgrowth velocity and the frequency of axon retraction. Additionally, we show that over-expressing TACC3 mitigates nocodazole-induced reduction in MT dynamics parameters suggesting that TACC3 could play a protective role against nocodazole induced MT depolymerization. Moreover, we find that TACC3 and its partner XMAP215, a well-characterized MT polymerase, cooperate to promote axon outgrowth and rescue axon growth defects. Finally, we show that reduction of TACC3 levels causes pathfinding defects in axons of developing spinal cord motor neurons in Xenopus laevis in vivo and increased TACC3 levels interfere with the growth cone response to the axon guidance cue Slit2. Currently we are investigating whether TACC3 could be a potential target of Abelson kinase downstream of the Slit2 guidance cue. Together, our results suggest that by regulating MT behavior, the +TIP TACC3 is involved in axon outgrowth and pathfinding decisions of neurons during embryonic development, and that TACC3 phosphorylation events, which remain to be elucidated, could be important regulators of this involvement.

Trim9 participates in a microtubule quality control pathway that ensures local nucleation in dendrites does not disrupt uniform polarity.
C. Feng¹, M.M. Rolls¹;
¹BMMB, Penn State University, University Park, PA

In Drosophila neurons, minus-ends of microtubules (MTs) are oriented away from the cell body in dendrites. One contributor to generating this non-centrosomal MT array is local nucleation in dendrites. g-Tubulin, the core MT nucleation protein, is concentrated at dendrite branch points where it can generate new microtubules. If these new microtubules were generated randomly in all directions, then local nucleation would disrupt uniform minus-end-out polarity. Here, we investigated how local nucleation is coupled to maintenance of uniform polarity. First, we closely monitored the behavior of MT plus-ends originating within dendrite branch points using EB1-GFP. Roughly one third of these new plus ends grow away from the cell body in a plus-end-out orientation. However, on average only 10% of microtubules between branch points are plus-end-out. This suggests that some kind of checkpoint prevents plus-end-out microtubules from leaving the branch point. Indeed when we examined the behavior of microtubules as they exited the branch point, the success rate was twice as high when they exited towards the cell body as opposed to away from it. We hypothesized that the polarity of pre-existing MTs might distinguish the two exits from one another. Consistent with this hypothesis, in genetic backgrounds where stable microtubules have mixed polarity, newly polymerizing MTs exited in all directions with a high success rate. To identify proteins required for this checkpoint, we carried out a candidate screen and identified Trim9 as a positive regulator of exit success. Without Trim9, new growing MTs had the same low success rate exiting all directions. Surprisingly, when expressed in Drosophila S2R+ cells, Trim9 colocalized with over-expressed EB1 on the MT lattice. To determine where Trim9 localized in neurons, we expressed mNeonGreen-Trim9 in Drosophila neurons. It strongly localized to dendrite branch points, in line with where it functions. We propose that Trim9 is part of a quality control mechanism that ensures that microtubules generated at dendrite branch points contribute to maintenance of uniform polarity, rather than its disruption.

TACC3, a microtubule plus-end tracking protein, regulates neural crest cell motility in vitro and in vivo.
E.A. Bearce¹, E.L. Rutherford¹, L. Carandang¹, B. Pratt¹, L.A. Lowery¹;
¹Biology, Boston College, Chestnut Hill, MA

Coordinated cell migration is critical during embryogenesis. During development, cells from multiple lineages delaminate from their point of origin to travel through the embryo, providing foundations for the heart, gut, vasculature, & nervous system. Cell motility relies on dynamic coordination of the F-actin and microtubule (MT) cytoskeletons. These systems function together to respond to chemical cues, directionally polarize, and generate force and traction for motility. Therefore, cytoskeletal proteins that impact motility are critical during embryogenesis, and disruption of these genes can give rise to developmental disorders. Our work focuses on how MT plus-end regulators impact migration of cranial neural crest (CNC) cells, a multipotent cell that differentiates to form muscle, cartilage, bone, & nerves of the face. We identified one MT regulator, transforming acidic coiled-coil 3 (TACC3), as a putative
effector of CNC motility. We previously showed that TACC3 functions as a MT plus-end tracking protein and regulates MT growth velocities in CNCs. Interestingly, TACC3 is one of 5 genes deleted in Wolf-Hirschorn syndrome, a genetic disorder that presents craniofacial defects consistent with disrupted CNC migration. Using in situ hybridization, we show that TACC3 is highly-expressed in motile CNCs in X. laevis. Manipulation of TACC3 protein levels is sufficient to alter CNC velocity in vitro. Overexpression (OE) drives increased single-cell migration velocities and explan dispersion. TACC3 KD results in marked motility defects, with fewer cells able to migrate persistently. In order to assess how TACC3 manipulation impacts cell velocity, we use confocal microscopy to examine localization of GFP-TACC3 in live cells, & effects of TACC3 manipulation on MT stabilization, adhesion turnover, and chemotaxis. Finally, KD but not OE of TACC3 significantly impacts pharyngeal arch morphology in vivo. Together, these data support a role for TACC3 in embryonic cell motility.

End binding proteins (EBs) are key regulators of growing microtubule plus ends. Recent work demonstrated that microtubule minus ends can also grow in cells, and that minus end dynamics are important for shaping non-centrosomal microtubule networks. However, the role of the EBs in controlling the organization of microtubule minus ends is poorly understood. Here, by using CRISPR/Cas9 technology, we have generated cell lines that lack EB2, EB3 and the C-terminal partner binding part of EB1. These cell lines show only mild defects in mitosis and microtubule plus end dynamics, but, surprisingly, they display severely perturbed microtubule minus end organization. In the studied cell lines, microtubule minus ends that are not attached to the centrosome are stabilized by CAMSAP2, and many of them are tethered to the Golgi apparatus. Disruption of EB1 and EB3 leads to shortening of CAMSAP2-decorated microtubule minus ends, their detachment from the Golgi and their relocation to the cell periphery. EB1 or EB3 are recruited to the Golgi through an interaction with myomegalin, and our data suggest that the weak binding of Golgi-associated EB1 and EB3 to stable microtubule lattices contributes to microtubule tethering to Golgi membranes and counteracts compaction of Golgi stacks. Furthermore, we find that disruption of EB1 and EB3 affects vesicle transport, cell motility on 2D substrates and cell invasion in 3D matrices. Our results demonstrate that EB proteins control diverse aspects of interphase cell architecture and have an unexpectedly profound impact on the organization of microtubule minus ends.
During angiogenesis, endothelial cells (ECs) utilize signaling molecules and microtubule (MT) associated proteins (MAPs) to control the dynamic and coordinated remodeling of the actin and MT cytoskeleton to become polarized. Rac1, a signaling molecule of the Rho GTPase family, promotes cell protrusion and enhances MT plus-end assembly into protrusions, thereby driving EC polarization. As ECs polarize, actin filaments assemble and become linked to focal adhesion (FA) complexes that mature at the positions where the cell interfaces with the extracellular matrix. Recent investigations have identified that a subset of elongating MTs undergo “capture” at FAs, and that FA-captured MTs promote directed cell migration, yet how MTs are designated for FA capture is not known. CAMSAPs are MAPs that associate with MT minus-ends, where they inhibit MT disassembly and promote plus-end MT growth. Septins are MAPs that promote actin stress fiber-mediated maturation of FAs and that spatially guide MT plus-end dynamics. Collectively, these data point to a potential mechanism used by ECs to delineate MT functions via association with CAMSAPs and septins. Here, we tested the hypothesis that FA capture of MTs is controlled by signaling from Rac1 to promote septin-mediated guidance of CAMSAP-associated MTs for FA capture. Live-cell fluorescence imaging of ECs revealed that MTs captured at FAs are predominantly nucleated at the Golgi-apparatus rather than the centrosome. Expression of a constitutively active Rac1 promoted increased CAMSAP stretch length on Golgi-derived MT minus-ends, while a dominant negative Rac1 had the opposite effect. Analysis of MT growth events revealed that CAMSAP-associated MTs consistently grew into septin stretches that localized adjacent to FAs, resulting in FA capture of MTs in almost all cases. Pharmacologic inhibition of myosin-II, to relieve contractile forces on FA-associated actin filaments, resulted in a significant reduction of both FA-associated septin and FA capture of MTs, and this effect was dependent on Rac1 activity. Expression of either CAMSAP or septin, or simultaneous expression of both proteins, increased EC migration in a wound-healing assay. These results suggest that Golgi-derived, CAMSAP-associated MTs represent a distinct population of MTs that are guided by peripheral septin for FA capture. Moreover, these data support a model in which a balance of Rac1 and myosin-II activity promotes CAMSAP-association with Golgi-derived MTs and increases septin localization to peripheral FAs to promote persistent and directional EC migration. Future investigations will mechanistically determine how CAMSAP-associated MTs are distinguished by septin, and how septin-mediated FA capture of MTs contributes to enhanced EC migration.

Oligodendrocytes are specialized glial cells in the central nervous system that produce myelin, the fatty layers of insulation that wrap around axons to facilitate efficient action potential conduction. Unlike Schwann cells in the peripheral nervous system that ensheathe a single axonal segment, one
Oligodendrocyte can ensheath multiple axonal segments and consequently extends multiple processes. These microtubule-rich processes are elaborate and highly branched, yet it is unclear how they are organized and how they form. We now show using live-cell imaging that microtubules in oligodendrocytes have uniform polarity, with growing EB3-labeled plus ends directed away from the cell body. Interestingly, though polarity is consistent throughout oligodendrocyte differentiation, speeds of polymerization vary at different developmental time points. In addition, we now show by immunostaining that oligodendrocyte processes contain Golgi outposts, which may act as a source of acentrosomal microtubule nucleation at sites that are far from the cell body. Previous experiments in Drosophila neurons have demonstrated roles for Golgi outposts in microtubule nucleation and dendrite branching. In order to screen for candidate Golgi outpost interactors, we used our lab’s RNA-Seq database to identify microtubule-associated proteins that are highly and specifically expressed in oligodendrocytes. We identify TPPP (tubulin polymerization promoting protein) and show that it selectively localizes to Golgi outposts but not to Golgi bodies in the cell body. Knockdown of TPPP results in aberrantly mixed microtubule polarity and increased branching in oligodendrocytes, but does not alter the speed of EB3-labeled plus ends, suggesting that contrary to its name, TPPP does not actually mediate microtubule polymerization in cells. An alternative possibility is that TPPP stabilizes microtubules by binding at the minus end and we are currently addressing this by using polarity marked microtubules and in vitro kinesin motility assays. In addition, we are using mass spectrometry to identify the Golgi outpost proteome, by purifying Golgi from rat pup brains followed by immunoprecipitation against TPPP. Finally, preliminary data from mice indicate that TPPP knockout may lead to sensorimotor deficits and anxiety-like behavior. Together, our data demonstrate that TPPP is required for uniform microtubule polarity and process branching in oligodendrocyte development.

**Mechanism of Catalytic Microtubule Depolymerization via KIF2-tubulin Transitional Conformation.**
T. Ogawa¹, S. Saijo², N. Shimizu², X. Jiang¹, N. Hirokawa¹;
¹Department of Cell Biology and Anatomy, Graduate School of Medicine, University of Tokyo, Tokyo, Japan, ²High Energy Accelerator Research Organization, Photon Factory, Institute of Materials Structure Science, Tsukuba, Japan

Microtubules (MTs) are dynamic structures that are fundamental for cell morphogenesis and motility. MT-associated motors work efficiently to perform their functions. Unlike other motile kinesins, KIF2 catalytically depolymerizes MTs from the peeled protofilament end during ATP hydrolysis. However, the detailed mechanism by which KIF2 drives processive MT depolymerization remains unknown. To elucidate the catalytic mechanism, the transitional KIF2-tubulin complex during MT depolymerization was analyzed through multiple methods, including atomic force microscopy, size-exclusion chromatography, multi-angle light scattering, small-angle X-ray scattering, analytical ultracentrifugation, and mass spectrometry. The analyses outlined the transitional conformation in which KIF2core domain binds tightly to tubulin dimers in the middle pre-hydrolysis state during ATP hydrolysis, a process critical for catalytic MT depolymerization. The X-ray crystallographic structure of the KIF2core domain displays the activated conformation that stabilizes the transitional KIF2-tubulin complex.
Little is known about how the crowded environment of the cytoplasm affects molecular processes within the cell. The cell often encounters changes in cytoplasmic density, for instance in the course of the normal cell cycle as well as in response to environmental changes. For instance, changes in osmolarity lead to loss of intracellular volume through loss of water. In vitro studies predict that molecular crowding may speed up processes such as microtubule polymerization. Here, we have probed the effects of cytoplasmic density on microtubules and actin in the fission yeast S. pombe. Addition of sorbitol, an osmotic agent, causes large reversible changes in cell volume and cytoplasmic density. Sorbitol causes a dose dependent decrease microtubule and actin dynamics. Strikingly, a high osmotic shock completely freezes microtubule and actin dynamics, while at intermediate dosage, microtubule polymerization and shrinkage are decreased. Potential explanations for these effects include steric crowding, effect on regulators, or a requirement for sufficient water molecules. These studies introduce a new system to study the effects of cytoplasmic density and a method to rapidly and reversibly tune cytoskeletal dynamics.

In order for the microtubule cytoskeleton to function in diverse processes, the dynamic property of cellular microtubules must be tightly controlled in time and space. The microtubule motor protein, kinesin, can transport cargo, regulatory proteins and other microtubule filaments along microtubules. Additionally, some kinesins directly control the dynamic behavior of their cellular track. Thus, kinesins are major regulators of the organization and function of the microtubule cytoskeleton. Kinesin-8 is a conserved subfamily of motor proteins and an important class of microtubule regulators in diverse species. Kinesin-8 from several species are known to be multifunctional proteins, and the budding yeast kinesin-8, Kip3, combines plus-end directed motility with microtubule stabilizing, destabilizing, and anti-parallel cross-linking activities in a single molecule. Moreover, Kip3 regulates numerous aspects of microtubule dynamics during distinct cellular processes. It is known that the N-terminal motor domain is sufficient for microtubule depolymerization, while the C-terminal tail is needed for microtubule cross-linking and spatially induced microtubule rescue. Yet, how Kip3 achieves multiple activities, and how they are selectively deployed to differentially control specific microtubules within the cell remains largely unknown. We performed a functional analysis of the Kip3 tail. Interestingly, the regions proximal and distal to the motor domain confer opposite sensitivities to microtubule destabilizing compounds. We show that the proximal region is sufficient for Kip3 localization to microtubule plus ends and the general regulation of astral microtubules within the cytoplasm. It also functions to regulate microtubule dynamics at the bud tip during early spindle positioning. Notably, the proximal region is sufficient to mediate the rescue of astral microtubules spatially within the bud compartment. In contrast, the distal tail region is required for proper spindle function during anaphase. Kip3 lacking this region is a gain of...
function for controlling spindle length; spindles do not reach full length. We show that the distal tail is a negative regulator of spindle disassembly during anaphase. This distal tail mediates the antagonism between the microtubule polymerase Stu2, and the destabilizing activity of Kip3 within the spindle. Furthermore, we reveal that the function of this molecular antagonism is to confer structural robustness to the dynamic spindle midzone. Overall, our data demonstrate that the distal tail region of Kip3 functions to temporally regulate the stability of the spindle midzone during anaphase.

Investigating the Structure and Functional Role of the C-Terminal Domain of the Drosophila XMAP215 Protein Family Member Minispindles.

Z. Xue1, R.C. Adikes1, B.F. Saway1; A.N. Gwyn1, K.C. Slep1;
1Department of Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Microtubules (MTs) are cytoskeletal polymers responsible for multiple cytoplasmic activities: enabling intracellular transport, stabilizing the cell’s shape, and forming the mitotic spindle. MT-associated proteins (MAPs) localize to MTs where they modulate MT dynamics through molecular and structural changes to the MTs. Members of a subgroup of MAPs that specifically localize to the MT plus end are referred to as +TIPs.

A group of highly conserved +TIPs, known as the XMAP215 family, accelerate MT assembly and promote MT growth. XMAP215 family members promote polymerization via TOG (tumor over expressed gene) domains that bind to tubulin heterodimers. TOG domains contain tandem HEAT repeats with highly conserved intra-HEAT loops essential for interacting with tubulin. Studies of XMAP215 family members in multiple species show that they play an essential role during interphase and mitosis, as their depletion leads to decreased MT growth rates and short spindles or defects in spindle architecture. Members of the XMAP215 family contain a varying number of N-terminal TOG domains, however, the structure and functional role of the C-terminal domain (CTD) remains unknown. Using bioinformatics, we show that the highly conserved central region of the CTD of XMAP215 family proteins contains HEAT repeats that strikingly resemble what is known to form a TOG domain. We hypothesize that the structural elements of the conserved CTD of the XMAP215 family of proteins are responsible for regulating MT dynamics by properly localizing the full-length molecule to MT plus ends. We show that the CTD predicted TOG domain, of the Drosophila XMAP215 family member, Msps, is required to properly localize Msps in Drosophila S2 cells. Previous studies have shown that dsRNA induced depletion of Msps leads to reduction of MT growth velocities and decreased mitotic spindle length. We show that constructs lacking the entire CTD or the CTD TOG domain fail to rescue MT growth rates and spindle length. Using secondary structure predictions and multiple sequence alignment analyses of the CTD TOG domain we identified conserved predicted surface exposed charged residues. We systematically mutated these residues and determined that particular small sets of residues (2-3 amino acids) within this region are required to localize Msps to MT plus ends and rescue growth rates. Previous studies show that the plus-end accumulation of Msps is severely reduced upon depletion of Sentin, a plus-end tracking protein. Therefore, we hypothesize that the CTD TOG domain interacts with Sentin. We are performing in vivo and in vitro assays to elucidate the Msps CTD TOG:Sentin interaction. Further experiments are being performed to elucidate the structure of this domain and its interaction with Sentin.

Structure, biochemistry, and activity of a CLASP family TOG.
S. Majumdar¹, L.M. Rice²;
¹Biophysics, UT Southwestern Medical Center, Dallas, TX

Microtubule (MT) dynamics are tightly regulated by associated proteins. Two conserved regulatory factors, XMAP215 family polymerases and CLASP family rescue factors, use tubulin-binding TOG domains to control MT dynamics. In S. cerevisiae, the polymerase STU2 and rescue factor STU1 produce different effects on MT dynamics but have similar architectures: two TOG domains followed by a basic region and a dimerization domain. The minimal functional unit for a MT polymerase appears to be two flexibly-linked TOGs that preferentially bind unpolymerized αβ-tubulin (curved conformation) plus a lattice-binding basic region. The minimal requirement for a rescue factor has not been defined. Our working hypothesis is that the divergent functions of the two families arise from differences in the structural and biochemical properties of CLASP TOGs and/or how they are linked. To provide a structural context for subsequent biochemical and functional studies, I determined the structure of the TOG2 domain from Stu1. The overall structure of this domain resembles that of another CLASP TOG and is characteristically distinct from that of polymerase TOGs in a way that suggests a change in the conformation-selectivity of TOG-tubulin interactions. The structure of STU1:TOG2 also reveals that part of the sequence that would normally link TOG1 to TOG2 forms a helix that docks onto the TOG2 domain in a novel way, indicating that the Stu1 TOGs are more rigidly coupled than the polymerase TOGs. Also in contrast to the polymerase TOGs, STU1:TOG2 shows appreciable affinity for both curved/unpolymerized αβ-tubulin and straight/polymerized αβ-tubulin. STU1:TOG1, on the other hand, does not show appreciable affinity for either polymerized or unpolymerized αβ-tubulin. These interactions with curved and straight αβ-tubulin both depend on the same conserved positions that mediate tubulin binding in polymerase TOGs. To begin investigating conformation-selectivity of interactions between STU1:TOG2 and αβ-tubulin, I measured the effects of the domain on MT polymerization dynamics in vitro. These assays revealed that STU1:TOG2 by itself – without a basic region or a dimerization element - suppresses catastrophe and promotes rescue. These results expand our understanding of TOG structure, biochemistry, and mechanism. They also indicate that in contrast to polymerases where two TOGs are required, a single CLASP-family TOG is sufficient to suppress catastrophe and promote rescue.

Reconstitution of Microtubule Dynamics from Budding Yeast Lysate.
Z.J. Bergman¹, J. Wong¹, D.G. Drubin¹, G. Barnes¹;
¹Molecular and Cell Biology, University of California-Berkeley, Berkeley, CA

Microtubules (MTs) are important for cellular structure, transport of cargoes, and segregation of chromosomes and organelles during mitosis. The stochastic growing and shrinking of MTs, known as dynamic instability, is necessary for these functions. The parameters of MT dynamic instability, such as the rates of growth and shrinkage and the frequencies of rescues and catastrophes have been shown to be cell cycle-dependent and tuned by MT-associated proteins (MAPs) when measured in cells. Previous work to characterize individual MAP effects on MTs has been performed either through in vivo studies, which vary widely by cell type, or in vitro studies that typically focus on individual protein activity but lack cellular context and can even display different dynamics due to cross-species components. In order to investigate the coordinated activity of all native MAPs on MT dynamics, we have developed a cell-free
assay using TIRF microscopy and whole cell lysate from the budding yeast, *Saccharomyces cerevisiae*. Here, we take lysate from GFP-tubulin-expressing yeast strains and observe MT polymerization off of pre-assembled seeds adhered to a coverslip. This allows observation of single MTs whose behavior may normally be obscured by cellular structures or other MTs in the mitotic spindle. Through use of cell-division cycle mutants (cdc), we have found that MT polymerization and dynamic instability are dependent upon the cell cycle even *in vitro*. Additionally, we have found that the two known yeast MT depolymerases, Kip3 and Kar3, heavily contribute to the overall dynamic instability of MTs. However, through combining the cdc and depolymerase mutations, we have learned that these dynamics are ultimately limited by the cell cycle of the harvested yeast. Kar3 is especially interesting because its function and localization are controlled by mutually exclusive binding partners, Cik1 and Vik1. Past studies have alluded to differences in the function of these two complexes and our work has expanded to show very distinct activities exclusive to each.

**Behaviors of Microtubules and other Steady-State Polymers Depend on Multiple Critical Concentrations.**  
E.M. Jonasson¹, E.C. Norby¹, A.J. Mauro², S.M. Mahserejian³, M.S. Alber², H.V. Goodson¹;  
¹Chemistry and Biochemistry, University of Notre Dame, Notre Dame, IN, ²Applied Computational Mathematics Statistics, University of Notre Dame, Notre Dame, IN

The concept of critical concentration is a central idea in the understanding of microtubules and other steady-state (energy-utilizing) biological polymers. Classically, the critical concentration (CC) is the concentration of subunits necessary to obtain polymer. However, the classical theory used to explain and predict CC fails to account for dynamic instability or energy utilization. It is as yet unclear how the classical theory should be adjusted to incorporate dynamic instability or how the behavior of an individual dynamically unstable filament relates to that of its population.

To address these questions, we used our previously established simulations to follow at multiple scales the behavior of systems of computationally modeled dynamic microtubules (MTs). We show that polymers like MTs that exhibit dynamic instability have not one but at least two experimentally relevant critical concentrations: one above which individual filaments can grow transiently (CC\textsubscript{indgrow}), and another above which a population of filaments will grow steadily (CC\textsubscript{pogrow}). Normal steady-state dynamic instability occurs between these two CC values. Most experimental approaches to measuring critical concentration yield CC\textsubscript{pogrow}. A surprising implication of this revised understanding is that the stereotypical steady-state microtubule dynamic instability behavior occurs at tubulin concentrations below the value traditionally believed to be the lower limit required for polymer assembly. We propose that whether a steady-state polymer is like MTs and displays dynamic instability or is like actin and can be modeled as an equilibrium polymer depends on how far apart these two critical concentrations are.

While aspects of this framework conflict with common assumptions, it helps explain a range of otherwise confusing experimental observations.

Site-occupancy calibration of taxane pharmacology. J.J. Pineda¹, M.A. Miller², R. Weissleder³, T.J. Mitchison⁴; ¹Dept. Systems Biology, Harvard Medical School, Boston, MA, ²Center for Systems Biology, Mass General Hospital, Boston, MA

Taxanes and epothilones are important anti-cancer drugs whose tumor-regressing mechanisms are poorly understood. They bind to an overlapping site in the microtubule lumen and stabilize the lattice. In cells, this inhibits dynamic instability and promotes ectopic nucleation and bundling of microtubules. At low concentration, they disrupt chromosome segregation with minimal mitotic arrest, and at high concentrations they promote strong mitotic arrest. Most taxane-site pharmacology is based on measurement of empirical IC50 values, and is has been unclear what fraction of the microtubule lattice must be taxane-bound to cause different biological effects. We developed a method for measuring taxane site occupancy in living cells using competitive displacement of the SirTb fluorescent probe quantified by automated microscopy. We then measured different readouts of taxane activity as a function of site occupancy in RPE1 cells. Perturbation of plus end dynamics was first observed at relatively low site occupancy (<20%), micronucleation occurred over a broad range, and mitotic arrest required high (>80%) site occupancy. When dose-response data for 3 epothilones and paclitaxel were normalized to site occupancy, their effects were very similar. By comparison with intravital imaging data in a mouse tumor model we estimate that therapeutic efficacy of paclitaxel requires ~60% site occupancy shortly after drug administration. Our assay will be useful for structure-activity characterization during drug development. We speculate that efficient formation of micronuclei at intermediate site occupancy is an important cellular activity of taxanes with a central role in promoting tumor regression.

Mechanisms to localize and regulate katanin activity. G.M. Burkart¹, R.V. Dixit²; ¹Biology, Washington University in St.Louis, St. Louis, MO

The microtubule severing protein katanin, a heterodimer of a p60 catalytic subunit and a p80 regulatory subunit, regulates the organization and turnover of the microtubule cytoskeleton by the localized destruction of microtubule polymers. In higher plants, katanin activity is essential for the formation of linearly organized cortical microtubule arrays, which determine the axis of cell expansion. Live imaging studies have shown that even though p60 binds to the sidewalls of cortical microtubules, severing activity is restricted to microtubule crossover and nucleation sites. We have hypothesized that both targeting and protective mechanisms are needed to precisely localize katanin severing activity. We are using genetic and biochemical approaches to investigate whether p80 plays a role in targeting p60 to particular microtubule locations. There are four p80 orthologs in Arabidopsis thaliana, and we found that all interact with p60 with p80-4 consistently shows the strongest interaction in yeast-two-hybrid studies. In addition, we discovered that severing activity is regulated by phosphorylation of three serine residues in the N-terminal domain of p60. Mutating all three residues to aspartate to mimic phosphorylation completely inhibits severing activity in vitro, whereas single site phosphomimetic mutants did not alter severing activity compared to wild-type p60. Furthermore, mutating these residues to alanine did not alter severing activity of p60. Both the phosphomimetic and phosphonull
mutants of p60 interact normally with all four p80 subunits and we are currently investigating whether microtubule binding and/or ATPase activity is affected in these p60 mutants. Using in vitro severing assays, we found that the microtubule bundling protein MAP65-1, a plant homolog of human PRC1, is a potent inhibitor of katanin-mediated microtubule severing. At low MAP65-1 concentrations, severing is inhibited at bundled microtubule segments and the severing rate of non-bundled microtubules is reduced. At higher MAP65-1 concentrations, severing is nearly completely inhibited, even on non-bundled microtubules, thus providing a mechanism to protect the sidewalls of linearly ordered cortical microtubules against katanin attack. Our ongoing biochemical and cell biological experiments seek to determine whether inhibition of p60 by MAP65-1 requires microtubule bundling activity and whether it involves sterically blocking p60 binding to microtubules. Together, these experiments are advancing us toward our ultimate goal of reconstituting targeted microtubule severing in vitro.

Aurora B kinase modulates an extended conformation of lattice-bound Kinesin-13 MCAK.
T. McHugh¹, J. Zou¹, J. Rappsilber¹, A. Bertin², J.P. Welburn¹;
¹Wellcome Trust Centre for Cell Biology, University of Edinburgh, Edinburgh, United Kingdom, ²Institut Curie, Paris, France

Kinesin-13 motors regulate precise microtubule dynamics and limit microtubule length throughout metazoans. The Kinesin-13 MCAK is an unconventional kinesin, which depolymerizes microtubules ends. Recently, MCAK has been proposed to undergo large conformational changes during its catalytic cycle, as it switches from solution to bound state and during regulation by phosphorylation. However the nature of the structural changes and how they are coupled with MCAK depolymerization activity remain unclear. Here, we show that MCAK has a compact conformation in solution using crosslinking and electron microscopy. When MCAK is bound to the microtubule ends, it adopts an extended conformation with the N-terminus and neck region of MCAK interacting with the microtubule. Interestingly, the region of MCAK that interacts with the microtubule is the region phosphorylated by Aurora B and contains an EB-binding motif. Phosphorylation of this region decreases the affinity of MCAK for the lattice, which results in a decrease in microtubule depolymerase activity. Therefore the N-terminus of MCAK form a platform to integrate downstream Aurora B kinase signals and in response fine-tunes its depolymerase activity.

Monte Carlo simulations of the dynamic microtubule cytoskeleton: The critical roles of the cell boundary and rescue transitions in shaping the array.
J.C. Leung¹, L. Cassimeris¹, D.J. Odde²;
¹Biological Sciences, Lehigh University, Bethlehem, PA, ²Biomedical Engineering, University of Minnesota, Minneapolis, MN

The role of specific proteins that modulate dynamic instability and the molecular mechanisms responsible for tubulin polymerization have been extensively studied, and yet we currently lack a comprehensive method to explore how the combined parameters of dynamic instability function together to shape an entire array of microtubules, or how changes in dynamic parameters influence the array's organization over time and space. Here we describe a relatively simple Monte Carlo model to simulate a cell's microtubule array from parameters including the radius of the cell, total tubulin
concentration, microtubule nucleation rate from the centrosome, and plus end dynamic instability. The model does not simulate molecular mechanisms underlying these parameters, but is accurate in accounting for the amount of tubulin assembled into polymer. The model includes two possible cellular states, which allows the system to switch to a new parameter set (e.g. interphase to mitosis). Outputs from the simulation include the free tubulin concentration, average microtubule lengths, microtubule length distributions, and examples of individual microtubule length history over time. Using this platform and published parameters measured in interphase LLCPK1 epithelial cells, we find that differences in the frequency of rescue, where microtubule polymers switch from shortening to growth phases, made the largest contribution to microtubule number, average length and free tubulin concentration. Simulating the switch from interphase to prophase plus end dynamics demonstrated that the decreased rescue frequency at prophase was the critical factor needed to rapidly clear the cell of interphase microtubules prior to mitotic spindle assembly. Simulations also predict that lowering the total tubulin concentration by ~ 15 - 20% results in microtubule plus ends that are distributed across a wider area and not confined to the cell boundary, indicating that sequestering modest amounts of tubulin could reshape the distribution of microtubule ends across the cell radius. The model and simulations are useful for predicting changes to the entire microtubule array after modification to one or more parameters, including predicting the effects of tubulin-targeted chemotherapies.

Investigating the role of the GTP hydrolysis rate in regulation of microtubule stability.
V. Farmer¹, A. Rahman², M. Zanic¹²;
¹Department of Cell and Developmental Biology, Vanderbilt University, Nashville, TN, ²Department of Chemical and Biomolecular Engineering, Vanderbilt University, Nashville, TN

Dynamic instability of microtubules, the switching between phases of microtubule growth and shrinkage, enables the microtubule network to remodel throughout the cell cycle. A growing microtubule end incorporates GTP-bound beta-tubulin subunits, which are subsequently hydrolyzed, resulting in a microtubule lattice consisting of GDP-bound beta-tubulin. The growing end maintains a cap of GTP-tubulin, thought to protect the microtubule against transitions from growth to shrinkage (known as ‘microtubule catastrophe’). Recent in vitro studies found that microtubule tip-tracking protein EB1 is sensitive to the nucleotide state of tubulin in the microtubule lattice, and can therefore be used as a marker for the stabilizing nucleotide cap (‘GTP cap’). Fluorescent EB1 reveals that EB1 localization resembles a ‘comet’ shape, decorating the end of a growing microtubule, consistent with the expected shape of the GTP cap. The size of the GTP cap is defined by microtubule growth and GTP hydrolysis rates, and thus modulation of either of these parameters has the potential of producing a more or less stable microtubule. Indeed, increasing microtubule growth rate, as achieved by increasing tubulin concentration in vitro, results in a linear increase of EB1 comet lengths. At the same time, increase in tubulin concentration leads to a moderate suppression of microtubule catastrophe. Here, we aim to perturb the rate of GTP hydrolysis, using a number of agents that have been implicated in modulating the GTP hydrolysis rate of tubulin, including glycerol, magnesium, and phosphate analogues. We use an in vitro biochemical reconstitution assay with total internal reflection fluorescence (TIRF) microscopy to investigate the effect of these perturbations on both EB1 comet size, as well as the corresponding rates of microtubule catastrophe. Our goal is to elucidate how the properties of the GTP cap influence microtubule stability.

H⁺ and Na⁺ elicited rapid changes of the microtubule cytoskeleton in the biflagellated green alga Chlamydomonas.
Y. Liu¹, P. Yang¹;
¹Biological Sciences, Marquette University, Milwaukee, WI

Although microtubules are known for dynamic instability, the dynamicity is considered to be tightly controlled to support a variety of cellular processes. Yet diverse evidence suggests that this is not applicable to Chlamydomonas, a biflagellate fresh water green alga, but intense autofluorescence from photosynthesis pigments has hindered the investigation. By expressing a bright fluorescent reporter protein at the endogenous level, we demonstrate in real time discreet sweeping changes in algal microtubules elicited by rises of intracellular H⁺ and Na⁺. These results from this model organism with characteristics of animal and plant cells provide novel explanations regarding how pH may drive cellular processes; how plants may respond to, and perhaps sense stresses; and how organisms with a similar sensitive cytoskeleton may be susceptible to environmental changes.

¹38, Institute for advanced biosciences, Grenoble, France, ²38, Grenoble Institut des Neurosciences, Grenoble, France, ³14, Centre d’Etudes et de Recherche sur le Médicament de Normandie, Caen, France, ⁴69, Centre de recherches en Cancérologie de Lyon, Lyon, France, ⁵38, Cellipse, Grenoble, France

Microtubule stabilization by chemotherapy is a powerful weapon in the war against cancer. Paclitaxel (PTX) has been used successfully for the treatment of solid tumors for decades. Several features, including side-effects and resistance of some cancers make this drug, although very useful, not always effective. The search for next generation microtubule stabilizing drugs with increased efficacy as well as for drugs sensitizing cancer cells to PTX is still intense.

With the aim to identify new chemical compounds that sensitizes cell to paclitaxel we screened a library of 8,000 compounds, to select those not toxic for cell cultures when applied alone, that became toxic when applied in combination with a non-toxic dose of paclitaxel.

This cytotoxicity screening, was performed in parallel on cells treated with the compounds alone and matched cells treated with a non-toxic low dose of PTX. Such an approach, using a combination of chemicals is conceptually similar to the screens based on synthetic lethality, but replacing the genetic perturbation by a chemical perturbation (PTX).

Among compounds active on cellular microtubule, we focused on a carbazole derivative the "T4" molecule. When applied in conjunction with PTX, a non-toxic dose of T4 with no effect on cell proliferation decreased by 2.5 fold the GI50 (50% of growth inhibition) of PTX.

To gain insight in the perturbation produced by T4 we studied its effect on microtubule dynamics and cell cycle. We were able to show that T4 slows down microtubule dynamics. This effect was enhanced when T4 was applied in conjunction with a non-toxic dose of PTX. Toxic doses of T4 blocks cells in mitosis before a complete metaphase and induces abnormal mitotic spindles with chromosomes...
Synergy, growing function promotes MMP14 trafficking, and is associated with MMP14 activity at focal adhesions.

A. Braun¹, K.A. Myers¹;
¹Biological Sciences, University of the Sciences in Philadelphia, Philadelphia, PA

Angiogenesis is a process by which new vasculature forms from existing vessels, using cues from the extracellular matrix (ECM) to stimulate endothelial cells (ECs) to extend branches, polarize, and migrate. Microtubules (MT) are polymers of the protein tubulin that undergo bouts of polymerization and depolymerization, a process termed dynamic instability. In addition to their structural role in defining EC morphology, MTs also function as an intracellular roadway along which molecular motor proteins traffic cargo. One major group of cargo trafficked along MTs are matrix metalloproteases (MMPs), which function to guide EC migration by locally degrading the ECM to promote directional cell movement. MMP14 is a unique metalloprotease that is membrane-bound and has been implicated in cell invasion in cancers. However, it is not known if, or how, MMP14 trafficking and localization is spatially regulated by MT dynamics. Additionally, MMP14 is known to localize to focal adhesions (FA), however it is not known how ECM density affects FA organization and MMP14 activity. We hypothesized that MMP14 trafficking to the cell surface would be increased in regions of the cell where MT growth is enriched. Further, we hypothesized that MT growth would be locally enriched near FAs, on ECMs that promote an increase in FA number. To test this hypothesis, ECs were cultured in low, intermediate, or high-density 3D collagen ECMs, and live-cell imaging of fluorescent MMP14 and EB3, a marker of MT growth, was performed. Experiments revealed that MMP14 was bi-directionally transported along MTs within cytoplasmic vesicles, and this was inhibited by nocodazole or paclitaxel, suggesting that MT dynamics are required for MMP14 trafficking. Additionally, EC engagement of intermediate density ECMs promoted increased MT growth speed and growth lifetime as well as enhanced MMP14 transport velocity. To monitor MMP14 function in living ECs, we developed a biosensor capable of measuring MMP14 activity with spatio-temporal specificity. MMP14 biosensor data showed that MMP14 activity is spatially restricted to the leading edge and within branched protrusions, where MMP14 activity appears co-localized with growing MT plus-ends. Biosensor data also revealed that active MMP14 was detected as discrete puncta localized at or directly adjacent to FAs, suggesting that MMP14 activity is influenced by proximity to FAs. Taken together, these data identify that EC engagement of intermediate density collagen ECMs promotes fast and long-lived MT assembly and increased MMP14 transport to regions of the cell where FAs are found. Ongoing studies are focused on investigating how MT and FA dynamics communicate to control MMP14 activity, and the consequences for ECM degradation and directional EC migration.

Analysis of Cytoskeletal Filament Bending via Curvature.
P. Wisanpitayakorn, K.J. Mickolajczyk, W.O. Hancock, L. Vidali, E. Tuzel;
1Physics, Worcester Polytechnic Institute, Worcester, MA, 2Biomedical Engineering, Pennsylvania State University, University Park, PA, 3Biology and Biotechnology, Worcester Polytechnic Institute, Worcester, MA

Cytoskeletal filaments such as microtubules and actin filaments play important roles in mechanical signal transduction allowing cells to respond to their environment. Measuring the mechanical properties of cytoskeletal structures is crucial for gaining insight into intracellular mechanical stresses and their role in regulating cellular processes. One of the ways to characterize such bio-filaments is by measuring their persistence length, the average length over which filaments stay straight. Here, we show how curvature distributions can be used as a tool to quantify bio-filament deformations, and investigate how the apparent stiffness of filaments depends on the resolution and noise of the imaging system. We present analytical calculations of the scaling curvature distributions as a function of filament discretization, and test our predictions by comparing Monte Carlo simulations to results from Fourier and tangent correlation analysis. We also apply our approach to microtubules and actin filaments obtained from in vitro gliding assay experiments with high densities of non-functional motors. Finally, the effect of motor density on the curvature of the filaments is tested with Brownian dynamics simulations to confirm the accuracy of experimental results. We discuss how curvature analysis improves accuracy of filament bending characterization in vivo, and provide a freely available easy-to-use ImageJ Plugin.

Multiple Functions of the Striated Rootlet Proteins of the Paramecium Basal Body.
M. Nabi, M.S. Valentine, J. Yano, J. Van Houten;
1Biology, University of Vermont, Burlington, VT

Paramecium ciliary basal bodies align in straight rows from posterior to anterior. Each basal body is connected to three rootlets (Post Ciliary, Transverse and Striated (SR)). The SR, the longest, projects from the basal body toward the anterior past several more anterior basal bodies. We previously found that the depletion of Meckelin (MKS3) misaligns SRs, disorganizes basal body rows (Picariello et al., 2014) and makes the SRs appear ragged and serpentine. In our study of the connection of MKS3 to the SR, we found that depletion of some SR proteins by RNA interference (RNAi) produced similar basal body mis-alignments. Therefore, we examined genes and proteins of the SR. The SR of Chlamydomonas is the best studied. Using the single SR Chlamydomonas gene SF Assemblin to search, we found thirty Paramecium genes in 13 paralog groups with one to eight genes in each. Proteins from 12 paralog groups were confirmed to be in the SR structure using immunofluorescence. MS analyses of density fractions from SR isolation show all 30 SR members are within the same density fraction as intact SRs. Cells were treated with RNAi for each paralog group; groups with more than one member were treated with RNAi to silence all the group members concurrently. We grouped the SR genes: 1, 2-6, 7-8-10, 11-13. Depletion of some individual SRs (e.g. 1, 3, 9) and groups (2-6; 8-10 and 11-13) showed distortions
of the basal body rows and misalignment of the SRs. Others showed a normal phenotype. Interestingly, RNAi for 8, 9 or 10 alone did not show a phenotype, but when all three groups within the larger group were targeted, there was a strong phenotype. Others like 1 or 7 with two genes in their paralog groups showed extreme phenotypes when reduced by RNAi. Isolated SRs show a striated pattern that matches that of Hufnagel et al., 1969. SRs from RNAi treated cells for SR 2, 3 or 4 are of control length and periodicity. RNAi for others (SR 1, 4 or 7) caused abnormal shapes and periodicity. There is a correlation between the RNAi SR surface misalignment phenotype and the isolated SR RNAi phenotype for shape and periodicity of the SR. Perhaps when lacking specific SR proteins, the rest fail to interact properly with each other through heptad repeats of coiled coil domains to maintain the rootlet structure and directionality toward the anterior.

The generation and sensation of fluid flow by cells: roles in development and disease.
D.T. Grimes1, R.D. Burdine3;
1Molecular Biology, Princeton University, Princeton, NJ

Like classical signal transduction cascades, the microscopic flow of fluids within biological systems provides cues critical for development, growth, and homeostasis. Organisms are permeated with networks of fluid-filled tubes while embryos contain cavities within which flows convey patterning information. Flows are critical for kidney morphogenesis, heart and vascular development, the migration of neurons, and the establishment of left-right asymmetry. However, we know very little about how flows are generated and sensed by cells. This remains a pressing concern given the increasing number of diseases associated with flow abnormalities including structural birth defects, polycystic kidney disease, heart disease, and cancer progression. Cilia, microtubule-based organelles that project from the cell surface, are central players in fluid biology. Motile cilia on specialized cells beat to generate fluid flow across epithelial sheets, while primary cilia, which are found on nearly all vertebrate cells, respond to external cues including flow forces.
We use forward and reverse genetics, as well as a range of cell biological approaches, in zebrafish to interrogate the mechanisms of flow generation and sensation by cells and the roles of these processes in development and disease. I will first report data which demonstrates a molecular link between the pathways that control cilia motility, cilia polarization, and the planar cell polarity of multi-ciliated cells centering on the human disease-associated protein C21ORF59.
Next, I will discuss our recent work that demonstrates a requirement for cilia motility in the brain/spine of zebrafish in maintaining spine straightness during growth. We used a thermogenetic approach to modulate protein function at distinct developmental times which identified a critical window when cilia motility is required for spine maintenance. Absence of cilia motility during this window results in the development of severe spinal curves. We are currently systematically ablating distinct cell populations within the brain and spine to ascertain which motile ciliated cells are involved in preventing spinal curves.
Our zebrafish work has led us to hypothesize a novel cell biological mechanism to explain the human disease Idiopathic Scoliosis (IS), a common spinal curvature that impacts up to 3% of the world's children. I will discuss the implications of our zebrafish data in the context of IS and suggest potential avenues for future work and disease treatments.

Biophysical interactions between cilia and mucus underlie directed fluid transport in the ventral epithelium of the planaria Schmidtea mediterranea.
G.R. Ramirez-SanJuan1,2, W.F. Marshall1, M. Prakash2;
1Biochemistry and Biophysics, University of California San Francisco, San Francisco, CA, 2Bioengineering, Stanford University, Stanford, CA

Directional flow is required for physiology and development of many organ systems; ranging from the respiratory tract, where flows are responsible for mucus clearance, to the brain, where they transport cerebrospinal fluid. Ciliated epithelia organize spatio-temporally, across different scales, to produce these large scale fluid flows. Here we use the planaria Schmidtea mediterranea as a model system to study how interactions between cilia and the extra-cellular environment, give rise to large scale fluid flows. Planarians secrete mucus and glide over this layer using motile cilia that move the mucus over a less dense periciliary layer (PCL). Using live imaging and techniques from fluid mechanics we characterize the dynamics of this system at different scales, ranging from individual cilia to tissue-scale mucus flows. We observe that only a subset of the cilia in the epithelium are required to be active during planaria gliding motility. This subset changes as the worm crawls and impacts the direction of overall motility and the surrounding fluid flow. Similarly, changes to the properties of the mucus influence the speed of the surrounding flow, ciliary and worm motility. Our results indicate that the ability to achieve directional flows depends both on cilia and the surrounding fluid. Studying cilia and mucus as a unit, with a focus on describing the biophysical properties that control mucus flow at a tissue scale, will provide a holistic understanding of how individual components integrate in ciliated epithelia to achieve directed fluid transport.

FBB18, a homologue of C21orf59, regulates cytoplasmic preassembly of outer and inner dynein arms in Chlamydomonas.
L. Wang1, G. Liu1, J. Pan1,2;
1MOE Key Laboratory of Protein Sciences, Tsinghua-Peking Center for Life Sciences, School of Life Sciences, Tsinghua University, Beijing, China, 2Laboratory for Marine Biology and Biotechnology, Qingdao National Laboratory for Marine Science and Technology, Qingdao, China

Dynein arms were preassembled in the cytoplasm, transported into cilia by intraflagellar transport, and docked onto specific sites on the doublet microtubules. Assembly factors are needed to assist stability and preassembly of dynein arm subunits into a functional complex. Knockdown of C21orf59 in zebrafish and planaria induces loss of outer dynein arms. C21orf59 mutations cause primary cilia dyskinesia in human. However, whether C21orf59 functions in the motile cilia or in the cytoplasm is not clear. Furthermore, the molecular mechanism of C21orf59 is not known. Here, we show that Chlamydomonas homologue of C21orf59, FBB18, is a preassembly factor for both outer and inner dynein arms (ODAs and IDAs). Most cells of a null mutant of FBB18 exhibited no or very short flagella of 2-4 mm long. ODAs and IDAs were partially or complete lost in the mutant cells shown by electron microscopy. This data is consistent with the immunoblotting results from the mutant flagellar samples, where outer arm dyneins DHCa and DHCb, and inner arm dyneins dynein b, c and d were not detected or greatly reduced. In the cytoplasm, these proteins were barely detectable. These data suggest that FBB18 is involved in preassembly and stability of the dynein arms in the cytoplasm. Deletion of the N-terminal coiled-coil
domain or the C-terminal sequence that contains a DUF2870 domain generated similar phenotype as the null mutants. Interestingly, deletion of the C-terminal 252-277 amino acids that mimics a truncation mutation in a human patient restored the flagellar length but not motility. Compared to DHCb, dynein c and e, DHCa and dynein b were lost in the flagella as well as in the cell body. DHCa, dynein b and c were co-immunoprecipitated with FBB18. These data suggest that FBB18 forms a large complex with subunits of dynein arm and involved in stability and preassembly of the dynein arms (This work was supported by the the National Natural Science Foundation of China (31330044, and 31671387) and Sino-German Science Center (GZ990) to JP).

Repetitive buckling of microtubules driven by axonemal dynein arrays reconstituted on a microtubule.
M. Shiraga, Y. Matsuda, J. Kirima, K. Oiwa;
1Graduate School of Life Science, University of Hyogo, Harima, Japan, 2Advanced ICT Research Institute, National Institute of Information and Communications Technology, Kobe, Japan

The complexity of the eukaryotic flagellar axoneme is derived from 200-600 types of modular building blocks assembled hierarchically. Nine doublet microtubules surround a pair of singlet microtubules. On each of nine doublet microtubules cyclically arrayed in an axoneme, dyneins are aligned in two rows, outer- and inner-arm dyneins. Each of the heavy chains is reported to have different mechanical properties. They are precisely arranged along doublet microtubules and regulated in a coordinated fashion to produce periodic flagellar beating. The coordination among these building block under strict spatio-temporal regulation makes flagella beat in an organized manner. To reveal the mechanism of coordination and regulation, we have carried out in vitro reconstitution of axonemal structures in a bottom-up manner and have compared mechanical properties of the reconstituted axonemes with those of intact ones. Tubulins were polymerized into microtubules from fragmented axonemes working as seeds. To these microtubule bundles with the same polarity, we added crude outer-arm dynein extract from Chlamydomonas axonemes. These dynein arms formed regular arrays (24nm-repeat) on the microtubules in a self-organized manner and made stiff microtubules bundles. On addition of ATP, a pair of microtubules occasionally displayed association and dissociation cycles. The repetitive buckling lasted a few minutes and the frequency of each buckling ranged from 1 to 3 Hz in the presence of 1 mM ATP. Occasionally, we found the microtubule bundles with both ends of the bundle were clamped. In these bundles, when the shear between microtubules at the middle part occurred, the microtubules were looped out and formed characteristic S-shaped bending and then recoiled. Force generated at the middle part was estimated using Euler formula to be ca. 1 pN per dynein arm. These cyclic interactions between dynein and microtubules were derived from the intrinsic nature of dyneins and were probably regulated by the degree of microtubule bending. These features could be the essence of the beating mechanism working in an axoneme. This work was supported by Grant-in-Aids for Scientific Research (C), the Japan Society for the Promotion of Science (JSPS, grant numbers 26440089 and 17K07376 to K.O.), and the Takeda Science Foundation (K.O.).

Conserved complexes regulating ciliary motility and waveform asymmetry.
K.R. Augspurger¹, J. Sakizadeh¹, J.T. Reck², R. Bower¹, D. Tritscher³, G. Fu³, D. Nicastro³, M.E. Porter¹;
¹Genetics, Cell Biology, and Development, University of Minnesota Medical School, Minneapolis, MN;
²Cell Biology and Biophysics, University of Texas Southwestern Medical Center, Dallas, TX.

Ciliary motility requires the coordination of multiple axonemal dyneins by regulatory complexes located within the 96 nm axoneme repeat, but little is known about the polypeptides that alter the waveform in response to internal or external stimuli. Several mutations have been identified in *Chlamydomonas* that alter flagellar motility, including some that convert the waveform from an asymmetric, ciliary type stroke to a symmetric, flagellar type stroke. Many motility mutations affect well-known axonemal structures such as the outer and inner dynein arms, central pair microtubules, radial spokes, and regulatory complexes located at the base of radial spokes (e.g., Heuser et al., 2009, 2012a, b). These structures are also highly interconnected (Nicastro et al., 2006; Heuser et al., 2012a, b). However, the polypeptides identified thus far represent less than half of the axonemal proteome. In addition, cryo-electron tomography (cryoET) has revealed the presence of several uncharacterized substructures in the 96 nm axoneme repeat. We are using improved proteomic approaches to reanalyze several motility mutants to identify polypeptides associated with these less-explored substructures and to probe their role in the regulation of motility. The *mbo* (move backwards only) mutants were first identified as cells that are unable to swim forwards with an asymmetric waveform, even when calcium is reduced below micromolar levels (Segal et al., 1985). Instead *mbo* mutants swim backwards using a symmetric waveform, similar to the photoshock response of wild-type cells triggered by a transient increase in intraflagellar calcium. iTRAQ based proteomics has identified a subset of ~19 polypeptides that are missing or reduced in different *mbo* mutants, including one inner arm dynein. Eleven polypeptides are algal specific, but eight are conserved in other species with motile cilia and flagella. Most MBO-associated polypeptides contain coiled coil domains, but three contain EF-hand or IQ motifs potentially involved in calcium/calmodulin binding. CryoET of *mbo2* mutant and *MBO2-SNAP*-tagged axonemes has revealed defects in a novel structure located within the 96 nm axoneme repeat. The further characterization of regulatory components in *Chlamydomonas* should provide insight into new regulators and the function of related proteins in other species and potentially identify new loci involved in primary ciliary dyskinesia (supported by NIH grants to M.E. Porter and D. Nicastro).

Comparative proteomics reveals candidates for novel ciliary central apparatus components.
L. Zhao¹, Y. Hou¹, T. Picariello¹, B. Craige¹, G.B. Witman¹;
¹Division of Cell Biology and Imaging, Department of Radiology, University of Massachusetts Medical School, Worcester, MA.

Normal ciliary and flagellar motility requires the integrity of the “9 + 2” axoneme, which is composed of 9 outer doublet microtubules with associated structures and a central apparatus (CA) consisting of two microtubules plus projections. To date, 22 proteins have been characterized as components of the CA, of which 19 are specific to the CA. However, cryo-EM analysis has revealed that the CA has a highly complex architecture, and it is likely that it contains many more proteins than have been localized to it. In an effort to identify novel CA components, we have compared the proteomes of isolated *Chlamydomonas* wild-type axonemes with that of the CA-less mutant pf18 by label-free quantitative proteomics. Comparative analysis reveals novel candidates for novel CA components, including a calcium/calmodulin-binding module. These findings provide new insights into the structure and function of ciliary and flagellar CA.
mass spectrometry. In two independent experiments, we identified a total of about 1100 proteins. Nearly all known subunits of the inner and outer dynein arms and radial spokes were identified and found to be present in a 1:1 ratio in the two proteomes, indicating that the approach detected most axonemal proteins and accurately reported their relative amounts in the two proteomes. 21 of 22 known intraflagellar transport (IFT) particle proteins were identified and found to be elevated 10-100X in the pf18 axonemes, consistent with the previously reported trapping of IFT particles in the lumen of CA-less mutants. In contrast, all 19 of the previously known CA-specific proteins were greatly reduced in the mutant proteome. Of uncharacterized proteins present in the wild-type proteome in amounts comparable to the known CA proteins, 54 were greatly reduced in the mutant proteome; these are good candidates for being CA components. Seventeen of these are highly conserved in humans. We have selected six of the conserved proteins for characterization by mutant analysis, super-resolution light microscopy, thin-section EM, and immuno-gold EM to confirm their location in the CA and to determine how their loss affects flagellar motility and axonemal structure. A more complete knowledge of the ensemble of CA components will be an important step toward understanding how the CA performs its essential functions in motile cilia and flagella. Moreover, the human genes encoding CA proteins are likely to cause primary ciliary dyskinesia when mutated, but patients would be expected to have normal situs solitus because nodal cilia, which initiate left-right asymmetry, lack the CA and thus would be unaffected. The availability of additional candidate genes will facilitate identification and diagnosis of such patients.

Antioxidant treatment prevents alcohol-induced ciliary dysfunction in Chlamydomonas reinhardtii.
C. Scarbrough1, M. Wirschell1;
1Biochemistry, University of Mississippi Medical Center, Jackson, MS

Excessive alcohol consumption has been shown to result in pulmonary dysfunction, in part, by compromising the motility of cilia in the upper airway that are critical for mucociliary clearance. The ciliary slowing effect of alcohol has been termed “Alcohol-Induced Ciliary Dysfunction” (AICD). We have previously demonstrated that AICD is conserved from mammals to the powerful model protist, Chlamydomonas reinhardtii (Yang et al., 2015). We determined that alcohol exposure reduces the activity of the outer dynein arm motors and, for the first time, identified specific ciliary proteins that show altered phosphorylation in response to alcohol. In mammalian models, AICD involves the generation of reactive oxygen and nitrogen species (ROS/RNS) and antioxidant treatment prevents AICD (Simet et al., 2013). However, the specific downstream targets that are modified by alcohol-induced changes in redox potential are unknown. Here, we demonstrate that antioxidant treatment prevents AICD in Chlamydomonas cells demonstrating that the protective role of antioxidants in AICD is conserved. Pretreatment of Chlamydomonas cells with two antioxidant compounds, N-acetylcysteine and Tempol, prevents the reduction in swimming speed induced by alcohol exposure. Of interest, Wakabayashi and King reported that altering redox conditions results in changes in ciliary beat frequencies, mediated by the ODA, which correlates with changes in protein-protein interactions of two ODA light chains and one ODA-docking complex subunit via mixed disulfides (Wakabayashi and King, 2006). How these changes ultimately alter ciliary beat frequencies is unclear, and the specific downstream targets of alcohol that are modified by ROS/RNS have yet to be identified. We will continue to utilize the exceptional experimental advantages of Chlamydomonas to determine if alcohol
exposure induces nitro-oxidative stress that targets redox-sensitive proteins that control outer dynein arm activity.

EFHC1 and EFHC2 are necessary for motile cilia function and A-tubule MIP recruitment.
B.A. Bayless,1 D. Stoddard,2,3 Y. Zhao,4 J. Gaertig,5 D. Nicastro,2,3, M. Winey1;
1Molecular and Cellular Biology, University of California, Davis, Davis, CA, 2Biology, Brandeis University, Waltham, MA, 3Cell Biology and Biophysics, University of Texas Southwestern Medical Center, Dallas, TX, 4Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO, 5Cellular Biology, University of Georgia, Athens, GA

Motile cilia are essential cellular structures that beat to move extracellular fluid in a unified direction. Disruption of ciliary beating has dire consequences on a number of essential processes including the generation of cerebral spinal fluid movement, mucus clearance from the lungs and movement of the egg down the fallopian tube during ovulation. The structural organization of thousands of motor proteins and regulators along a microtubule-based scaffold is critical for the function of motile cilia. They are composed of nine sets of modified doublet microtubules arranged radially around a central pair of microtubules. Ciliary doublet microtubules are unique in that they are extremely stable and resistant to the mechanical forces associated with ciliary beating. Recent advances in cryo-electron tomography have made it possible to map the structure of doublet microtubules with molecular resolution. We now know that there are a number of densities on the luminal surfaces of the doublet microtubules termed Microtubule Inner Proteins (MIPs), however, their composition and function remain unexplored. We have identified the role of two proteins, EFHC1 and EFHC2, in motile cilia function and MIP formation. We find that Tetrahymena thermophila homologs of EFHC1 and EFHC2, Bbc73 and Bbc60, respectively, localize to the doublet microtubules of both basal bodies and cilia. Strains with single or double null alleles of Bbc73 and Bbc60 exhibit motile cilia beating and assembly defects. Interestingly, when axonemes are visualized using cryo-electron tomography, knockout of either Bbc73 or Bbc60 results in independent loss of a number of A-tubule MIPs. Furthermore, we find that introduction of Bbc60-GFP into Bbc60 knockout cells rescues the loss of MIPs associated with Bbc60 absence and imparts and extra density in the region of MIP4. We hypothesize that this extra density corresponds to the additional density of the GFP tag on Bbc60 and represents the first evidence of the identification of a MIP protein. To identify other MIPs associated with EFHC proteins we used mass spectrometry to identify axoneme proteins lost in EFHC mutant Tetrahymena cells. CAPS was identified as a potential MIP protein and Tetrahymena cells that are heterozygous for CAPS show swimming defects that are consistent with deficiencies of motile cilia beating. Overall, our data reveal a major role for EFHC proteins in the function of motile cilia through the recruitment of a complex network of MIPs to the A-tubule of doublet microtubules.

FMG-1B glycoprotein is necessary for expression of force at the Chlamydomonas flagellar surface.
R.D. Sloboda¹, M. Sa-eed¹, R.A. Bloodgood²;
¹Biological Sciences, Dartmouth College, Hanover, NH, ²Cell Biology, University of Virginia School of Medicine, Charlottesville, VA

When there is insufficient water to allow swimming via flagellar beating, Chlamydomonas cells initiate an alternative form of motility in which cells glide along a surface in a flagella-dependent manner. Bidirectional movements of microspheres along the flagellar surface are thought to be a proxy for gliding motility and thus can be used to reveal the activity of the motor used for gliding motility. While flagellar beating requires outer doublet-associated axonemal dynein, force transduction for gliding motility and microsphere movement is dependent upon Intraflagellar Transport (IFT) and cytoplasmic dynein 1b/2 (Shih et al. 2013). An extensive literature (mostly from the Bloodgood lab) provides circumstantial evidence that the mechanical coupling of the intraflagellar force transduction machinery to the surface of a microsphere or a planar substrate for gliding is mediated by the transmembrane glycoprotein FMG-1B, which comprises most of the protein of the flagellar membrane. Using strains obtained from the Chlamydomonas Library Project (CLiP; https://www.chlamylibrary.org/) having insertions in the 5’ or 3’ UTRs of FMG-1B, we have demonstrated that FMG-1B is required for microsphere movement. First, we determined that strains containing an insertion in the 5’ UTR, but not the 3’UTR, fail to synthesize FMG-1B, consistent with disruption of ribosome binding due to an insertion in the 5’ UTR. Immunoblot analysis of whole flagella showed no detectable FMG-1B in the 5’-UTR mutant, while the 3’UTR mutant expressed WT levels of FMG-1B. Second, immunofluorescence microscopy showed a reduction in flagellar staining in the 5’-UTR mutant relative to the 3’UTR mutant and WT strains. Third, TEM analysis of the mutant lacking FMG-1B showed a dramatic reduction of the prominent glycocalyx normally observed on the flagellar surface suggesting that this glycocalyx is composed of the large ectodomain of FMG-1B; the 3’UTR mutant had a WT appearance. All three strains had normal length flagella, suggesting that FMG-1B is not necessary for flagellar membrane assembly or flagellar stability despite contributing most of the protein in the flagellar membrane. Importantly, microsphere motility was greatly reduced in the 5’UTR mutant, demonstrating that FMG-1B is necessary for the expression of force at the flagellar surface. We are currently assessing the precise position of the insertions in these mutant strains, as the data from CLiP on the position of the insertions are provided with only 75% accuracy. We are also in the process of assessing the effect of these mutations on gliding motility.

Exploring the role of FoxJ1 transcription factor in a new species of planarian “Dugesia guanajuatiensis”.
C. Guerrero-Hernández¹, E.M. Duncan¹, S.H. Nowotarski¹, V. Doddihal¹, L. Guo¹, E. Ross¹, A. Sánchez Alvarado¹,²;
¹Stowers Institute for Medical Research, Kansas City, MO, ²Howard Hughes Medical Institute, Kansas City, MO

Cilia are cell surface associated, microtubule-based, filamentous organelles with wide spread distribution among protozoans and most metazoan phyla. The transcription factor FoxJ1(DNA-binding
forkhead) is the master regulator of motile cilia. Here, we focus on the diploid mexican planarian, *Dugesia guanajauiensis* (*Dgua*), and the role *Dgua* - *Foxj1* plays in the function of its cilia. In stark contrast to other planarian species, *Dgua* consistently moves by peristaltic waves of whole body contractions or inchworming rather than a canonical gliding motion. *In situ* hybridization showed that *Dgua-foxj1* is widely expressed in the ventral and dorsal motile ciliated cells, and is also expressed in the pharynx, auricles and in the brain. Immunofluorescence and scanning electron microscopy revealed that *Dgua* has patchy cilia on its ventral epithelium, whereas a naturally gliding species, *Schmidtea mediterranea*, has a complete lawn of cilia. We examined the role of *Dgua-foxj1* in the function of ventral cilia by RNAi and treated animals experienced a further loss of motility. Contributions of *Dgua-foxj1* to the maintenance of cilia will be discussed.

A phase separated organelle for dynein arm assembly in ciliated cells.

R.L. Huizar\(^1\), C. Lee\(^1\), J.B. Wallingford\(^1\);

\(^1\)Department of Molecular Biosciences, University of Texas at Austin, Austin, TX

Motile cilia are responsible for a multitude of functions in the human body, including mucociliary clearance in the lung, cerebrospinal fluid circulation in ventricles, gamete propulsion, and laterality determination during early development. The wavelike motion of cilia is the result of dynein arm complexes that exert force to bend microtubules within cilia through coordination of multiple motor protein subunits. The cytoplasmic preassembly and stabilization of these dynein arms has been shown to involve a group of proteins known as axonemal dynein assembly factors (DNAAAFs) working in conjunction with chaperone machinery to fold and complex subunits prior to ciliary transport and docking. However, the mechanism by which this process occurs remains unclear. Here, we describe that many known DNAAAFs colocalize with one another at in multiciliated cell-specific cytosolic granules, which we term DynAPs (Dynein Assembly Particles). DynAPs display compositional similarity to known liquid-liquid phase separated organelles, including enrichment of stress granule components. Physical properties of DynAPs are akin to those observed in other cytoplasmic phase separated organelles, including fusion and rapid exchange of material with the cytosol. Further, we demonstrate that human disease-related molecular changes in DNAAAFs are associated with alteration of these physical properties and lead to downstream defects in dynein assembly and ciliary beating.

Altered centrosomal trafficking disrupts cilia assembly and signal transduction in Down syndrome.

D.F. Galati\(^1,2\), A.T. Pham\(^1,2\), K.D. Sullivan\(^2,3\), J. Espinosa\(^2,3\), C.G. Pearson\(^1,2\);

\(^1\)Cell and Developmental Biology, University of Colorado-Anschutz Medical Campus, Aurora, CO, \(^2\)Linda Crnic Institute for Down Syndrome, University of Colorado-Anschutz Medical Campus, Aurora, CO, \(^3\)Pharmacology, University of Colorado-Anschutz Medical Campus, Aurora, CO

Ciliopathies share substantial phenotypic overlap with Down syndrome (DS; trisomy 21), including the presence of congenital heart defects, craniofacial abnormalities and altered cerebellar development. Whether these similarities result from cilia defects in DS cells is not known. To begin to address this...
possibility, we investigated cilia formation and ciliary signaling in DS cells. Trisomy 21 increases the expression of the chromosome 21 gene Pericentrin. At normal expression levels, Pericentrin localizes ciliary assembly and signaling proteins to the centrosome via a trafficking network that traverses cytoplasmic microtubules. In DS, excess Pericentrin disrupts the spatial organization of this ciliary trafficking network. This is because excess Pericentrin increases gamma-tubulin levels at the centrosome, which causes increased and disorganized cytoplasmic microtubules. In turn, the altered microtubule network disrupts dynamic Pericentrin trafficking events to and from the centrosome. Pericentrin is required to localize the cilia assembly factor, IFT20, to the centrosome for eventual loading into the ciliary compartment. In DS, Pericentrin trafficking defects reduce the centrosomal level of IFT20, which, ultimately, decreases cilia formation. When cilia do form in the presence of excess Pericentrin, they do not properly transduce Sonic hedgehog (Shh). These results demonstrate that increased gene dosage of ciliary trafficking proteins disrupts the dynamic recruitment of ciliary assembly and signaling proteins. We propose that altered ciliary trafficking is a potential disease mechanism that may contribute to ciliopathy-like phenotypes in Down syndrome and other aneuploid disorders.

Cardiac valve abnormalities in PKD are due to defects in ciliogenesis, and ciliogenic programs involving the exocyst are conserved across organs.
D.B. Fulmer1,2, B. Fogelgren3, K.A. Toomer4, L. Guo4, R.A. Norris5, J.H. Lipschutz1,6;
1Department of Medicine, Medical University of South Carolina, Charleston, SC, 2Department of Regenerative Medicine and Cell Biology, Medical University of South Carolina, Charleston, SC, 3Department of Anatomy, Biochemistry, and Physiology, University of Hawaii at Manoa, Honolulu, HI, 4Ralph H. Johnson VAMC, Charleston, SC

Cardiac valve abnormalities are associated with polycystic kidney diseases including: ADPKD, Joubert and Meckel’s syndromes. Our recent work showed that primary cilia are present on developing cardiac valves, but are reduced in adulthood, and that normal valve development requires functional cilia. Mutations in members of the highly-conserved eight protein exocyst complex result in Joubert and Meckel’s syndromes. We previously showed in Madin Darby canine kidney (MDCK) cells that shRNA-induced knockdown of Exoc5, a central exocyst component, inhibited ciliogenesis, led to increased cell proliferation, and resulted in low intracellular calcium levels that did not increase in response to fluid flow. Cell polarity was not grossly affected. Exoc5 overexpression in MDCK cells resulted in longer cilia, with normal intracellular calcium levels that showed an enhanced response to fluid flow. The exocyst appears to be necessary for ciliogenesis by trafficking vesicles from the Trans-Golgi network carrying ciliary proteins such as polycystin-2. We showed in zebrafish that exoc5 knockdown, with antisense morpholinos, resulted in altered ciliogenesis, nephrogenesis, and cardiac edema. We recently generated Exoc5+/− mice, and kidney-specific knockout of Exoc5 resulted in a nephropathosis phenotype in mice surviving to 30 days. We also showed that Cdc42 localizes the exocyst to the nascent cilium, and that Cdc42 and the exocyst genetically interact in zebrafish. We generated Cdc42 kidney-specific knockout mice, which also resulted in a nephropathosis phenotype. Here, we report that homozygous mutation of exoc5 in zebrafish leads to a non-functional protein and reproduces the morphant phenotype, with defects that include cardiac edema and severe cardiac valvular stenosis. Rescue of exoc5 mutants with human EXOC5 mRNA reverses the phenotype. In exoc5 mutant zebrafish, the Hippo pathway is turned on with significantly higher levels of active Mob1. The Hippo pathway has previously been linked, by us and others, to PKD. In mice, cardiac valve specific knockout of Exoc5, using a Nfatc1 driver line, leads to bicuspid aortic valve disease that is highly penetrant. In summary, cardiac
valvulogenesis is dependent on normal ciliogenesis, and ciliogenesis in cardiac valves, in turn, is dependent on the exocyst. These data show that ciliogenic programs are conserved across organs and species, which helps explain the association of ciliogenic abnormalities and PKD. In addition, these animal models may be useful for testing therapeutic compounds.

Two-Color STORM Reveals that Disruption of Ciliary Transition Zone Architecture Causes Joubert Syndrome.

X. Shi1, G. Garcia2,3, J.F. Reiter2,3, B. Huang1,3;  
1Pharmaceutical Chemistry, University of California - San Francisco, San Francisco, CA, 2Cardiovascular Research Institute, University of California - San Francisco, San Francisco, CA, 3Biochemistry and Biophysics, University of California - San Francisco, San Francisco, CA

Diverse human ciliopathies, including nephronophthisis (NPHP), Meckel syndrome (MKS) and Joubert syndrome (JBTS), can be caused by mutations affecting components of the transition zone, a ciliary domain near its base. The transition zone controls the protein composition of the ciliary membrane, but how it does so is unclear. To better understand the transition zone and its connection to ciliopathies, we defined the arrangement of key proteins in the transition zone using two-color stochastic optical reconstruction microscopy (STORM). This mapping revealed that NPHP and MKS complex components form nested rings comprised of nine-fold doublets. The NPHP complex component RPGRIP1L forms a smaller diameter transition zone ring within the MKS complex rings. JBTS-associated mutations in RPGRIP1L disrupt the architecture of the MKS and NPHP rings, revealing that vertebrate RPGRIP1L has a key role in organizing transition zone architecture. JBTS-associated mutations in TCTN2, encoding an MKS complex component, also displace proteins of the MKS and NPHP complexes from the transition zone, revealing that RPGRIP1L and TCTN2 have interdependent roles in organizing transition zone architecture. To understand how altered transition zone architecture affects developmental signaling, we examined the localization of the Hedgehog pathway component SMO in human fibroblasts derived from JBTS-affected individuals. We found that diverse ciliary proteins, including SMO, accumulate at the transition zone in wild type cells, suggesting that the transition zone is a waypoint for proteins entering and exiting the cilium. JBTS-associated mutations in RPGRIP1L disrupt SMO accumulation at the transition zone and the ciliary localization of SMO. We propose that the disruption of transition zone architecture in JBTS leads to a failure of SMO to accumulate at the transition zone, disrupting developmental signaling in JBTS.

Primary Ciliary Deficits in the Dentate Gyrus of the Fragile X Syndrome Mouse Model.

B. Lee1, H. Lee1;  
1Physiology, UTHSCSA, San Antonio, TX

The primary cilium is the non-motile cilium present in most mammalian cell types, extending from the cell surface and functioning as an antenna for cells to sense signals. Although primary cilia are well-known to be important in regulating sonic hedgehog (Shh) signaling in developing brains, the function of the primary cilium in the adult brain, especially in neurons, has not been fully understood. Evidence has shown that the ablation of primary cilia in adult-born neurons of the dentate gyrus (DG) results in reduced dendritic arborization, synaptic strength, and adult neurogenesis. Moreover, losing cilia in adult
mouse brains demonstrated hippocampal-dependent learning and memory deficits, which often are phenotypes of neurodevelopmental disorders. Fragile X syndrome (FXS), a neurodevelopmental disorder, is a common form of inheritance for intellectual disabilities with a high risk for autism spectrum disorders, and is known to show cellular and behavioral phenotypes in FXS patients, which are recapitulated in Fmr1 knockout (KO) mice. Although Fmr1 KO mice show the abnormal spine morphology, reduced dendritic arborization of neurons, and reduced neurogenesis in the DG, the cellular phenotypes of primary cilia in the neurons of FXS have not been studied yet. To investigate the primary cilia in FXS, we analyzed the number of primary cilia in the hippocampus and the cortex of adult Fmr1 KO mice. As a result, Fmr1 KO mice showed reduced numbers of primary cilia in the DG but not in the CA1 or CA3 of the hippocampus, nor in the cortical regions of brain. Loss of primary cilia in the DG of Fmr1 KO mice is age-dependent as we observed the reduced number of primary cilia both in the later stages of development and in adults, but not in the early developmental stage in the DG of Fmr1 KO mice. Moreover, the reduction in cilia numbers in the DG of Fmr1 KO mice is mainly from neuronal cells and not from non-neuronal cells. Here, we demonstrate for the first time that the structural deficit of the neuronal primary cilia is observed in the mouse model of FXS.

A Comprehensive Portrait of Cilia and Ciliopathies from a CRISPR-based Screen for Hedgehog Signaling.

D.K. Breslow1,2, S. Hoogendoorn3, A.R. Kopp3, D.W. Morgens4, M.C. Bassik4, J.K. Chen3,5, M.V. Nachury2,6; 1Molecular, Cellular Developmental Biology, Yale University, New Haven, CT, 2Molecular Cellular Physiology, Stanford University, Stanford, CA, 3Chemical Systems Biology, Stanford University, Stanford, CA, 4Genetics, Stanford University, Stanford, CA, 5Developmental Biology, Stanford University, Stanford, CA, 6Ophthalmology, University of California, San Francisco, San Francisco, CA

The primary cillum is a signaling center that shapes embryonic development and is the unifying cause of developmental disorders known as ciliopathies. However, our understanding of how the cilium functions as an essential organizing center for Hedgehog signal transduction remains incomplete. We have conducted a functional genomic screen for Hedgehog signaling by engineering antibiotic-based selection of Hedgehog-responsive cells and applying genome-wide CRISPR-mediated gene disruption. The screen robustly identifies factors required for ciliary signaling with few false positives or false negatives. Functional characterization of hit genes uncovers novel components of key ciliary structures (including the EvC zone and the transition zone), a ciliopathy-associated ciliary protein required for Hedgehog signal transduction, and a tetrameric protein complex containing ε- and δ-tubulin that is required for centriole maintenance. The screen also provides an unbiased tool for classifying ciliopathies, revealing several poorly characterized syndromes to be ciliopathies ‘in hiding’ and indicating that many forms of congenital heart defects are likely ciliopathies. Collectively, this screen enables a systematic analysis of ciliary function and of ciliopathies and, more broadly, the platform presented here offers a versatile tool for dissecting diverse biological processes through CRISPR-based functional genomics.
Leber Congenital Amaurosis (LCA) is the most severe type of retinal dystrophies causing a very rapid and severe loss of vision in human and related experimental models. Like many of the other pathologies causing visual impairment, LCA causes an evident dysfunction at the photoreceptor level, leaving the other neuronal components in the vision network seemingly unaffected. There have been 18 identified genes associated with LCA, several of these encode for proteins related to ciliary function. We investigated an autosomal recessive form of LCA, Lebercilin (LCAS), which is specifically involved in the regulation of the intraflagellar trafficking in ciliated cells. Lebercilin protein has been best characterized in photoreceptors, and has been shown to be critical for intracellular transport of rhodopsin through the connecting cilium to the outer segment (OS) layer. Loss of lebercilin results in excess protein accumulation in the ONL leading to cell death. Loss of photoreceptors can be documented even before the outer segments have fully developed, suggesting that this early onset retinal dystrophy (EORD) could involve an additional cell compartment proceeding photoreceptor maturation. We hypothesize that ciliation in retinal pigmented epithelial (RPE) cells would be affected by loss of LCAS in murine and human experimental models leading to early pathologic consequences. Although it is known that RPE cells play an essential role in epithelial transport, protection against oxidative stress, secretion and phagocytosis for proper functionality and morphology of the photoreceptors, its role in retina degeneration, paradoxically, has been just recently appreciated. In order to investigate the pathophysiology of LCAS and understand how the RPE cells play a role in this EORD, we used patient iPSC-derived RPE cells and RPE flat mount from LCAS knockout mice. We observed a severe impairment of ciliogenesis and related alteration in RPE size, distribution and maturation. This new, so far unreported, phenotype could help to explain the severity of the LCAS depletion in the visual system, by affecting not only the retina directly but also by profoundly altering the physiology of its supporting cells. This complex mechanism of action, could lead to additional insight into the pathology of other EORDs where developmental impairments of the visual system effects neurodegeneration of the retina.

Multi-subunit molecular motors of the dynein family power the essential beating of cilia and flagella. Defective ciliary motility can lead to a severe congenital human ciliopathy called primary ciliary dyskinesia (PCD, OMIM: 242650) characterised by respiratory distress in new-borns which can progress to life-threatening complications. A major cause of PCD is a failure in dynein motor function or assembly. The majority of PCD causing mutations are found in genes encoding structural sub-units of the outer dynein arm (ODA) motor complex, the most common of these disease genes is Dynein Axonemal
Heavy Chain 5 (DNAH5). Human DNAH5 is the largest of the axonemal dynein genes and encodes a peptide 4624 amino acids long. Given their length and complex secondary structure, axonemal dyneins require a cytoplasmic chaperone relay both for folding of individual subunits as well as multimeric assembly. While the precise molecular mechanism of these chaperones remains unclear, these Dynein Axonemal Assembly Factors (DNAAFs) are required for the correct localisation and assembly of the Outer Dynein Arms (ODAs). These DNAAFs are also mutated in PCD, as demonstrated by our disease mouse model, which has a null mutation in Zmynd10, where rapid clearance of axonemal dyneins from the cytoplasm of motile ciliated mouse epithelia cells results from the PCD mutation. In order to characterise the process that results in the correct folding, trafficking and localisation of axonemal dynein heavy chains in ciliated mammalian cells, we have undertaken an endogenous tagging approach with a highly versatile SNAP tag in both wild type and mutant backgrounds. In parallel, we are investigating translational control of axonemal dyneins using RNA-FISH and the SunTag, and ask whether this is perturbed in the Zmynd10 null mouse model.

New insight on the TTBK2-dependent Sonic hedgehog activation from a CRISPR-based screen.
A. Loukil¹, S. Goetz¹;
¹Department of Pharmacology and Cancer Biology, Duke University, Durham, NC

Primary cilia are evolutionarily conserved, microtubule-based organelles that protrude from the surface of most differentiated cells. These specialized antennas act as a signaling hub critical for the development and the function of many tissues and organs. The primary cilium senses and translates extracellular cues into cellular responses. Ciliary dysregulations lead to a wide range of severe developmental abnormalities that include brain malformations, skeletal defects, retinal degeneration and polycystic kidney disease. Cilia-related diseases are commonly called “ciliopathies”, which comprise a spectrum of rare genetic disorders, such as Bardet-Biedl and Joubert Syndromes. The Sonic hedgehog (Shh) pathway is one of the major developmental pathways that is tightly controlled at the primary cilium. In a previous work, our lab discovered a novel link between cilia and a neurodegenerative disease by demonstrating that a kinase mutated in a hereditary cerebellar ataxia, Tau Tubulin Kinase 2 (TTBK2), is essential for primary cilia assembly, and for the activation of Shh signaling. TTBK2 mutants, lacking neural primary cilia, display drastic disruption of the Shh-dependent patterning in neural tube and limb. To investigate the molecular mechanism by which TTBK2 regulates Shh pathway, we performed a CRISPR/Cas9 screen based on the Shh activation. We used a mouse kinome CRISPR library that targets 713 mouse kinase genes. Our results focus on mapping the enrichment or depletion of sgRNA in hypomorphic Ttbk2 cells versus control cells. From these studies, we expect to unveil new mechanisms involved in cilia formation, and specifically to identify proteins that cooperate with TTBK2 to regulate cillum assembly.
The primary cilium is an organelle present on many cell types in mammals. In epithelial cells, it typically extends from the apical surface of cells into a lumen, serves as a sensor for a broad variety of molecular environmental stimuli, and contributes to cell polarity and polarized secretion. In autosomal dominant polycystic kidney disease (ADPKD), inherited mutations in polycystins 1 or 2 (encoded by PKD1 and PKD2), which function as a heterodimeric signaling complex at the cell cilium, abnormally activate signaling pathways regulating cell proliferation, migration, and response to environmental cues. By contrast, in cancers such as adenocarcinomas, which arise from mucus-secreting glands, ciliary dynamics are often affected, in parallel with multiple changes in cell signaling and metabolism. Intriguingly, studies of the signaling defects associated with ADPKD have increasingly identified parallel defects to those seen in cancer, in spite of the very different presentation of ADPKD and solid tumors. We have been evaluating targeted signaling inhibitors in ADPKD models to probe the biological differences between this disease and cancer, and to determine whether advanced cancer drugs are effective in ADPKD. Given recent models for ciliary dependence of defective polycystin signaling in ADPKD, we have also been assessing whether signaling inhibitors that impact cysts also impact ciliary biology. In published and ongoing work, we have found that small molecule inhibitors of heat shock protein 90 (HSP90; with ganetespib or STA-2842) or the epidermal growth factor receptor (EGFR; with erlotinib) in Pkd1-/− mice reduces initial renal cyst formation and slows the progression of these phenotypes in mice with pre-existing cysts. Conversely, inhibition of Aurora-A (AURKA; with alisertib) exacerbates cyst formation. Treatment of kidney epithelial cells with HSP90 inhibitors leads to the fast resorption of primary cilia. In contrast, treatment of Pkd1-/− mice with the Aurora-A kinase inhibitor MLN8237 (alisertib) caused defective ciliary resorption and morphological abnormalities of cilia. Surprisingly, erlotinib also increased ciliary length and stabilized cilia from resorption. These results indicated that 3 of 3 assessed cancer drugs had striking effects on cell ciliation, which identifies new protein regulators of ciliary assembly and disassembly, and could account for some of the clinical profile of these compounds in treatment of adenocarcinomas and other tumors. Based on this work, we have developed and applied an in vitro system allowing us to screen a larger panel of anti-cancer drugs to evaluate changes in ciliary dynamics and signaling.

Cytokinesis 2

At late mitosis, the mother cell divides leaving two daughter cells connected by a thin intercellular bridge (ICB). During abscission of the ICB, the ingestion of the cleavage furrow is formed, and the
central spindle microtubules are compacted into the structure known as midbody (MB). MBs are tubulin-rich structures that are known to play a key role in coordinating membrane transport and cytoskeleton re-arrangements during abscission by recruiting known abscission regulators such as ESCRT complex as well as Rab11 and Rab35 containing endosomes. In this study we have set out to identify and characterize novel abscission regulators. To that end we purified intact midbodies from HeLa cells and completed their proteome analysis to identify the proteins that associate with MBs during late telophase. Proteomic analysis identified over 600 proteins including many known MB resident proteins. Here we focused on Rab GTPases since their have been proposed to mediate actin dynamics and endosome targeting at the abscission site. Proteomic analysis of MBs identified 18 post-Golgi Rabs as putative MB associated proteins. Among them were Rabs that were previously shown to be present at the MB and to mediate abscission, namely Rab11a, Rab11b and Rab35. To further characterize whether all identified Rabs function during abscission we next overexpressed dominant-negative mutants of all identified new Rabs and tested the effect of these mutants in completing cytokinesis. We found that over-expression of Rab14 dominant-negative mutant significant increased the number of cell that failed to complete cytokinesis. Next we used shRNA as well as CRISPR/Cas9 approaches to down-regulate or knock-out Rab14. Consistent with the involvement of Rab14 in regulating abscission depletion of Rab14 led to increased multi-nucleation as well as arrest of cells in late telophase. All Rab GTPases function by recruiting and/or activating various effectors proteins. Thus, next we immune-precipitated Rab14 from late telophase cells and identified proteins that directly interact with Rab14 in GTP-dependent fashion. Finally, we then tested the involvement of Rab14-interactions proteins in mediating abscission. Based on all these data, we propose that Rab14 is a novel regulator of cytokinesis that function by regulating the targeting of endosomes to the ICB during late telophase and consequently affecting the abscission of daughter cells.

Oxidoreduction of F-actin controls the timing of cytokinetic abscission.
S. Frémont1, J. Bai2, H. Hammich3, G. Romet-Lemonne3, O. Pylypenko3, A. Houdusse1, A.F. Echard4;
1Cell Biology and Infection, Institut PASTEUR, Membrane Traffic and Cell Division Lab, Paris, France

At the end of each division, the mother cell is physically cleaved into two new daughter cells by a mechanism known as cytokinesis. Failure in cytokinesis leads to genetic instability and can promote tumorigenesis in vivo. Cytokinetic abscission, the final stage of cytokinesis, corresponds to the severing of the intercellular bridge connecting the two daughter cells. The mechanism mediating the final scission event crucially depends on the local constriction of ESCRT-III helices after complete cytoskeleton disassembly. While the ESCRT-associated enzyme Spastin cuts the microtubules of the intercellular bridge, the mechanism that actively clears F-actin at the abscission site is unknown. We found that oxidation-mediated depolymerization of actin by the redox enzyme MICAL1 (Molecules Interacting with CasL) is key for cytokinetic abscission. We observed that the depletion of MICAL1 delays cytokinetic abscission in human cells, due to a dramatic increase of F-actin within the intercellular bridges that impairs ESCRT-III recruitment to the abscission site. MICAL1 is recruited to the abscission site by the Rab35 GTPase through a direct interaction with a flat three-helix domain found in MICAL1 C-terminus. Mechanistically, in vitro single filament assays show that MICAL1 is activated by Rab35. We propose that MICAL1 oxidation weakens longitudinal interactions between actin subunits within the filaments, making the filaments more fragile and leading to enhanced F-actin depolymerization rates. We will also present unpublished data revealing the mechanisms that counteract F-actin oxidation during cytokinesis. Altogether, the levels of oxidized vs. reduced actin controls local F-actin depolymerization vs. stabilization and thus the timing of cytokinetic abscission.

Actin isoform-specific array organization during cytokinesis is differentially controlled by the formins DIAPH1 and DIAPH3.
A. CHEN, A.R. Wilde
1Biochemistry, University of Toronto, Toronto, ON, 2Molecular Genetics, University of Toronto, Toronto, ON

Cytokinesis is the final stage of cell division that divides one cell into two new daughter cells, each with a complete genome. The acute spatio-temporal control of actin cytoskeleton re-organization drives cytokinetic furrow ingression. However the actin cytoskeleton at different sites on the plasma membrane may have different roles during cytokinesis. Actin at the poles moves towards the ingression furrow in a process called cortical flow whereas de novo production of actin occurs at the site of the furrow. Interestingly these functional differences correlate with the different distribution of β-actin, at the furrow and γ-actin at the cortex. We demonstrate β-actin production at the furrow is driven by the actin isoform specific nucleation activity of the formin DIAPH3, a process that requires both RhoA and anillin. In contrast, DIAPH1 localizes to the mitotic cell cortex and is required for correct γ-actin organization at the cortex of dividing cells. DIAPH1 is activated by a comparable molecular mechanism as DIAPH3, but instead utilizing RhoA and IQGAP1. Our data suggest differential localized activation of formins by activators and enhancers is required for the production and function of isoform specific actin arrays required for the successful completion of cytokinesis.

Hold Me Tight! PIP2 and Sktl Are Required for Association of Plasma Membrane with the Contractile Ring During Cytokinesis.
L.L. Fabian, S. Yildirim, R. Wong, H. Wei, G. Polevoy, J.A. Brill
1Cell Biology, Hospital for Sick Children, Toronto, ON, 2Institute of Medical Science, University of Toronto, Toronto, ON, 3Molecular Genetics, University of Toronto, Toronto, ON

Cytokinesis, the process by which the cytoplasm is divided between daughter cells at the end of mitosis, is essential for growth and development, and defects in cytokinesis lead to genomic instability and cancer progression. Successful cytokinesis requires precise coordination and control of plasma membrane and cytoskeleton reorganization, including formation and maintenance of an actomyosin-based contractile ring at the cleavage furrow. Phosphoinositides, essential membrane lipids involved in diverse biological processes, are required for successful completion of cytokinesis. In addition, adaptor molecules including anillin and septins are likely involved in anchoring the contractile ring to the plasma membrane. However, the precise role of the phosphoinositide PIP2 during cytokinesis is not well established and little is known about the dynamic localization of contractile ring components at the cleavage site and their association with the plasma membrane. Here, we further dissect the role of PIP2 in cytokinesis using live imaging as well as pharmacological and genetic studies. We show that the PIP5-kinase Sktl localizes to the contractile ring and that PIP2 synthesis by Sktl at the cleavage furrow is required for successful cytokinesis. In addition, we demonstrate that normal PIP2 levels are required for maintenance of contractile ring-associated proteins myosin, actin, anillin and septins at the cleavage furrow and for linking the contractile ring to the plasma membrane. Contractile ring components were displaced from the cleavage furrow upon reduction of PIP2 levels by ectopic expression of a PIP2
phosphatase or mutating sktl. Increasing PIP2 levels by inhibiting PIP2 hydrolysis or overexpressing Sktl led to defective localization of septins. Upon furrow and plasma membrane regression during cytokinesis failure, septins remained associated with the contractile ring, which detached from the plasma membrane. In addition, experiments using a myosin light chain kinase inhibitor indicate that dynamic association of actin and septins with the furrow is regulated by myosin activation. Overall, our results suggest that local synthesis and turnover of PIP2 play crucial roles in establishing successful cell division by maintaining association of contractile ring complexes with the plasma membrane at the equator of dividing cells.

The Aurora kinase A activator TPXL-1 mediates aster-based clearing of contractile ring proteins from the cell poles during cytokinesis.
S. Mangal1, T. Kim2, K. Oegema2, E. Zanin1;
1Department Biology II, Ludwig-Maximilians University, Planegg-Martinsried, Germany, 2Department of Cellular and Molecular Medicine, Ludwig Institute for Cancer Research, La Jolla, CA

At the end of cell division the mother cell splits into two daughter cells in a process called cytokinesis. During cytokinesis a contractile actin-myosin ring assembles between the two segregating chromosome masses beneath the plasma membrane. The position of the contractile ring is determined by signals from the mitotic spindle and thereby chromosome segregation is tightly coupled to cleavage furrow formation. A stimulatory signal from the mitotic spindle promotes cortical contractility at the cell equator. In parallel, an inhibitory signal from the centrosomal microtubule asters prevents the accumulation of contractile ring components at the cell poles. Attempts to reveal the molecular basis of the inhibitory signal have been hindered by the absence of a robust assay. To identify the inhibitory signal from the centrosomal asters, we established a microscopy assay in the one-cell C. elegans embryo. Using this assay, we identified TPXL-1, the homologue of human TPX2, to be required for clearing the contractile ring component anillin from the cell poles. TPXL-1 is an established activator of aurora A kinase and localizes to the centrosome and the astral microtubules. In tpxl-1 mutant embryos the kinetochoore microtubules are extremely short resulting in a small mitotic spindle at anaphase onset. To determine whether the short mitotic spindle or TPXL-1 depletion itself causes defects in aster-based suppression, we increased spindle length in tpxl-1 mutants by depleting the kinetochore component hcp-4. Rescuing spindle length in tpxl-1 mutants did not rescue the defects in aster-based suppression, suggesting that TPXL-1 has a direct role in this process. Next we tested whether aster-based clearing of anillin depends on the ability of TPXL-1 to activate aurora A kinase. To this end we generated wild type (TPXL-1\textsuperscript{WT}) and Aurora A binding-defective (TPXL-1\textsuperscript{RD}) RNAi-resistant TPXL-1 transgenes. We find that in the absence of endogenous TPXL-1, TPXL-1\textsuperscript{WT} but not TPXL-1\textsuperscript{RD} supports clearing of anillin from the cell poles. Our findings suggest that aurora A kinase activation by TPXL-1 is essential for the removal of contractile ring components from the cell poles. In summary, we identified TPXL-1 and aurora A kinase as the first molecular components of the aster-based mechanism that inhibits the accumulation of contractile ring proteins at the cell poles during cytokinesis.
Phosphorylation of a linker region masks Cdc15’s F-BAR domain to regulate its membrane and protein binding capacity, oligomerization, and contractile ring localization.

M. Mangione¹, N.A. McDonald¹, K.L. Gould¹;
¹Cell and Developmental Biology, Vanderbilt University, Nashville, TN

F-BAR proteins coordinate actin cytoskeleton rearrangements at membranes using membrane-binding F-BAR domains coupled to protein-binding or signaling domains. Appropriate location and timing of F-BAR protein activity is vital to ensure the success of many processes, such as endocytosis, cell migration, neurite outgrowth, and cytokinesis. Various regulatory mechanisms have been proposed, including phosphorylation and autoinhibition. Here we determined the molecular mechanism by which phosphorylation inhibits the S. pombe cytokinetic F-BAR protein Cdc15. Cdc15 binds the plasma membrane at the division site through an N-terminal F-BAR domain and scaffolds critical components of the cytokinetic ring (CR) through a C-terminal SH3 domain. An intrinsically disordered region between the F-BAR and SH3 domains is phosphorylated on >35 sites during interphase. Hyperphosphorylation correlates with Cdc15 localization to the cytoplasm and inability to bind protein partners or oligomerize, while dephosphorylation is required for Cdc15’s stable association with the plasma membrane, oligomerization, and interaction with CR proteins.

Our data indicate that phosphorylation of the disordered linker region enables direct interaction between the phosphorylated linker and the F-BAR domain, which obstructs membrane binding. First, intramolecular fluorescence resonance energy transfer (FRET) assays of Cdc15 with acceptor and donor fluorophores at opposite termini reveals that interphase Cdc15 exhibits a FRET signal indicative of a “closed” conformation with nearby N- and C-termini. Additionally, a phosphomutant with abolished phosphorylation on 27 sites loses FRET signal throughout the cell cycle, indicating the protein’s conformation is “open” and that conformation is controlled by phosphorylation. Next, the F-BAR domain binds directly to the phosphorylated linker; the SH3 domain is neither necessary nor sufficient for this interaction. Finally, when bound by the phosphorylated linker, Cdc15’s F-BAR domain cannot interact with synthetic membranes.

We are currently investigating if a phosphothreshold exists for Cdc15’s conformational change using a series of intermediate phosphomutants. Preliminary results indicate that increasing the number of dephosphorylated residues (i.e. by abolishing phosphorylation via mutation) promotes the open conformation. Ongoing studies will attempt to pinpoint this threshold using intramolecular FRET analysis of phosphomimetics and in vitro phosphorylation of Cdc15. Together our findings provide a detailed model of F-BAR protein regulation by phosphorylation-dependent intramolecular inhibition. Since many F-BAR proteins are phosphorylated and contain disordered regions, this may be a common mechanism of regulation within the F-BAR family.

CCDC11 is Essential for Cytokinesis and Cell-cell Adhesion via Regulation of RhoA Protein Stability.
1Department of Pediatrics and Genetics, Yale School of Medicine, New Haven, CT, 2Department of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, 3Department of Medicine (Nephrology),, Washington University in St. Louis, St. Louis, MO, 4Department of Chemical Biology, Scripps Research Institute, La Jolla, CA

Spatiotemporal regulation of RhoA is critical for cytokinesis and cell-cell adhesion. Here we show that the heterotaxy gene CCDC11 is a novel regulator of cytokinesis and cell-cell adhesion. In multiple heterotaxy patients, mutations in CCDC11 were identified, and CCDC11 depletion in zebrafish and Xenopus lead to left-right (LR) patterning defects. LR patterning is established by monocilia function at the LR organizer (LRO). Interestingly, we found that CCDC11 knockdown led to multiple cilia per cell, due to cytokinesis failure. We show that loss of CCDC11 results in failure of contractile ring ingestion. In addition, CCDC11 loss leads to defec-tts in cell-cell adhesion with reduced junctional localization of key adhesion molecules like β-catenin and cadherin. Abnormalities in cytokinesis and cell-cell adhesion can occur with the misregulation of RhoA, and CCDC11 co-localizes with RhoA at the contractile ring during cytokinesis. We found that CCDC11 is essential for proper total RhoA protein levels (GDP and GTP bound forms), as total RhoA is reduced upon CCDC11 depletion. Notably, RhoA transcript levels are unchanged, suggesting that CCDC11 affects RhoA protein stability in the cell. Finally, using IP-Mass Spec of CCDC11, we have identified promising candidates that interact with CCDC11 and may help unravel how CCDC11 regulates RhoA at the molecular level.

The F-BAR domain of Cdc15 simultaneously scaffolds protein partners and binds membrane to promote cytokinesis.
C.E. Snider1, N.A. McDonald1, A.H. Willet1, S.E. Collier1, M.D. Ohi1, K.L. Gould1;
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN

Cytokinesis is the final step in cell division in which two daughter cells are physically separated. Many eukaryotic cells, including the model organism *Schizosaccharomyces pombe*, divide using an actin- and myosin-based contractile ring (CR) that is physically linked to the plasma membrane. In *S. pombe*, the F-BAR protein Cdc15 binds the membrane at the division site through its F-BAR domain and recruits additional proteins that help to link the plasma membrane to the CR. While most protein partners bind Cdc15’s SH3 domain, Cdc15’s F-BAR domain binds directly to Cdc12, the sole essential cytokinetic formin that nucleates the actin of the CR. To better understand this novel F-BAR domain-protein interaction, the Cdc12 binding site on Cdc15 was mapped to a negatively charged surface patch on the F-BAR domain’s cytosolic face (opposite of the plasma membrane binding face). Consistent with membrane- and Cdc12-binding occurring on opposite faces of the F-BAR, Cdc15 F-BAR binds both membrane and a Cdc12 N-terminal peptide simultaneously in vitro. Surprisingly, although Cdc12 mutants that cannot bind Cdc15 display mild cytokinetic defects in cells, mutating the Cdc15 F-BAR patch (cdc15-3A) to disrupt Cdc12 interaction results in severe morphological and cytokinetic defects. *cdc15-3A* mutant cells have a branched and elongated morphology and are delayed in building and
constricting the CR. We found no evidence of structural defects in circular dichroism and electron microscopy studies of purified mutant F-BAR and observed that Cdc15-3A is produced at wild-type levels and localizes properly in cells. Thus we hypothesized that the Cdc15 F-BAR patch interacts with additional proteins. While many CR proteins are not affected by the cdc15-3A mutant, we find that CR localization of the conserved calcineurin phosphatase is eliminated. These results indicate that the cytosolic faces of F-BAR domains can serve as landing pads to facilitate complex cytoskeletal rearrangements and signaling events at the plasma membrane.

Modeling contractile ring dynamics in the Caenorhabditis elegans zygote.
D.B. Cortes¹, S. Ryan¹, F. Nedelec², A.S. Maddox¹;
¹Biology, University of North Carolina Chapel Hill, Chapel Hill, NC, ²Cell Biology and Biophysics, EMBL Heidelberg, Heidelberg, Germany

Cytokinesis is required for cell proliferation with failures potentially leading to aneuploidy and cancer. The actomyosin contractile ring is a dynamic structure responsible for driving cytokinesis. Proper cytokinesis requires assembly of contractile ring components at the cell equator, in the cortex. Actin, myosin, crosslinkers, and regulators then reorganize as the ring matures from a wide band to a tight cable, becoming contractile. Previous work has provided insight into the changes that occur in ring and cell structure. However, less is known about changes on the mesoscopic and molecular scales due to imaging limitations. Several models have given insight to mechanisms of contractility, including actin treadmilling and minifilament adaptive response to force-load, but the predictive power of these is limited by the simplification of myosin minifilament and actin dynamics. Herein we set out to further bridge the gap between the models of cytokinetic ring components and quantitative cell biology, by first establishing a model of contractility where myosin minifilaments are modeled. We developed this model of cytokinesis using the software Cytosim, which provides unparalleled resolution on a molecular scale. In our model actin treadmilling and shortening, both of which have been implicated in models of contractility, provide for a dynamic actin meshwork. We built upon previous models depicting the catch-slip bond nature of myosin II motors binding to actin filaments and built full minifilaments as multiple motor heads protruding off either end of 300nm rods. To further refine our model we queried the changes in protein concentration of several components of the ring including myosin, actin, anillin, and septin. Previous methods for visualizing cytokinesis result in uneven illumination and detection of structures across the cytokinetic ring, with the illumination plane orthogonal to the contractile ring plane; making quantitative analysis of the ring less precise. To this end we used custom chambers to position C. elegans zygotes such that the entire contractile ring forms in the illumination plane of a focused light sheet. This setup allowed us to quantify the contractile ring densities of components over the length of cytokinesis. Using this system, we generate contractile rings, on the scale of C. elegans zygote contractile rings, that exhibit protein density dynamics like those measured in our in vivo data and show a model for how these rings may contract. Our initial estimates for all major structural components yield simulated rings that close at biologically-relevant timescales, exert force that constricts a “membrane,” and form mesoscopic contractile foci.

Regulation of Abscission by Class 1 Rab11-Family-Interacting-Proteins.
N.V. Iannantuono1, C. Laflamme2, G. Emery3;
1Biologie Moléculaire, Université de Montréal, Montréal, QC, 2Biochemistry and Molecular Biology, McGill University, Montréal, QC, 3Pathologie et Biologie Cellulaire, Université de Montréal, Montréal, QC

Introduction: Cytokinesis occurs at the end of mitosis/meiosis wherein the cytoplasms of daughter cells are separated in two giving rise to two independent daughter cells. Evidently, this process needs to be highly regulated as deficient abscission, (the final cutting process) can lead to diseases such as Lowe-Syndrome and cancer. Importantly, the modulation of both the lipid composition and the actin cytoskeleton at the site of ingression and abscission needs to be tightly regulated to ensure this process is completed correctly. We recently identified an axis involving recruitment of class 1 Rab11-Family-Interacting Proteins (Rab11FIPs), the small GTPase Rab35 and its effector OCRL, an inositol polyphosphate 5-phosphatase, to the intercellular bridge in order to modulate the lipid composition and promote abscission. Methods and Results: Using immunofluorescence/time-lapse microscopy, we found that Rab11FIP1 is recruited to the intercellular bridge (ICB). Moreover, siRNA-mediated Rab11FIP1 knockdown induces binucleation, abscission timing delay and accumulation of actin at the ICB. This phenotype is reminiscent of the loss of Rab35 or OCRL function. It can be rescued through the re-expression of the isoforms Rab11FIP1B and Rab11FIP1C but not Rab11FIP1A. Furthermore, the observed cytokinesis defects can also be rescued through the removal of over-accumulated actin in the ICB by treating cells with the actin-depolymerizing drug LatrunculinA. Finally, we detected an interaction between Rab11FIP1B and Rab35 in cells using CoIP assays. We were also able to show that both OCRL and Rab35 levels at the ICB decrease when cells are treated with siRab11FIP1. Conclusion and Relevance: Our work shows that Rab11FIP1 is involved in the spatio-temporal regulation of OCRL at ICB, which is necessary for the progression to abscission. Overall, this project will aid in better understanding cytokinesis, a fundamental cellular mechanism that impacts virtually every cellular process.

The recruitment and organization of ESCRT-III abscission machinery is spatiotemporally regulated by septins.
E.P. Karasmanis1, D. Hwang1, J.R. Bowen1, K. Nakos1, E.T. Spiliotis1;
1Biology, Drexel University, Philadelphia, PA

Cytokinetic abscission is the final step of mitosis and involves the constriction and fission of membrane connecting the two daughter cells, which is mediated by the endocytic sorting complex required for transport (ESCRT). Assembly of the ESCRT machinery is spatially and temporally regulated, but the mechanisms underlying this regulation are not well understood. Septins are GTP-binding proteins that interact with the cytoskeleton and cell membranes. Septins are required for the completion of cytokinesis, but their roles in abscission are unclear. Here, we show that following cleavage furrow ingression, septins localize to distinct microtubule and membrane domains of the emerging midbody. High- and super-resolution microscopy show that in mitotic MDCK epithelial cells, SEPT2/6/7/9 complexes are organized as two membrane-bound rings that flank the center of the midbody (stem body). Time-lapse microscopy reveals that ESCRT-III (CHMP2A/CHMP4B) rings assemble flanking the stem body, in between and adjacent to the two septin rings. As CHMP2A/CHMP4B fluorescence increases, septin ring fluorescence decreases. Strikingly, septin ring disassembly is temporally coincident
with the remodeling and expansion of CHMP2A/CHMP4B rings into nested helical spirals that appear as cones at the site of membrane fission. Knock-down of SEPT9, which has been previously shown to disrupt abscission specifically, prevents the recruitment of an early ESCRT-III component (CHMP6) and results in ESCRT-III (CHMP4B/CHMP2A) ring disorganization and diminished recruitment. In later stages of cytokinesis, SEPT9 depletion abrogates the remodeling the ESCRT-III rings into cones and interferes with the completion of abscission. We have found that SEPT9 interacts with the early ESCRT component TSG101 (ESCRT-I) but SEPT9 depletion does not affect TSG101 recruitment and localization. We hypothesize that SEPT9-TSG101 interaction is critical for recruitment and proper assembly of ESCRT-III components. On-going work aims to investigate this hypothesis in order to gain a better understanding of how ESCRT-III assembly is spatiotemporally and functionally linked to septins.

Adaptor proteins are essential for Septin-mediated cytokinesis.
D. Safavian1,2, K. Fung2, W.S. Trimble1,2;
1Cell Biology program, The Hospital for Sick Children, Toronto, ON, 2Department of Biochemistry, University of Toronto, Toronto, ON

Cytokinesis is a carefully orchestrated process which drives the division of the cytoplasm following the equal separation of genetic material into the daughter cells. The successive events leading to cytokinesis can be divided into four stages; appearance of the cleavage plane, ingestion of the cleavage furrow to the cell middle, formation of the intercellular microtubule-based bridge and the midbody, and the final separation of daughter cells, referred to as abscission. Despite extensive studies on cytokinesis, understanding of the key mechanisms that regulate abscission is still limited. We are particularly interested in the Septin family of GTP binding proteins, known to be essential for cytokinesis in yeast and animal systems. Nevertheless, the precise role of Septins in cytokinesis regulation has yet to be determined. We have demonstrated that SEPT9 is indispensable for the successful completion of cytokinesis, where SEPT9 deficiency causes defects in midbody abscission and constitutively necessitates the dividing cells to halt at the telophase stage. Septins have been identified as molecular scaffolds, as these proteins have protein-binding motifs that connect to protein-binding partners and recruit proteins to a particular site in the cell. In order to unravel the mechanism of cytokinesis in mammalian cells, we are interested in identifying the downstream signaling proteins that are involved in septin-mediated cell abscission. Thus, we hypothesized that SEPT9 may recruit specific factors that are critical for abscission to the midbody, hence regulating cell division. Vesicle transport to the abscission site, mediated by the exocyst complex, is necessary to proper completion of cytokinesis. SEPT9 has been previously identified as an essential factor for targeting exocyst complex to the midbody, providing mechanistic insight into the role of septins during abscission. Similar to scaffolds, adaptor proteins contain protein-binding motifs that mediate protein-protein interactions, thus influencing the signal transduction pathways. In confocal micrographs, we have recently observed adaptor proteins Cin85 and CD2AP, which are associated with the regulation of actin cytoskeleton, to be localized to the midbody in dividing cells. The western blot analysis revealed that the N-terminus of SEPT9 recruits these adaptor proteins to the abscission site, and we further revealed that the depletion of either of these two adaptor proteins results in abscission defects and causes the formation of a persistent connection between the two daughter cells. Interestingly, our novel collective data can shed light on the downstream signaling pathways regulating cytokinesis and may lead to potential therapeutic approaches for diseases caused by cell division failure.
Formation of the mitotic spindle lies at the heart of cell division, and it is necessary for correct and faithful chromosome segregation. Generation of the mitotic spindle is highly dynamic, and it requires tight spatio-temporal control of microtubule (MT) nucleation. Centrosome mediated microtubule nucleation has been well-characterized; however, other MT nucleation pathways exist. The process of branching MT nucleation requires the augmin complex and the γ-tubulin ring complex (γ-TuRC). The augmin complex recruits γ-TuRC to spindle MTs during mitosis and it has been proposed that branching MT nucleation contributes to spindle midzone MT-density and the efficiency of cytokinesis. To better understand how MT branching contributes to the efficiency of cytokinesis and to the establishment and maintenance of the cleavage furrow, we employed multi-color, live-cell TIRF microscopy to visualize MTs as well as augmin complex and γ-TuRC components during cytokinesis (C-phase) in Drosophila S2 cells. MT branching from equatorial astral microtubules is prevalent during late anaphase and possibly contributes to the robustness of cleavage furrow positioning by increasing the abundance of MT tips in the vicinity of the furrow. Live-cell imaging allowed us to observe and quantify numerous characteristics of MT branching nucleation during C-phase. Nascent branch sites on mother MTs exhibit an increase in α-tubulin fluorescence followed immediately by the appearance of a polymerizing daughter MT. Live-cell TIRF imaging of stable cell lines co-expressing α- and γ-tubulin, to identify bona-fide branch points, revealed that daughter MTs branch at an average angle of ~35°. The lag time between γ-tubulin binding to a mother MT and daughter MT birth is ~12 sec, and the mean life-time of daughter MTs is ~20 sec. Three-color TIRF imaging of DgtS (augmin complex subunit), γ-tubulin (γ-TuRC), and α-tubulin revealed that the augmin complex associates first with mother MTs and a subset of augmin complexes recruit γ-TuRC from the cytosol to nucleate daughter MTs. Upon daughter MT depolymerization γ-TuRC at the branch point dissociates from the mother MT while the augmin complex often remains and can support another round of branching MT nucleation. This work presents the first direct visualization in animal cells of branching MT nucleation and its central constituents in real-time.

In nonmuscle cells, actin is organized into either branched or linear networks, whose polymerization is mediated by the Arp2/3 and formin families of actin nucleators, respectively. Arp2/3 acts downstream of Rho family GTPases to form dendritic networks of actin that are crucial for lamellipodial cell protrusions. But while the role of Arp2/3 in two-dimensional cell motility is well characterized, less is known about its roles in large cells such as oocytes and embryonic blastomeres. During the early cleavages, Arp2/3 is recruited to the cortical cytoskeleton, where it is cleared from the cleavage furrow during cytokinesis. This removal of branched actin networks is critical for embryonic cleavage, as misregulation of Rac signaling blocks cytokinesis in an Arp2/3-dependent manner. In contrast, in highly
atypical cleavages such as those seen during oocyte meiosis, Arp2/3 is enriched in the polar body and is required for polar body extrusion. Arp2/3 may also play a role in polar lobe formation in mollusk embryos, where a transient constriction perpendicular to the cleavage plane sequesters vegetal cytoplasm during the first two embryonic cleavages. Arp2/3 is highly enriched at the vegetal pole prior to- and during polar lobe formation, with a clear boundary visible between the Arp2/3-enriched vegetal pole and the myosin II-mediated polar lobe constriction. Vegetal Arp2/3 is retained between the first and second cleavages, only to dissipate after the reabsorption of the polar lobe into the D blastomere. While it remains unclear how the polar lobe constriction is activated, Arp2/3 enrichment at the vegetal pole and initiation of lobe constriction is mechanistically distinct from cytokinesis, as Aurora inhibitors block cytokinesis without effecting lobe initiation. Together, these results suggest that while the selective exclusion of Arp2/3 may be important for the generation of cortical tension and contractility (e.g. contractile ring), the active recruitment of Arp2/3 may promote more extrusive forms of cytokinesis by affecting the local biophysical properties of the cortex.

Cytokinesis in plants involves exquisitely choreographed intracellular transport.
C. Triplet van Oostende1, D. Guillet2, T. Triplet3, E. Pandzic4, P.W. Wiseman5, A. Geitmann1;5;
1Department of Biological Sciences, Université de Montréal, Montreal, QC, 2Department of Chemistry, McGill University, Montreal, QC, 3Computer Research Institute of Montreal, Montreal, QC, 4University of New South Wales, Sydney, Australia, 5Department of Plant Science, McGill University, Ste-Anne-de-Bellevue, QC

Cell division in plant cells requires the deposition of a new cell wall between the two daughter cells. The assembly of this plate involves exquisitely coordinated movement of cargo-vesicles whose size is below the diffraction limited resolution of the optical microscope. We combined high spatial and temporal resolution confocal laser scanning microscopy with advanced image processing tools and fluorescence fluctuation methods to distinguish three distinct phases during the formation of the cell plate: Massive and highly choreographed delivery of vesicles first generates a disk shaped cell plate region at the equatorial plane of the cell. Subsequently, a primary rapid expansion phase is fuelled by intracellular transport mediated by the microtubular cytoskeleton followed by a secondary, slow expansion phase during which the extremity of the circular plate seeks contact with the mother wall and brings about the separation of the two portions of cytoplasm. Different effects of pharmacological inhibition emphasize the distinct nature of the assembly and expansion mechanisms characterizing these phases. The biphasic pattern is proposed to serve to optimize both efficiency and precision of cell plate formation.

Precise tuning of cortical contractility regulates mechanical equilibrium during cell division.
1Cell and Developmental Biology, Vanderbilt University, Nashville, TN, 2Biomedical Engineering, Vanderbilt University, Nashville, TN

The animal cell cortex comprises a thin network of actin filaments underneath the plasma membrane. Contractile force generation by myosin II (MII) in the cortex drives shape changes during cell division, cell migration and tissue morphogenesis. During the cytokinetic (C)- phase of cell division, large
contractile forces and cortical remodeling are required at the equatorial cortical network to drive furrow ingression. Outward pressures created by furrow ingression must be balanced by MII contractility at the polar cortical network. The roles for the two MII isoforms, MIIA and MIIB, in the establishment of a mechanical equilibrium between these two cortical networks are not understood. We found MIIA depletion resulted in slower cleavage furrow ingression, and a loss of both MIIA and MIIB filaments in the furrow, with no changes at the polar cortex. MIIB depletion, in turn, resulted in intense blebbing at the polar cortex, with no changes in furrow ingression. We predicted the cortex of MIIB depleted cells should be softer; however, AFM measurements revealed no changes in stiffness. This suggested molecular scale behaviors may be driving cortical mechanics, which may not be reflected in macroscopic measurements such as cell stiffness. We therefore sought to develop a robust coarse-grained mathematical description of cortical behavior, incorporating experimentally measured kinetic parameters. Measurement of localization patterns and lifetimes of MII isoforms during C-phase revealed MIIA had faster turnover and more transient kinetics compared to MIIB. Modeling the cortex based on active gel theory surprisingly revealed no significant differences in outward pressure and cortical tension in the two knockdown conditions. Instead, our model predicted differences in the duty ratios of MII isoforms and total contractility must account for the observed differences in cortical stability in the two knockdown conditions. We verified these predictions using both MII chimeras and biophysical assays. We further found Rho kinase and Myosin Light Chain Kinase regulated the recruitment and turnover of MII isoforms, respectively. Our working model posits that in the unperturbed state, competition between MIIA and MIIB regulates cortical turnover, while competition between MLCK and ROCK regulates the turnover of MII itself. Depletion of either isoform leads to compensation at the polar cortex, driving the cell to extremes of contractility, with MIIA and MIIB depletion leading to hypo- and hyper-contractility, respectively, leading to cytokinetic failure. Therefore, our data support a model where an intermediate level of contractility leads to efficient cytokinesis, allowing MIIA driven ingression at the equator balanced by MIIB driven tension generation at the poles.

An optogenetic tool for studying asymmetric cell division.

A. Monnard1,2, C. Cabernard2;
1Biozentrum, University of Basel, Basel, Switzerland, 2Department of Biology, University of Washington, Seattle, WA

Asymmetric cell division (ACD) is an evolutionarily conserved mechanism used by stem and progenitor cells to form differentiating progeny while maintaining a self-renewed stem/progenitor cell. Drosophila neuroblasts (NBs), the precursors of the fly’s central nervous system, provide a good model system to study ACD. Recently it was shown that two different pathways – the spindle-dependent and polarity-dependent pathways - co-regulate cleavage furrow positioning during ACD of NBs. The polarity pathway initiates non-muscle Myosin II (Myosin; Myo, hereafter) relocalization on the apical pole, whereas spindle-dependent cues are necessary for Myo clearing on the basal NB cortex. This spatiotemporal regulation of Myo allows NBs to generate a large apical neuroblast and a small differentiating ganglion mother cell (GMC) on the basal side. Spindle cues are delivered to the cellular cortex by the centraspindlin complex, composed of the kinesin-like Pavarotti (Pav) and the Rho family GAP Tumbleweed (Tum). It is assumed that spindle cues activate RhoGEF, which will in turn activate RhoA and will ultimately lead to Myo phosphorylation and therefore, activation. In order to understand the role of spindle cues, their downstream signaling cascade and their link to polarity, we created i) photorecruitable versions of Tum (LOVTum),
corresponding to the different structural domains of Tum (Pav binding domain, RhoGEF binding domain, RhoGAP domain), ii) a photorecruitable version of active RhoGEF (LOVGEF), iii) a photorecruitable version of active RhoA (LOVRhoA) and iv) a photorecruitable version of the polarity protein Miranda (LOVMira).

We sought to understand the cortical response to the recruitment of local spindle cues from the different LOVTum versions and their ability to create furrowing during the cell cycle. We found that physical cell size can be perturbed by local LOVTum recruitment and also found a spatiotemporal dependency in the ability of local LOVTum recruitment to create furrows. Additionally, we observed similar responses with LOVGEF and LOVRhoA, and found that apical recruitment of LOVMira induced ectopic furrowing in telophase.

Study of cisplatin induced ROS using C. elegans as a post-mitotic cell model.
D. Raj1, J. Warzecha1, G. Kao1, P. Naredi1;
1Sahlgrenska Cancer Center, Gothenburg University, Gothenburg, Sweden

Cisplatin is a platinum based chemotherapeutic widely used for cancer treatment. However, tumor resistance to cisplatin limits its use. The ability to reverse resistance could significantly improve cisplatin therapy in patients. To enhance the efficiency of cisplatin mediated death more information on the molecular mechanisms and targets is needed. We study the targeting of ASNA-1 as a way to increase cisplatin sensitivity. Knockdown of the human ASNA1 causes cisplatin sensitivity in melanoma and ovarian tumour cell lines and knockdown in C.elegans has the same effect. Cisplatin mediates killing via effects on nuclear and non-nuclear targets in mitotic and post-mitotic cells. Heightened ER stress and induction of ROS levels are among the proposed killing mechanisms. Most studies of cisplatin in mammalian cells are performed in mitotic cells and a model for the effects of cisplatin on post-mitotic tissues is needed since these cells comprise a significant part of every tumor. Somatic cells in adult C.elegans are exclusively post-mitotic and provide a useful model to study the phenomenon. In normal conditions mammalian cells control reactive oxygen species (ROS) levels by protection systems. Cancer cells exhibit greater ROS than normal cells and cisplatin mediated death is thought to act in part by increasing ROS levels that consequently trigger cell death or DNA damage. How important that role is in post-mitotic cells remains an open question.

We found robust activation of oxidative stress response genes and ROS mediated damage upon cisplatin exposure. Moreover cisplatin induced lethality that could be blunted by antioxidant treatment. The DAF-16 and SKN-1/NRF2 pathways mediate oxidative defence in worms, but only the SKN-1 pathway appears to be important in the process. Mutants in upstream activators of SKN-1 are sensitive implying that oxidative stress regulation is important for cisplatin mediated killing. Curiously, the skn-1(zu67) mutants are much more resistant than mutants of the upstream kinases. Moreover, DAF-16 mutants which express high levels of asna-1 mRNA, are resistant to cisplatin even in high dosages. Survival of daf-16 mutants could be dependent on overexpression of asna-1. However mutants with high levels of ROS do not display increased sensitivity. Unexpectedly, in the asna-1 supersensitive mutants oxidative defence response appears to be intact. Taken together this indicates that oxidative stress defence is necessary but not sufficient for resistance of post-mitotic cells to cisplatin.

CedA mediated mechanism of cell division in E. coli under chromosomal over replication condition.
P. SHARMA¹, B. Kundu¹;
¹KUSUMA SCHOOL OF BIOLOGICAL SCIENCES, INDIAN INSTITUTE OF TECHNOLOGY DELHI, NEW DELHI, India

In Escherichia coli, the process of cell division and chromosome replication occurs with high precision, coordination and regulation. This systemic and highly coordinated process is imprecise in DnaAcos cell, a cold sensitive mutant of E. coli. When these cells are grown at 30°C, chromosomal over-replication occurs due to multiple initiation signals at origin of replication site resulting into their filamentous morphology. Cell division in these cells is induced by over expression of cell division activator protein known as CedA. CedA is a 12 KDa, 87 amino acid long protein which is structurally homologous to other double stranded DNA binding proteins and known to interact with RNA polymerase multisubunit enzyme complex. The preferential DNA binding sites of CedA have been reported by Abe et al. in 2015. The regulatory action of CedA that initiates cell division without affecting the chromosomal over-replication in DnaAcos cells follows an unknown mechanism yet to be deciphered. In our present study, CedA is cloned, expressed, purified and characterized by mass spectrometric analysis (MALDI ToF/MS). CedA interacting proteins were identified by pull down assay using purified recombinant His6-tagged CedA. We identified nine CedA-binding proteins (CBPs) viz. PDHA1, RL2, DNAK, LPP, rpoB, G6PD, GLMS, RL3 and YBCJ, characterized by mass spectrometric analysis (MALDI ToF/MS and ESI nLC/MS). These CBPs are mainly associated with energy metabolic pathways and transcriptional regulation in E. coli suggesting multifaceted role of CedA in cell cycle regulation. The interaction of CedA with RNA polymerase subunit β (rpoB), one of the identified CBPs, is of major significance based on previous reports. The interplay between CedA, rpoB and DNA may provide a clue to decipher the mechanism behind CedA mediated cell division in E. coli. DNA sequence to which CedA preferentially binds is custom synthesized to study its interaction with CedA and rpoB by fluorescence spectroscopy and BioLayer Interferometry. The binding constants of these interactions clearly indicate that rpoB binds to DNA with higher affinity as compared to CedA. The biophysical results are well supported by in silico docking analysis that shows more intermolecular hydrogen bonds formation in rpoB-DNA complex as compared to CedA-DNA complex. Based on our findings we hypothesize a mechanism in which CedA recruit rpoB to specific DNA site(s), that initiates transcription of key cell division regulatory elements in E. coli cells under chromosomal over-replication conditions.

The regulation of Z ring dynamics in bacterial cytokinesis.
G.R. Squyres¹, S.R. Barger², B.R. Pennycook³, J. Ryan⁴, A.W. Bisson-Filho¹, E.C. Garner¹;
¹Department of Molecular and Cellular Biology, Harvard University, Cambridge, MA, ²Department of Cell and Developmental Biology, SUNY Upstate Medical University, Syracuse, NY, ³MRC Laboratory for Molecular Cell Biology, University College London, London, United Kingdom, ⁴Department of Biology II and Center for Integrated Protein Science Munich, Ludwig Maximilian University of Munich, Munich, Germany

In bacteria, cell division is carried out by the divisome, a set of proteins that localize to midcell and are required for cytokinesis. Decades of research have elucidated the identities of these proteins, including
FtsZ, a bacterial homolog of tubulin, as well as enzymes that synthesize cell wall at the division site. Like eukaryotic cells, filaments of FtsZ assemble into a ring structure, called the Z ring, that constrains as the cell divides. Unlike in eukaryotes, however, there are no known molecular motors in the division complex. The molecular mechanisms that underlie force generation and cytokinesis in bacteria have thus remained a mystery. Recently, it has become clear that protein dynamics in the divisome play a key role in the cytokinesis process. Using Total Internal Reflection Fluorescence (TIRF) microscopy, we have shown that FtsZ filaments treadmill around the division site, and elucidated the significance of these dynamics in bacterial cell division. We conclude that the Z ring consists of treadmill FtsZ filaments, that these dynamics power the motion of the essential cell wall synthesis enzyme Ppb2B, and that FtsZ treadmillig is required to distribute cell wall synthesis at the division site as an essential part of the bacterial cytokinesis process. Now, we are investigating whether and how FtsZ filament assembly and dynamics are regulated. Given that artificial perturbations to FtsZ’s treadmill dynamics can have dramatic effects on cytokinesis in bacteria, we reasoned that these dynamics might be regulated by the cell to ensure proper division. Additionally, there are proteins in the divisome whose proposed function is to bind to FtsZ filaments and alter their stability, which could alter both filament structure and treadmill dynamics. First, we introduce single molecule lifetime measurements as a quantitative metric of FtsZ’s treadmill dynamics which is independent of both spatial resolution and filament density, allowing us to sensitively measure treadmill in the Z ring even as it constricts. We combine these measurements with 3D Structured Illumination Microscopy (3D-SIM) imaging to probe the structure of the Z ring with high spatial resolution. Finally, we use these assays to ask whether and how proteins that bind to FtsZ control filament structure and stability during the bacterial cell cycle.

Screening gene deletion collection of Cryptococcus neoformans to elucidate the role of septin proteins in cytokinesis.

J.M. Zielinski, P. Stempsinski, E. Huey, E. McCormack, A. Rubin, S. Chandrasekaran, L. Kozubowski; Genetics and Biochemistry, Clemson University, Clemson, SC, Biology, Furman University, Greenville, SC

Cryptococcus neoformans is a basidiomycetous yeast, able to infect immunocompromised individuals due to its ability to grow at host temperature. Septins are conserved filament forming GTP-binding proteins that assemble as a complex at the site of cell division and contribute to cytokinesis. In C. neoformans, septins are not required for cytokinesis at 24°C but are essential at the host temperature of 37°C. Moreover, septins become essential at 24°C when the calcium-dependent protein phosphatase calcineurin is inhibited. While the role of septins in cytokinesis is conserved in most eukaryotes, their exact contribution to this process remains elusive. Additionally, mechanisms of cytokinesis in C. neoformans are largely unknown. To define the roles of the septin complex and to identify other proteins involved in cytokinesis in C. neoformans, we performed a screen for genes necessary for growth at 37°C based on a collection of ~4,500 strains containing single deletions of non-essential genes. We searched for strains that at 37°C or in the presence of calcineurin inhibitor exhibited elongated bud morphology, a phenotype characteristic of septin mutants and indicative of cytokinesis failure. Our screen revealed 12 candidate genes, including 2 that were previously associated with cytokinesis and/or stress response (non-muscle myosin II and chitin synthase regulator), and 2 that encode hypothetical proteins. We tested candidate genes identified in the screen for synthetic interaction with the septin deletion to probe for the potential involvement in septin pathway. In addition, we examined if the candidate genes are involved in septin complex assembly and dynamics by introducing fluorescently
tagged septin to the identified deletion strains. Our research provides a better understanding of cytokinesis in C. neoformans and may lead to identification of novel antifungal drug targets against cryptococcosis.

Molecular delineation of CENP-T deposition in mammalian cell division cycle.

M. Ding1,2, F. Zheng1, Q. Wang1, J. Jiang1, F. Yang1, J. Fang1, X. Liu1,2, C. Fu1, X. Yao1,2;

1Anhui Key Laboratory for Cellular Dynamics Chemical Biology, University of Science and Technology of China, Hefei, China, 2Physiology, Morehouse School of Medicine Keck Center for Molecular Imaging, Atlanta, United States

The landmark determinant of chromosome inheritance, the centromere, is specified in many eukaryotes by an epigenetic mark. A two-step mechanism has been proposed to account for the epigenetic specification of centromere identity and function centered on CENP-A. Our early study demonstrated that define a novel molecular mechanism underlying the temporal regulation of CENP-A incorporation into the centromere by accurate Mis18β-HJURP interaction (Wang et al., 2014. J. Biol. Chem. 289, 8326-36). However, it has remained elusive as to other histone-fold containing proteins such as CENP-S/X and CENP-T/W in centromere specification and plasticity control. Here, we show that HJURP interacts with CENP-T and HJURP knock-out abrogates centromere localization of CENP-T. The CENP-T-interacting domain was mapped to C-terminal domain of HJURP which physically binds to the histone-fold of CENP-T. Interestingly, expression of HJURP-deficient CENP-T mutant perturbs accurate chromosome segregation, suggesting that precise loading of CENP-T to centromere is essential for achieving metaphase alignment. Currently, we are using super-resolution imaging to conduct precise localization of CENP-A and CENP-T and assess their temporal order of assembly in cell division cycle.

Microtubule sliding in the bridging fiber pushes kinetochore fibers apart to segregate chromosomes in human cells.

P. Risteski1, K. Vukušić1, R. Buđa1, A. Bosilj2, A. Milas1, N. Pavin1, I.M. Tolić1;

1Division of Molecular Biology, Ruđer Bošković Institute, Zagreb, Croatia, 2Department of Physics, Faculty of Science, University of Zagreb, Zagreb, Croatia

During cell division, microtubules of the mitotic spindle segregate chromosomes by exerting forces on kinetochores, protein complexes on the chromosomes. The central question is what forces drive chromosome segregation. The current model for anaphase in human cells includes shortening of kinetochore fibers and separation of spindle poles. Both processes require kinetochores to be linked with the poles. Here we show, by combining laser ablation, photoactivation and theoretical modeling, that kinetochores can separate without any attachment to one spindle pole. This separation requires the bridging fiber, which connects sister kinetochore fibers. The number of bridging fibers per spindle correlates with the variable chromosome numbers in HeLa cells, suggesting a one-to-one relationship. Bridging microtubules in intact spindles slide apart together with kinetochore fibers, indicating strong crosslinks between them. We conclude that sliding of microtubules in the bridging fibers drives pole separation and pushes kinetochore fibers poleward by the friction of passive crosslinks between these
fibers. Thus, sliding in the bridging fiber works together with the shortening of kinetochore fibers to segregate chromosomes.

Multimerization of NDC80 kinetochore complexes is essential for efficient microtubule force-coupling.
V.A. Volkov1, P.J. Huis in 't Veld2, M. Dogterom1, A. Muschico2;
1Department of Bionanoscience, Delft University of Technology, Delft, Netherlands, 2Department of Mechanistic Cell Biology, Max Planck Institute of Molecular Physiology, Dortmund, Germany

During mitosis, chromosomes connect to microtubules in the mitotic spindle through kinetochores, multi-protein complexes that self-assemble on the centromeric chromatin. The key connection is formed by the microtubule-binding NDC80 complex (NDC80C). Microtubule-kinetochore interfaces across species contain multiple copies of NDC80C, but the relevance of this multimerization for the kinetochore’s ability to follow growing and shrinking microtubules, and support faithful chromosome segregation, remains elusive. We reconstituted outer kinetochore modules with a precisely controllable number of NDC80 complexes and characterized their interaction with microtubules at a single-microtubule level. Step-wise addition of NDC80 complexes exponentially increased microtubule-binding times and the combination of three NDC80 complexes rendered a kinetochore unit able to follow depolymerizing microtubule ends. We used optical tweezers to show that such trivalent NDC80C assemblies stalled and rescued microtubule depolymerization in a force-dependent manner. Our measurements allowed us to distinguish NDC80C binding to depolymerizing microtubule ends from NDC80C binding to the microtubule lattice or to the stable ends. This revealed that the NDC80C-induced stalling of microtubule depolymerization is mediated by a unique connection that forms between the oligomerized NDC80C and the end of a shrinking microtubule. We thus conclude that the multimerization of NDC80C results in kinetochore modules that can hold on to depolymerizing microtubules and modulate microtubule dynamics. Our findings provide a mechanistic explanation for the importance of NDC80 multimerization in vivo.

Characterizing the role of BuGZ in mitosis.
H.K. Shirnekh1, R.P. Hughes1, J.G. DeLuca1;
1Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

BuGZ is a mitotic protein recently identified through two independent RNAi screens: one targeting putative human transcription factors to isolate essential regulators of glioblastoma stem cell expansion (Toledo et al., 2014. Dev Cell 28, 282-294) and one targeting spindle matrix proteins in mouse embryonic stem cells (Jiang et al., 2014. Dev Cell 28, 268-281). We have previously shown that BuGZ is a kinetochore component that binds to and stabilizes the mitotic protein Bub3. Bub3 plays a key role in spindle assembly checkpoint signaling: it is responsible for recruiting BubR1 to kinetochores, and together with Mad2 and Cdc20, this group of proteins forms the Mitotic Checkpoint Complex (MCC), which binds to and inhibits the Anaphase Promoting Complex in the presence of unattached kinetochores. Additionally, Bub3 is responsible for recruiting Bub1 to kinetochores, which has roles in both the checkpoint and in regulating kinetochore-microtubule attachment and chromosome alignment. BuGZ binds Bub3 through a highly conserved GLEBS domain, which is found in the other mitotic Bub3
binding partners, BubR1 and Bub1. Inhibition of BuGZ compromises chromosome alignment and results in defects in chromosome segregation, but which functions of BuGZ contribute to this process currently remain unclear. In the current study, we have investigated how BuGZ and Bub3 are loaded onto kinetochores and the mechanism by which BuGZ contributes to chromosome alignment. Using a series of mutants, we have mapped the domain requirements for BuGZ kinetochore recruitment and determined how BuGZ kinetochore-association affects the recruitment of BubR1 and Bub1. We are currently determining which domains of BuGZ are required to rescue the mitotic defects observed upon depletion of the full length BuGZ protein, including increased inter-kinetochore distances, a weakened spindle assembly checkpoint, and chromosome alignment defects. In addition, we have carried out size exclusion chromatography to analyze BuGZ- and Bub3- containing complexes in different cell cycle phases and our results point to a model in which BuGZ stabilizes Bub3 protein levels and facilitates Bub3 loading onto kinetochores in early mitosis, which, in turn, facilitates Bub1 and BubR1 kinetochore loading.

Distinct surfaces of the microtubule-binding domain of the Ska1 kinetochore complex facilitate microtubule tip-tracking.
E.V. Tarasovец1, I. Whitney2, J. Monda2,3, E.M. Wilson-Kubalek4, R.A. Milligan4, E.L. Grishchuk3, I.M. Cheeseman2,3;
1Physiology Department, University of Pennsylvania, Philadelphia, PA, 2Whitehead Institute for Biomedical Research, Cambridge, MA, 3Department of Biology, Massachusetts Institute of Technology, Cambridge, MA, 4Department of Cell Biology, The Scripps Research Institute, La Jolla, CA

Interactions between kinetochore complexes and dynamic microtubule plus ends are crucial for proper chromosome segregation during mitosis. The spindle- and kinetochore-associated multi-subunit Ska1 complex is essential for linking kinetochores to microtubules in mammalian cells. Although prior work has analyzed the association of the Ska1 complex with the ends of depolymerizing microtubules in vitro, its behavior on elongating microtubules has not been determined. To investigate whether Ska1 can autonomously track the polymerizing microtubule ends, we have used an in vitro assay with dynamic microtubules and two-color TIRF imaging. We observed binding and diffusion of GFP-labeled Ska1 complex on both the GDP-containing and GMPCPP microtubule lattices. Ska1 complex was enriched on the GMPCPP microtubules, suggesting a higher affinity of Ska1 for the GTP-containing tubulin structures as are found at the tip of a polymerizing microtubule. Indeed, we now demonstrate that the Ska1 complex can autonomously track the polymerizing microtubule ends in vitro, reinforcing the model that it helps mitotic chromosomes to associate processively with dynamic microtubule ends. This tip-tracking activity for the Ska1 complex is likely to be driven by a combination of affinity and diffusion-based mechanisms. In addition to binding to the microtubule lattice and curved protofilament structures, we demonstrate that Ska1 binds to soluble tubulin and can promote its oligomerization. We hypothesize that Ska1 interacts with diverse tubulin structures in multiple modes via several interaction surfaces on the microtubule binding domain of Ska1, and that this multimodal binding may contribute to Ska1 microtubule tip tracking. To test these hypotheses, we generated mutants on distinct surfaces of the Ska1 microtubule binding domain that disrupt binding to soluble tubulin, but do not prevent its binding to the microtubule walls. Interestingly, all these mutants failed to track the ends of elongating microtubules. Thus, presence of multiple positively charged tubulin-binding patches in the Ska1 microtubule binding domain is essential for its tip-tracking activity. In summary, our work establishes a molecular requirements for Ska1 microtubule-dependent functions in mammalian cells by

Tuesday-135
demonstrating that interactions between multiple surfaces of Ska1 and tubulin substrates underlie its ability to track the dynamic microtubule end.

A role of Kinesin-5 in controlling Ndc80 functions at kinetochore.
A. Suzuki1, A. Gupta2, S. Biggins2-3, K.S. Bloom1, E.D. Salmon1;
1Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Basic Science, Fred Hutchinson Cancer Research Center, Seattle, WA, 3Howard Hughes Medical Institute, Seattle, WA

In eukaryotes, chromosome segregation machinery mediated by the dynamicity of spindle microtubules (MTs) is an essential and highly conserved process. There are two kinesin-5 family members called Kip1 and Cin8, in budding yeast. Both Kip1 and Cin8 are responsible for crosslinking antiparallel MTs and pushing spindle poles apart. We found the kinetochore localization of both Kip1 and Cin8 was greatest at metaphase and significantly reduced in anaphase. In addition, Kip1 and Cin8 localized close to the MT binding domains of the kinetochore protein Ndc80. The biochemical experiments found that Cin8 directly interacts with Dam1 complex. We confirmed that Dam1 complex is essential for the kinetochore localization of Cin8 in vivo. Depletion of either Kip1 or Cin8 induced a major delay in mitotic progression. In addition, it also induced significant reduction of tension at the MT binding domains of Ndc80 measured by a tension biosensor without changing the stoichiometry of core-kinetochore proteins. These phenotypes observed in kinesin-5 depletion were similar to observed phenotypes when the N-terminal tail was deleted from Ndc80. Interestingly, there was no additional phenotype when either Kip1 or Cin8 was depleted in Ndc80 tailless mutants. These results indicate that the mitotic delay induced by either kinesin-5 deletion or Ndc80 tailless lies within the same pathway. To achieve proper force production at the MT binding domains of Ndc80, the N-terminal tail of Ndc80 needs to be de-phosphorylated properly by PP1 (Protein Phosphatase 1). Biochemical studies showed that Cin8 directly binds PP1, and Cin8 mutated at PP1 binding sites induces a prolonged mitosis like Cin8 deletion. These results indicate that yeast kinesin-5 controls the MT binding affinity of Ndc80 for proper mitotic progression through the interaction with PP1 and Dam1 complex.

Centromeric Protein Dynamics Change in Response to Physiological Changes of Early Embryogenesis in C. elegans.
L. Smith1, C. Barnhardt2, P.S. Maddox2;
1Genetics and Molecular Biology, University of North Carolina, Chapel Hill, NC, 2Biology, University of North Carolina, Chapel Hill, NC

Centromeres in eukaryotic cells carry out fundamental functions during all mitotic cell divisions; they are required for kinetochore assembly, microtubule attachment, and chromosome segregation. The histone-3 variant CENtromeric-Protein-A (CENP-A) is required for establishing the centromere. CENP-A is a relatively unique mitotic protein, as its subcellular localization does not change throughout the cell cycle. Embryogenesis requires millions of cell divisions in vertebrates, however, the dynamics of CENP-A in early development are not known. Here we report the dynamic behavior of CENP-A during early embryogenesis of C. elegans. In order to understand if CENP-A (HCP-3 in C. elegans) dynamics are consistent during the early cell cycles of the C. elegans embryo like they are in cell cultures, we temporally aligned and measured 4D images of early embryos whose only copy of CENP-A is labeled
with GFP. This allowed us to create representative profiles of HCP-3 dynamics throughout each early cell cycle, and throughout entire cell lineages; lineages are fixed in C. elegans as opposed to chaotic development in other organisms. Using this analysis method, we found that HCP-3 levels within each nucleus do not return to their original pre-mitotic levels in response to mitotic dilution during early development, in opposition to that found in somatic growth. In fact, the quantity of HCP-3 loaded onto chromatin each subsequent cell cycle decreases throughout early embryogenesis. We also find that HCP-3 levels rise nearer the end of the cell cycle, occurring after the rise observed for canonical histones during the S-Phase of each cell cycle. In order to resolve these two observations, we assessed protein turnover rate and stability by measuring fluorescence recovery after photobleaching (FRAP) in early embryos. From these data, we were able to ascertain how a cell lineage is able to modulate its amount of nuclear HCP-3 in each cell cycle by changing protein stability and nuclear import levels.

Mad1 promotes tumor progression through destabilization of p53.

J. Wan1, B.A. Weaver1;

1Cell and Regenerative Biology, University of Wisconsin-Madison, MADISON, WI

Mitotic arrest deficient 1 (Mad1) plays a well-characterized role in the mitotic checkpoint. However, interphase roles of Mad1 that do not impact mitotic checkpoint function are still largely uncharacterized. We have found that overexpression of Mad1, which is common in human breast cancer, results in decreased protein stability of the tumor suppressor p53 in multiple cell types. To gain mechanistic insight into this process, we first determined whether increasing expression of Mad1 alters its localization. Upregulated Mad1 localizes to puncta within interphase nuclei in both breast cancer tissue and cultured cells. We found that upregulated Mad1 localizes to ProMyelocytic Leukemia Nuclear Bodies (PML NBs), which have been implicated in the stabilization of p53. Immunoprecipitation results indicate that Mad1 and PML interact and that the C-terminal domain (CTD) of Mad1 and the N-terminal domain of PML are required for this interaction. Within the CTD of Mad1, the SUMO-Interacting Motif (SIM) is critical for the localization of Mad1 to PML NBs. MDM2 is an E3 ubiquitin ligase that targets p53 for degradation. In response to DNA damage, PML sequesters Mdm2 to the nucleolus, which stabilizes p53. In cells with elevated levels of Mad1, Mad1 interrupts the interaction between PML and MDM2. Mad1, rather than MDM2, is sequestered to the nucleolus after DNA damage, suggesting that Mad1 displaces MDM2 from PML. The displaced MDM2 is no longer sequestered in the nucleolus, freeing it to ubiquitinate p53, resulting in p53 destabilization. Upregulation of Mad1 accelerates growth of orthotopic mammary tumors, which show decreased levels of p53 and its downstream effector p21. In addition to causing a low rate of chromosome missegregation, our results show an unexpected interphase role for Mad1 in promoting tumor formation and progression by destabilizing p53.

Numerical Chromosomal instability (CIN) is a form of genomic instability characterized by an increased rate of chromosome missegregation. It is unclear how cancer cells acquire the CIN phenotype. We have
developed a simple computational method that measured the degree of aneuploidy or structural rearrangements of large chromosome regions of >500 human breast tumors from TCGA data to identify the drivers of CIN. RNA analysis demonstrates that aneuploid tumors overexpressed regulators of mitosis, including proteins in the centromere signaling network and key kinetochore proteins. Aneuploid tumors also overexpress regulators of the DREAM complex that regulates the transcription of mitotic genes. Overexpression of the DREAM regulators E2F1, MYBL2 and FOXM1 was sufficient to increase the rate of lagging anaphase chromosomes in a nontransformed vertebrate epithelial tissue validating the results of our computational analysis of human tumors and connecting our aneuploidy measurements to CIN. Highly aneuploid human breast tumors were also highly enriched in TP53 mutations. There was strong co-association of DREAM regulators with TP53 mutations in human breast tumors suggesting that tumors require both events to gain evolutionary fitness. Our data suggest a two-step model for the generation of CIN in breast tumors. First, the overexpression of DREAM complex regulators overexpresses key mitotic regulators to generate anaphase lagging chromatids at higher rates. Second, loss of p53 function allows cells that have missegregated chromosomes to escape the resulting induction of senescence or cell death allowing cells with aneuploidy to undergo selection within the tumor.

Spatial architecture of the biochemical pathways that recruit the Ndc80 complex in human kinetochores.
A.A. Kukreja¹, A.P. Joglekar¹,²,³, S. Kavuri²;
¹Biophysics, University of Michigan, Ann Arbor, MI, ²Cell Developmental Biology, University of Michigan, Ann Arbor, MI, ³Biomedical Engineering, University of Michigan, Ann Arbor, MI

The human kinetochore is a multi-protein machine that binds ~20 spindle microtubules (MTs) to drive chromosome segregation during cell division. Although the biochemical bases of the functions that the kinetochore performs to segregate chromosomes are well-understood, defining the underlying mechanisms has proven to be challenging. This is because the kinetochore is highly complex in composition (hundreds of copies of eight protein components), and large in size (a ~200 nm diameter disk-shaped surface). To understand the molecular mechanisms underlying kinetochore functions, its spatial architecture must be defined. Specifically, the nanoscale architecture of its protein components relative to the 25 nm diameter of a MT, and sub-micron scale organization of ~20 such MT attachments over its ~200 nm wide surface must be determined to reveal how kinetochore components interact with one another, with regulatory proteins, and with the MT lattice. Here we elucidate the nanoscale architecture of the human kinetochore, using FRET to reveal the distribution of its components both around the circumference of the MT (by measuring FRET between multiple copies of the same protein) and along its axis (by measuring FRET between two different proteins). We initiated this analysis with the MT-binding Ndc80 complex, the linchpin of kinetochore-MT attachment. FRET measurements along Ndc80’s 50 nm length reveal its configuration relative to the MT lattice. We find that the MT-binding domains of adjacent Ndc80 molecules are clustered, whereas the centromere-anchored ends are more sparsely distributed. Furthermore, Ndc80 molecules are staggered along the MT lattice by 15-30 nm. Surprisingly, in unattached kinetochores, this Ndc80 architecture remains relatively unchanged except at its MT-binding domains, which separate from one another. We next probed the spatial architecture of the two parallel Ndc80 recruitment pathways initiated by the centromeric proteins CENP-C and CENP-T. Surprisingly, we detect little to no FRET between the Ndc80 recruitment domains of CENP-C or CENP-T, nor between Mis12 complexes, which link Ndc80 to these
recruitment domains. These measurements reveal that Ndc80 recruitment pathways are spatially separated by ≥ 10 nm, in stark contrast to budding yeast kinetochores. Interestingly, using RNAi-mediated protein knockdown of either CENP-C or CENP-T, we find that FRET at the MT-binding end of Ndc80 is not abolished. Thus, despite being spatially separated, Ndc80 molecules recruited by the two parallel pathways converge at the MT lattice. Our data elucidate the spatial architecture of the two biochemical pathways that organize the human kinetochore, and establish a foundation for defining a complete picture of its MT-binding machinery.

HPV oncoproteins cause specific types of chromosomal instability in head and neck cancer.
L.C. Funk1,2,3, D.L. Lee3, P.F. Lambert3,4, R.J. Kimple4,5, B.A. Weaver1,2,3,
1Cell and Regenerative Biology, University of Wisconsin-Madison, Madison, WI, 2Molecular and Cellular Pharmacology, University of Wisconsin-Madison, Madison, WI, 3Oncology, University of Wisconsin-Madison, Madison, WI, 4Carbone Cancer Center, University of Wisconsin-Madison, Madison, WI, 5Human Oncology, University of Wisconsin-Madison, Madison, WI

Aneuploidy, a karyotype that differs from a multiple of the haploid, is a hallmark of cancer. Aneuploidy can be caused by an ongoing rate of chromosome missegregation during mitosis, known as whole chromosomal instability (CIN). Work from our lab and others has shown that while low rates of CIN promote tumorigenesis, high levels of CIN can be tumor suppressive. Human papillomavirus (HPV), specifically HPV subtype 16, is a growing cause of head and neck cancer worldwide. In cervical cancer, HPV is associated with CIN, which has been attributed largely to the expression of its E6 and E7 oncoproteins. HPV+ head and neck cancer patients show improved responses to radiation therapy than HPV- head and neck patients, potentially due to an increased basal rate of CIN. Here, we tested the ability of HPV E6, E7, or E6+E7 expression to induce CIN in normal oral keratinocytes (NOKs). Expression of E6 alone robustly induced misaligned chromosomes and multipolar spindles with supernumerary centrosomes, while E7 expression alone produced more moderate increases. Combined expression of E6 and E7 exacerbated the phenotypes observed in NOKs expressing E6 alone. Interestingly, HPV+ patient-derived xenograft (PDX) models of head and neck squamous cell carcinoma showed less evidence of mitotic defects than NOKs expressing E6 alone. A subset of HPV+ PDX tumors showed an increase in misaligned chromosomes when compared to HPV- tumors, but no increase in lagging chromosomes was observed. Together, these data suggest HPV infection causes an incompletely penetrant increase in specific types of CIN in head and neck cancer.

Ndc80 complex as an intrinsic regulator of molecular friction at mitotic kinetochores.
V.M. Demidov1, S.K. Tripathy1, F.I. Ataullakhanov2, E.L. Grishchuk1;
1Physiology, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, 2Center for Theoretical Problems of Physicochemical Pharmacology, Moscow, Russia

The microtubule wall–binding Ndc80 complex serves as the primary molecular glue connecting mitotic kinetochores to spindle microtubules. During metaphase chromosome oscillations, Ndc80 is thought to form mobile diffusive bonds that enable sister kinetochores to glide repeatedly toward the plus- and minus-ends of the microtubules without detaching. To investigate the biophysical underpinning of this striking behavior, we adopted a highly sensitive dual-trap three-bead assay employing ultrafast force-
clamp spectroscopy in vitro. Microtubule-wall gliding of single Ndc80 molecules was examined under controlled forces, imitating the forces and motions the Ndc80 experiences during metaphase. Unexpectedly, we find that the character of Ndc80 motility and its velocity depend strongly on the direction of force. When pulled toward the microtubule minus-end, Ndc80 obeys the typical prediction for a diffusive MAP: it moves smoothly with little molecular friction, in correspondence with the relatively fast rate of its unloaded diffusion. However, Ndc80 strongly resists forces pulling it toward the microtubule plus-end, exhibiting frequent pauses that are indicative of catch-bond-like behavior. Strikingly, the strongly-bound Ndc80 retains the ability to glide continuously on the microtubule lattice, translocating almost 10-times slower than under the same force acting in the opposite direction. These results strongly suggest that Ndc80 has the ability to serve as an intrinsic direction-specific regulator of molecular friction at human kinetochore. We propose that low internal friction at the force-generating, leading sister kinetochore maximizes the useful work available from the microtubule depolymerization motor to transport the chromosome. The increased friction at the trailing kinetochore should help to prevent its slipping from the microtubule plus-ends, as this kinetochore is dragged passively in this direction by its sister.

Investigating in vivo variation in the strength of the spindle assembly checkpoint.

A.R. Gerhold1, J. Labbé4, P.S. Maddox2;

1Institute for Research in Immunology and Cancer, University of Montreal, Montreal, QC, 2Department of Biology, University of North Carolina, Chapel Hill, NC

The spindle assembly checkpoint (SAC) is a highly conserved mitotic regulator that prevents chromosome segregation errors during cell division, thereby maintaining genome stability. Variation in the strength of the SAC (i.e. the ability to delay mitotic progression in the presence of spindle assembly defects) is a widespread, but poorly understood feature of checkpoint regulation. Using in situ live imaging, we have shown that C. elegans germline stem cells have a stronger SAC than somatic embryonic blastomeres, providing an excellent opportunity to examine variability in SAC activity in vivo and to uncover cell fate-specific adaptations. Here we show that the embryonic progenitors of the adult germline, the P lineage blastomeres, also display a stronger SAC, relative to their somatic peers. Using both Nocodazole treatment of permeabilized embryos and a novel, inducible monopolar spindle assay, we find that cells in the germline lineage exhibit longer mitotic delays than cells with a somatic fate. These differences are entirely dependent on an intact checkpoint and only partially attributable to differences in cell size, which has recently been reported to impact SAC strength in C. elegans embryos. In the 2-cell embryo, we find that roughly half of the difference in checkpoint strength, between the larger somatic AB and the smaller germline P1 blastomere, is due to cell size, with the remainder requiring the asymmetric partitioning of cytoplasmic cell fate determinants downstream of the PAR polarity proteins. To further dissect lineage-specific adaptation of SAC strength, we are using live imaging and a semi-automated tracking and fluorescence quantification approach to monitor the levels and dynamics of key kinetochore and SAC proteins in different cell lineages during embryogenesis. Altogether our results suggest that germline cell fate correlates with enhanced SAC activity, raising the interesting possibility that variation in SAC strength is adaptive, and reveal a novel relationship between asymmetric cell division and SAC regulation.

Spatiotemporal delay of chromosome alignment causes chromosomal instability.
K. Kuniyasu1, K. Iemura1, K. Tanaka1;
1Department of Molecular Oncology, Institute of Development, Aging and Cancer, Tohoku University, Sendai, Japan

The number of chromosomes is kept 46 in normal human cells. In contrast, most solid tumors have abnormal numbers of chromosomes (aneuploidy), usually resulting from high rates of chromosome missegregation (chromosomal instability: CIN). As defects in the essential processes for mitotic progression lead to cell death, it is plausible that CIN in tumors is caused by the defects in the non-essential processes for mitotic progression. For equal chromosome segregation, kinetochores on sister chromatids have to attach to the ends of microtubules (end-on attachment) from opposite spindle poles (bi-orientation). After nuclear envelope breakdown, kinetochores bind to the microtubule lateral surface, referred to as lateral attachment, and quickly move toward the spindle equator. Lateral attachment is then converted to end-on attachment before establishing bi-orientation. Forming end-on attachment at the spindle equator would be advantageous to establish bi-orientation, because there are comparable numbers of microtubules from both spindle poles. Therefore, we hypothesized that efficient chromosome alignment at the spindle equator contributes to bi-orientation establishment and high-fidelity chromosome segregation. Here we verified the hypothesis in several experimental settings. Recently, we reported that a chromokinesin Kid is involved in efficient chromosome alignment (Nat Commun, 2015). Kid-depleted cells progressed through mitosis without mitotic arrest, but took longer time to align chromosomes and showed increased chromosome missegregation. We found that cells depleted of other motor proteins non-essential for mitotic progression also showed increased time to align chromosomes as well as elevated levels of chromosome missegregation. Increased chromosome missegregation was also seen when these motor proteins were overexpressed, a condition often found in cancer cells, suggesting that expression levels need to be within a proper range. We also generated tetraploid cells that have twice as many chromosomes as normal cells as another situation having difficulty in chromosome alignment. Tetraploid cells also showed increased time to align chromosomes and increased levels of chromosome missegregation. Furthermore, abnormal kinetochore-microtubule attachment was preferentially seen in late-aligning chromosomes. These data suggest that spatiotemporal delay of chromosome alignment causes chromosomal instability, which might be related to CIN in cancer cells.

Mechanisms of quantitative transmission of CENP-A nucleosomes through the germline.
A. Das1,2, V. Fu3, A. Iwata-Otsubo1, B.E. Black2, M.A. Lampson1;
1Biology, University of Pennsylvania, Philadelphia, PA, 2Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, 3Genetics, Children's Hospital of Philadelphia, Philadelphia, PA

Accurate inheritance of genetic information is achieved by replicating DNA and partitioning it equally into daughter cells to quantitatively transmit correct copy numbers of genes. Centromeres direct partitioning of chromosomes, but their position on chromosomes is not specified by a particular DNA sequence. They are instead epigenetically defined by the presence of a histone H3 variant, CENP-A, and the location is inherited by maintaining CENP-A nucleosomes. This poses a unique challenge in the germline as CENP-A nucleosomes are maintained quantitatively through both a prolonged prophase I
arrest in mammalian oogenesis and widespread histone replacement in spermatogenesis. Maintaining CENP-A chromatin through gametogenesis preserves centromere structure and ensures reproductive success, but the underlying mechanisms remain unclear. We considered two possible mechanisms for determining the number of CENP-A nucleosomes inherited. First in a template-dependent model, each nucleosome directs local stoichiometric loading of a new CENP-A nucleosome, analogous to semi-conservative DNA replication. Second in a template-independent model, a fixed number of CENP-A nucleosomes is assembled regardless of the abundance of pre-existing CENP-A nucleosomes. To distinguish between these models in the male and female mouse germline, we perform crosses between male and female cenpa +/- mice, which each have reduced CENP-A levels at centromeres, to produce cenpa +/- progeny with wild type expression of CENP-A protein. If epigenetic centromere inheritance is template-dependent, the progeny should inherit a reduced number of CENP-A nucleosomes centromeres despite having normal expression of CENP-A protein. If it is template-independent, CENP-A levels at centromeres will be restored to wild type. In the male germline, CENP-A levels at centromeres are only partially restored after a single generation, indicating epigenetic memory in support of the template-dependent model. We conclude that to maintain centromere identity through the germline, both the position and the quantity of CENP-A nucleosomes is inherited epigenetically.

The kinetochore-dependent and -independent formation of the CDC20-MAD2 complex and its functions in HeLa cells.

J. Li¹, N. Dang¹, D. wood², J. Huang¹;
¹Newcastle University, institute for Cell and Molecular Biosciences, Newcastle, United Kingdom,
²Newcastle University, Northern Institute for Cancer Research, Newcastle Upon Tyne, United Kingdom

The mitotic checkpoint complex (MCC) is formed from two sub-complexes of CDC20-MAD2 and BUBR1-BUB3, and current models suggest that it is generated exclusively by the kinetochores after nuclear envelope breakdown (NEBD). However, neither sub-complex has been visualised in vivo, and when and where they are formed during the cell cycle and their response to different SAC conditions remains elusive. Using single cell analysis in HeLa cells, we show that the CDC20-MAD2 complex is cell cycle regulated with a “Bell” shaped profile and peaks at prometaphase. Its formation begins in early prophase before NEBD when the SAC has not been activated. The complex prevents the premature degradation of cyclin B1. Tpr, a component of the NPCs (nuclear pore complexes), facilitates the formation of this prophase form of the CDC20-MAD2 complex but is inactive later in mitosis. Thus, we demonstrate that the CDC20-MAD2 complex could also be formed independently of the SAC. Moreover, in prolonged arrest caused by nocodazole treatment, the overall levels of the CDC20-MAD2 complex are gradually, but significantly, reduced and this is associated with lower levels of cyclin B1, which brings a new insight into the mechanism of mitotic “slippage” of the arrested cells.

Spindle assembly checkpoint function in the mouse preimplantation embryo.
C. Vázquez-Diez1, G. FitzHarris1,2;
1Centre de Recherche du Centre Hospitalier de l’Université de Montréal, Montréal, QC, 2Département d’Obstétrique et Gynécologie, Université de Montréal, Montréal, QC

Chromosome segregation errors during early embryonic divisions result in embryos comprising a mixture of euploid and aneuploid cells. While such mosaicism is commonly observed in human embryos, how and why it arises remains elusive. Here, we examine the presence, strength and sensitivity of the spindle assembly checkpoint (SAC) in mouse preimplantation embryos. We combine immunofluorescence and live cell imaging approaches to examine chromosome segregation dynamics and SAC function in cleaving embryos. Fast-acquisition live imaging of H2B:RFP-expressing embryos under standard conditions revealed pre-anaphase misaligned chromosomes in ~5% of divisions, suggesting that SAC function is weak in early mouse embryos. To ascertain whether a SAC operates in preimplantation development, embryos were treated from the two-cell to blastocyst stage with the specific SAC inhibitor AZ3146. Immunofluorescence analysis revealed a higher incidence of micronuclei after SAC inhibition (p=0.038). Consistent with this, live imaging experiments show that SAC inhibition results in premature anaphase with increased chromosome misalignment and chromosome segregation errors such as lagging chromosomes (p=0.002). In addition, SAC inhibition is capable of overcoming the mitotic arrest induced by high concentrations of the spindle poison Nocodazole. Thus, a SAC operates in embryos. We next probed SAC strength performing live imaging of embryos in Nocodazole at different developmental stages. Surprisingly, only at morula stage, we observe no anaphase delay despite an increased rate of chromosome mis-segregation, suggesting that a failure to activate SAC signaling in response to spindle damage results in chromosome segregation errors. Interestingly, unlike in mouse oocytes and C. elegans embryos, experimentally reducing cell volume by cytoplasmic removal does not strengthen the SAC in mouse morula stage embryos. Taken together, our results demonstrate that embryos possess a SAC that does limit chromosome mis-segregation, but it is not sufficiently effective to prevent all errors. SAC insufficiency provides a potential mechanistic explanation for mosaicism.

Quantitative analysis of the biochemical cascade that generates the Mitotic Checkpoint Complex.
C. Chen1, A. Fontan2, I.M. Cheeseman3,4, A.P. Joglekar1,2;
1Department of Biophysics, University of Michigan, Ann Arbor, MI, 2Cell Developmental Biology, University of Michigan, Ann Arbor, MI, 3Whitehead Institute for Biomedical Research, Massachusetts Institute of Technology, Cambridge, MA, 4Department of Biology, Massachusetts Institute of Technology, Cambridge, MA

Accurate chromosome segregation during cell division requires that kinetochores of sister chromatids attach to microtubules emanating from opposite spindle poles. In the absence of microtubule attachment, kinetochores generate a diffusible signal that inhibits the Anaphase Promoting Complex/Cyclosome (APC/C) throughout the cell to delay anaphase onset. This inhibitory signal, known as the Mitotic Checkpoint Complex (MCC), is a complex of four signaling proteins: Bub3, BubR1, Cdc20, and Mad2. To prevent anaphase onset, an unattached kinetochore must recruit all four signaling proteins rapidly, and then efficiently assemble them into the MCC. The mechanisms that realize these
objectives are poorly understood, primarily because of two reasons. First, the biochemical cascade that recruits the signaling proteins is extremely complex and incorporates parallel recruitment pathways. Second, the biochemical reactions that lead to MCC formation are spatially localized in a nanoscale volume. To circumvent these difficulties and dissect the mechanisms of MCC assembly, we have engineered a system to ectopically drive the biochemical cascade that assembles the MCC in human cell lines using the knowledge that the phosphorylation of signaling proteins by the Mps1 licenses downstream reactions. Our system uses chemically induced dimerization of the kinase domain of Mps1 with various functional regions of either KNL1, Bub1, or Mad1, three signaling proteins that act as scaffolds in the biochemical cascade that generates the MCC. Upon activation (dimerization in vivo), this system delays the onset of anaphase in a dose-dependent manner. Using this ectopic activation system, we conducted quantitative analyses for various functional regions of all three proteins to study how the duration of mitosis scales with the concentration of the activator complex. Such ‘dose-response’ analysis revealed a novel, prozone-like effect involving BubR1 in MCC generation, wherein the limited abundance of BubR1 produced non-monotonic dose-response characteristics. We will continue employing the ectopic activation system to understand the molecular mechanisms that enable rapid and highly efficient MCC assembly in unattached kinetochores.

The mitotic apparatus of a dividing cell comprises functionally distinct subpopulations of microtubules whose dynamics are intricately regulated by diverse proteins to ensure proper spindle formation and accurate DNA segregation. Previous studies showed that KIF18B, a member of the Kinesin-8 family that destabilizes microtubules, localizes to the plus tips of astral microtubules and attenuates astral microtubule length and number during prometaphase. Plus-tip localization of KIF18B is mediated by EB1 binding to the Kif18B tail, but how KIF18B and EB1 coordinately regulate microtubule dynamics at plus-tips is still not fully understood. Additionally, KIF18B also contains putative nuclear localization signals (NLS) in the tail, which may serve as regulatory sites for the Ran pathway. To dissect how EB1 and the Ran pathway modulate KIF18B function, we developed in vitro FRET biosensors to examine the interactions of Kif18B with EB1 and importin α and to map their binding sites. Using these biosensors, we show that the tail of Kif18B interacts independently with either EB1 or importin α/β and that binding of EB1 to Kif18B can be competitively inhibited by importin α/β. Furthermore, addition of RanQ69L, a GTP analog of Ran, disrupts the interaction between importin α/β and the tail of KIF18B. The tail of Kif18B also binds to microtubules, and its binding to microtubules is inhibited by importin α/β but not by EB1. Using site-directed mutagenesis, we identified two NLS and two EB1 binding sites within the tail domain of Kif18B. The tail of KIF18B contains one non-classical bipartite NLS and one monopartite NLS. Mutation of both NLS sites is required to abolish intermolecular FRET between the tail of KIF18B and importin α/β. Mutation of the NLS sites also reduces the affinity of the tail for microtubules, suggesting that importin α/β binding is used to modulate the interaction of Kif18B with microtubules. The EB1 binding sites do not contain the classical SxIP motif described for EB1 binding, but are rather variations of this site, SFLP and ARLP. Taken together, these data suggest that the presence of redundant binding sites may ensure robust binding of Kif18B with EB1 and importin α/β in vivo. Alternatively, the additional
sites could serve to fine tune Kif18B interaction with its binding partners in a temporal and context-dependent manner in vivo. Testing the importance of these interactions in vivo will give further insights into how KIF18B regulates the dynamics of astral microtubules during mitosis.

Chromosome velocities in the absence of microtubules in *Mesostoma ehrenbergii* spermatocytes are affected by drugs that alter myosin.
E. Fegaras¹, A. Forer²;
¹Biology, York University, Toronto, ON

Throughout cell division in *Mesostoma* spermatocytes the three bivalent chromosomes oscillate towards and away from either pole, at average speeds of 5-6 µm/min, without stopping until anaphase. In experiments reported at previous ASCB meetings, after nocodazole (NOC) was added to cells to depolymerize the microtubules all chromosomes selectively detached from only one pole, curled to one side, and quickly moved towards the opposite pole with initial velocities of up to 200 µm/min or more. Chromosomes then slowed down as they neared the opposite pole. Confocal microscopy confirmed there are no remaining kinetochore-microtubule connections at the detached pole, indicating that this rapid movement does not appear to be due to microtubules.

The current work addresses the following question: if not microtubules, what is responsible for the very rapid chromosome movements to opposite poles? We tested whether myosin might be involved by adding ML7 or BDM, which inhibit MLCK and myosin ATPase respectively, to prometaphase spermatocytes for 5-10 minutes, after which we added 10 µM NOC in conjunction with either ML7 or BDM. If myosin plays a role in chromosome movement then inhibiting myosin should decrease the speed of chromosome movement or stop the movement altogether. In all cells treated with NOC plus ML-7 chromosomes moved more slowly to the opposite pole as compared to NOC alone (average 16 µm/min vs. 35 µm/min). In approximately half of the cells treated with NOC plus BDM chromosomes did not move and in the other half of cells chromosomes moved more slowly at an average 13 µm/min. These results seem to indicate that myosin is involved in the high speed chromosome movements after NOC treatment. We will further test this by seeing if chromosome movement is sped up with Calyculin A, which hyper-activates myosin.

Elastic tethers extend between the telomeres of separating anaphase chromosomes in a broad range of animal cells.
E. Fegaras¹, M.L. Duquette², L.V. Paliulis³, M. Ono², D. Preece², M.W. Berns², A. Forer¹;
¹Biology, York University, Toronto, ON, ²Bioengineering and Institute for Engineering in Medicine, University of California San Diego, San Diego, CA, ³Biology, Bucknell University, Lewisburg, PA, ⁴Beckman Laser Institute and Department of Bioengineering Medicine, University of California, Irvine, CA

“Tethers”, originally described in crane-fly spermatocytes, are elastic components that extend between separating telomeres in anaphase. They exert force on chromosome arms opposite to the direction the anaphase chromosomes move. Our experiments using laser microbeam irradiation of anaphase cells to cut chromosome arms and to cut the tethers themselves show that tethers exist in a broad range of animal cells from Turbellarian flatworms to humans. Thus they are previously unrecognised components of general mitotic mechanisms. They extend between separating telomeres until late anaphase and
cause the arms of the chromosomes to be stretched by about 10%, as indicated by shortening of arms when their tethers are cut. Tethers need to be accounted for in general models of mitosis in terms of forces on chromosomes and in terms of what their roles might be.

1Cell Biology and Biophysics, The European Molecular Biology Laboratory (EMBL), Heidelberg, Germany, 2Developmental Biology, The European Molecular Biology Laboratory (EMBL), Heidelberg, Germany

Intriguingly, in the early mammalian embryo, chromosomes are compartmentalised in a parent-of-origin specific manner. In contrast to many other animal species, karyogamy in mammals does not occur through fusion of the pronuclei after fertilisation but instead parental chromosomes are brought together after replication on the metaphase plate of the first mitosis. Surprisingly, maternal and paternal chromatin occupies distinct hemispheres in the nuclei of the two-cell embryo, and this separation only gradually decreases during subsequent stages of development. Both the mechanism underlying parental genome separation and its functional importance for embryonic development are currently unclear. Utilising the high spatio-temporal resolution of our recently developed inverted light-sheet microscope, we reveal that the formation of two separate bipolar spindles around each parental pronucleus keeps maternal and paternal genomes apart during the first cleavage of the zygote. Based on this mechanistic understanding we were able to experimentally mix parental chromosomes during the first embryonic division in order to understand if separate nuclear compartments are required for normal development.

GTSE1 REGULATES SPINDLE MICROTUBULE DYNAMICS TO CONTROL AURORA B KINASE AND KIF4A CHROMOKINESIN ON CHROMOSOME ARMS.
A.R. Tipton, J.D. Wren, J.R. Daum, J.C. Siefert, G.J. Gorbsky

In mitosis, the dynamic assembly and disassembly of microtubules are critical for normal chromosome movement and segregation. Microtubule turnover varies among different mitotic spindle microtubules, dictated by their spatial distribution within the spindle and by their interactions with each other and with other organelles such as kinetochores, chromosome arms, and the cell cortex. How turnover among the various classes of spindle microtubules are differentially regulated and the resulting significance of differential turnover for chromosome movement remains a mystery. As a new tactic, we used GAMMA, a bioinformatic method, to identify novel regulators of mitosis. GTSE1 (G2 and S phase expressed protein 1) was selected for further analysis based on previous findings demonstrating GTSE1 association with microtubules. GTSE1 is expressed exclusively in late G2 and M phase. Additionally, GTSE1 has been shown to function as an EB1-dependent plus-end tracking protein. However, following nuclear envelope breakdown in mitosis, GTSE1 microtubule plus-end tip tracking is inhibited until anaphase onset and instead the protein decorates the microtubule lattice. During this time GTSE1 binds
preferentially to the most stable populations of mitotic spindle microtubules and promotes their turnover. Cells depleted of GTSE1 show defects in chromosome alignment at the metaphase plate coupled with an increase in the proportion of stable mitotic spindle microtubules. Photoactivation data show that GTSE1 fosters turnover of the most stable population of microtubules within the mitotic spindle from prometaphase to anaphase onset. At anaphase onset, GTSE1 returns to tip tracking and redistributes to the ends of astral microtubules. We speculate that this redistribution prevents GTSE1 from destabilizing midzone microtubules during anaphase and telophase. Cells depleted of GTSE1 display hyper-stabilized spindle microtubules, which in turn affects the activity of the mitotic kinase, Aurora B, on chromosome arms with negligible effects on Aurora B at centromeres. The loss of Aurora B activity on chromosome arms diminishes accumulation of the chromokinesin Kif4A. In sum, we have identified a novel pathway in which GTSE1 is an upstream regulator of microtubule stability, chromosome alignment, spindle pole integrity, and timely mitotic progression.

Interplay between microtubule bundling and sorting factors ensures acentriolar spindle stability during C. elegans oocyte meiosis.
T.J. Mullen¹, S.M. Wignall¹;
¹Molecular Biosciences, Northwestern University, Evanston, IL

During mitosis, duplicated centrosomes nucleate microtubules and form the spindle poles. However, oocytes of most species lack centrioles, so spindles assemble using a different pathway. Recently, we reported that acentriolar spindle assembly in C. elegans oocytes proceeds by: 1) formation of a cage-like microtubule array inside the disassembling nuclear envelope, 2) sorting of microtubule minus ends to the periphery of the array, and 3) focusing of these ends into nascent poles that coalescence until bipolarity is achieved. Moreover, we demonstrated that the kinesin-12 family motor KLP-18 acts during the sorting step to force the minus-ends outwards where they can be organized into the spindle poles (1). Now, we have uncovered additional insights into the principles underlying this specialized form of cell division, through studies of KLP-15 and KLP-16, two highly homologous members of the minus-end-directed kinesin-14 family. Fixed and live imaging of KLP-15/16-depleted oocytes revealed that following nuclear envelope breakdown, microtubules form a transient cage-like structure, but then microtubules collapse into a disorganized ball-shaped structure surrounding the chromosomes. These results suggest that KLP-15/16 bundle and organize microtubules during acentriolar spindle assembly, and consistent with this proposed function, these proteins localize to spindle microtubules during the cage stage and remain microtubule-associated throughout the meiotic divisions. However, despite the severe spindle assembly defects observed following KLP-15/16 depletion, we were surprised to find that these disorganized microtubules were then able to reorganize into a spindle capable of segregating chromosomes during anaphase, revealing the existence of additional mechanisms that can act to bundle and organize spindle microtubules. This phenotype therefore enabled us to identify factors promoting microtubule organization and assembly during anaphase, whose contributions are normally imperceptible in wild-type worms. First, we discovered that SPD-1 (PRC1), which loads onto microtubules in early anaphase, is required for the formation of anaphase microtubule bundles in the absence of KLP-15/16. Moreover, we found that KLP-18, which sorts microtubules during spindle assembly, can then function during anaphase to sort these bundles into a functional orientation capable of mediating chromosome segregation. Therefore, our studies have revealed an interplay between distinct mechanisms that together promote spindle formation and chromosome segregation in the absence of structural cues such as centrioles. Chromokinesin Kif4 is required for faithful chromosome segregation in mammalian oocytes.
C.M. Heath1, S.M. Wignall1;
1Molecular Biosciences, Northwestern University, Evanston, IL

Spindles in female meiotic cells (oocytes) lack centrosomes, which usually serve to nucleate microtubules and organize spindle poles. Despite the importance of oocyte meiosis to successful reproduction, how acentrosomal spindles interact with chromosomes and mediate accurate segregation is poorly understood. We are investigating the contribution of a kinesin, Kif4, to the meiotic divisions in mouse oocytes. Kif4 is a plus-end directed microtubule motor in the kinesin-4 family that contributes to chromosome organization and midzone formation in mitotically-dividing cells. However, its roles in oocyte meiosis are less well understood. Using immunofluorescence microscopy, we found that, similar to mitosis, Kif4 localizes to chromosomes from prometaphase to metaphase. However, in oocytes Kif4 displayed a dynamic localization pattern during these stages, as it was excluded from kinetochores and only on chromosomes arms during prometaphase but then became kinetochore-enriched at metaphase, the stage at which kinetochore-microtubule attachments are formed in mouse oocytes. During anaphase, Kif4 relocalized to the spindle midzone; it first appeared in stretches along microtubules and then concentrated into distinct ring-like structures that appeared to organize bundles of microtubules. Other midzone proteins, MgcRacGAP (part of the centralspindlin complex) and PRC1 (protein regulator of cytokinesis 1), also localized to these structures. During mitosis, PRC1 bundles microtubules and binds to Kif4, and our localization data suggest that this relationship is maintained in oocytes. Together, the observed Kif4 localization pattern raised the possibility that this motor could be involved in chromosome dynamics and spindle midzone formation in oocytes. Consistent with this idea, depletion of Kif4 using morpholinos resulted in severe anaphase defects, including chromosome bridges and defective midzone formation, indicating that Kif4 has important functions in oocytes. Building on these results, we also found that treatment of oocytes with AZD1152, an Aurora B/C kinase inhibitor, inhibited localization of Kif4 to metaphase chromosomes and to the anaphase spindle midzone, suggesting that Aurora B/C regulate Kif4 localization. In addition, this treatment caused severe chromosome architecture and segregation defects, some of which resemble Kif4 depletion defects. Moreover, the anaphase spindles appeared disorganized and unstable, indicating that Aurora B/C plays an important role in anaphase spindle organization and thus proper chromosome segregation. Taken together, our work has revealed essential roles for Kif4 during the meiotic divisions and forms the basis for further understanding mechanisms promoting accurate chromosome segregation in acentrosomal oocytes.

Proper rotation of the mitotic spindle requires an equatorial spindle centering mechanism in human cells.
I. Zulkipli1,2, R.L. Shrestha1,3, J. Clark1, V.M. Draviam4;
1Department of Genetics, University of Cambridge, Cambridge, United Kingdom, 2Universiti Brunei Darussalam, Brunei, Brunei Darussalam, 3National Institutes of Health, Bethesda, United States, 4Cell and Molecular Biology, Queen Mary University of London, London, United Kingdom

Successful rotation requires a well-defined rotational center. The mitotic spindle is precisely rotated to a pre-determined position, which determines the plane of cell division and thus, the position of
daughter cells within tissues. While it is known that Dynein powers spindle rotation in human cells, it is not clear how the center of rotation is controlled. To address this we analyzed spindle movements in 100s of single-cells exposed to protein depletion or drug treatment regimens and uncovered a role for MARK2 in maintaining the spindle at the geometric center of human epithelial cells. In MARK2 depleted cells, spindles fail to rotate and instead glide along the cell cortex; this failure to center and rotate normally leads to a failure in establishing the correct plane of cell division. Surprisingly, spindle off-centering in MARK2 depleted cells is not due to excessive pull by cortical Dynein. We show that MARK2 modulates mitotic microtubule growth and length, and increasing microtubule stability is sufficient to rescue the off-centering of spindles in MARK2-depleted cells. Thus, we report a novel MARK2-dependent spindle centering mechanism and provide the first insight into a spindle centering mechanism that ensures the proper rotation of spindles and plane of division in human cells.

Rapid degradation of gamma-TuRC component GCP2 causes spindle collapse in mitosis.

E.A. Turcotte¹, S.G. Regmi¹, V. Aksenova¹, A. Arnaoutov¹, M. Dasso¹;

¹Division of Molecular and Cellular Biology, National Institute of Child Health and Human Development, Bethesda, MD

The gamma-tubulin ring complex (gamma-TuRC) acts as a structural scaffold for microtubule nucleation. The complex is composed of GCP2, GCP3, GCP4, GCP5 and GCP6, and localizes to centrosomes, microtubules, kinetochores and the nuclear envelope. GCP2 and 3 bind gamma-tubulin to form the highly conserved gamma-tubulin small complex (gamma-TuSC), and upon association with GCP4, 5 and 6 comprise gamma-TuRC. Studies aimed at elucidating the role of gamma-TuRC components in microtubule nucleation have traditionally relied on siRNA-based approaches which require long incubation to achieve complete protein depletion. With the aim of depleting the protein in minutes, we biaxially inserted an Auxin-Inducible Degron (AID) tag onto the endogenous locus of GCP2 using CRISPR/Cas9 in DLD-1 cells. In the resultant cells, the bulk of GCP2 was degraded within 15 minutes of auxin addition, becoming undetectable within 45 minutes. Under GCP2-depleted conditions, we observed that GCP3 and gamma-tubulin are displaced from the centrosome, whereas other gamma-TuRC members remain unaffected. The majority of GCP2-depleted cells arrested in metaphase with a monopolar-like spindle. Some of the arrested cells eventually appeared to exit mitosis and decondense their chromosomes, possibly indicating spindle assembly checkpoint failure after extended arrest. Notably, live imaging showed that even established bipolar spindles underwent spindle collapse after rapid degradation of GCP2. Our results indicate that mitotic DLD-1 cells can maintain extensive microtubule arrays in the absence of gamma-TuRC, but that the normal spindle morphology and function are dramatically impaired. We will discuss our efforts to understand these defects at the level of microtubule dynamics and spindle organization.

In the *C. elegans* early embryo, the pronuclei complex migrates to the cell center and rotates such that the mitotic spindle forms along the anterior-posterior axis. Subsequently, the spindle undergoes transverse oscillations as it moves toward the posterior. This asymmetric spindle positioning is crucial for asymmetric cell division and proper development. The contributions of pushing, cortical pulling, and cytoplasmic pulling forces to those dynamic centrosome positioning events are not fully understood. To study these processes, we constructed a novel laser ablation system capable of creating nearly arbitrary 3D cuts of astral microtubules at any desirable timing. We used this system to dissect the relative contribution of pushing and pulling forces throughout pronuclei and spindle motions. Our results suggest that all of these motions are dominated by net pulling. We used microinjected fluorescent nanodiamonds to track cytoplasmic fluid flow, which indicates that cortical pulling forces dominate over cytoplasmic pulling at all stages. We used computer simulations and mathematical modeling to interpret our experimental data. Taken together, our results strongly argue that cortical pulling drives pronuclear migration and rotation, metaphase spindle positioning, asymmetric spindle positioning and all aspects of spindle oscillations.

$^{1}$Faculty of Natural System, Institute of Natural Science and Technology, Kanazawa University, Kanazawa, Japan, $^{2}$Division of Translational and Clinical Oncology, Cancer Research Institute, Kanazawa University, Kanazawa, Japan, $^{3}$Cell-Bionomics Research Unit, Innovative Integrated Bio-Research Core, Institute for Frontier Science Initiative, Kanazawa University, Kanazawa, Japan, $^{4}$Bio-AFM Frontier Research Center, Kanazawa University, Kanazawa, Japan

Glycogen synthase kinase (GSK)-3 mediates fundamental cellular signaling pathways and emerges as a potential therapeutic target in many cancer types including colorectal cancer (CRC). During mitosis, GSK3 localizes in mitotic spindles and centrosomes, however its function is largely unknown. We previously demonstrated that translocated promotor region (Tpr: a nuclear pore component) and dynein (a molecular motor) cooperatively contribute to mitotic spindle formation. Such knowledge encouraged us to investigate putative functional interaction among GSK3, Tpr and dynein in mitotic machinery in CRC cells. Here we show that, inhibition of GSK3 attenuated proliferation of CRC cells and induced cell cycle arrest at the G2/M phase and their apoptosis. Morphologically, GSK3 inhibition disturbed chromosome segregation, mitotic spindle assembly and centrosome maturation during
mitosis and ultimately resulting in mitotic cell death. These changes in CRC cells were associated with decreased expression of Tpr and dynein as well as disruption of their functional colocalization with GSK3 in mitotic spindles and centrosomes. Clinically, we showed that Tpr expression was increased in CRC databases and primary tumors of CRC patients respectively. Furthermore, Tpr expression in SW480 cells xenografted in mice is reduced following treatment with GSK3β inhibitors. Together, these results indicate that GSK3 sustains steady mitotic process for proliferation of CRC cells via interaction with Tpr and dynein, thereby suggesting that the therapeutic effect of GSK3 inhibition depends on the induction of mitotic catastrophe in CRC cells.

Ectopic JNK activity during aging increases symmetric divisions by altering spindle pole orientation.
D.J. Hu¹, H. Jasper¹,²;
¹Buck Institute for Research on Aging, Novato, CA, ²Immunology Discovery, Genentech, San Francisco, CA

Proliferation of stem cells (SC) is carefully regulated to maintain tissue regeneration without becoming cancerous. As animals age, SC function becomes aberrant and leads to failure in tissue maintenance, contributing towards many age-associated diseases and ultimately, limiting lifespan. Signaling pathways that maintain SC activity, including JNK, become overactive in the aging condition and cause overproliferation and cell fate defects. The mechanisms in which these pathways cause these stem cell defects, however, are not well understood. Using the Drosophila intestine as a genetically accessible model to explore stem cell function, we find that spindle pole orientation in stressed or aging intestinal stem cells (ISCs) is dramatically shifted parallel to the basement membrane, generating more symmetric divisions. Overactivating JNK phenocopies the age-associated spindle pole orientation defect while disrupting JNK in stressed or aging conditions is sufficient to restore proper spindle pole orientation. We find evidence supporting that JNK regulates spindle pole orientation both directly and transcriptionally. Restoring normal spindle pole orientation in aging and age-associated conditions not only restores cell fate, but also preserves the barrier function of the intestine and increases overall longevity, providing a mechanism to the aging process. These results deepen our understanding of the cell fate regulation in the aging barrier epithelia and provide insight into mechanisms preserving long-term tissue homeostasis.

Activated Ezrin controls cortical MISP levels to ensure correct NuMA localization and spindle orientation.
I.M. Hoffmann¹; Y.T. Schlosser¹;
¹F045, Cell Cycle Control and Carcinogenesis, German Cancer Research Center, DKFZ, Heidelberg, Germany

Correct spindle orientation is achieved through signaling pathways that provide a molecular link between the cell cortex and astral microtubules in an F-actin dependent manner. Activation of ERM proteins (Ezrin/Radixin/Moesin) controls localization of LGN and NuMA force-generator complexes at the cell cortex. Here we show that the actin-binding protein MISP that has been implicated in spindle orientation directly interacts with Ezrin. Moreover, activated Ezrin ensures appropriate cortical MISP
levels in mitosis by preventing its excessive accumulation. Enrichment of MISP in turn abolishes cortical NuMA polarization and leads to hyper-stabilization of astral microtubules. On the contrary, loss of MISP results in enhanced cortical NuMA localization. Cdk1-dependent phosphorylation of MISP is required for polarized NuMA localization. Our data implicate that MISP functions as a molecular linker between Ezrin and NuMA. We propose that enrichment of MISP at the cortex promoted by SLK/LOK-activated Ezrin is required for proper NuMA localization and spindle orientation.

Importin alpha/beta regulates XCTK2 localization within the spindle and promotes parallel microtubule cross-linking and sliding.
S.C. Ems-McClung, L.N. Weaver, C.E. Walczak;
1Medical Science Program, Indiana University, Bloomington, IN, 2Biology, Indiana University, Bloomington, IN

The mitotic spindle is critical for the accurate segregation of chromosomes into daughter cells. A major regulator of spindle assembly is the small GTPase Ran, which forms a gradient of RanGTP around the chromatin that extends to the spindle poles. RanGTP activates spindle assembly factors (SAFs) by releasing the inhibitory action of importin alpha/beta. Our previous work demonstrated that XCTK2, a Kinesin-14 that cross-links and slides microtubules (MTs), was regulated by the Ran system; and we proposed that the Ran gradient around the chromosomes would release the importins from XCTK2, allowing it to cross-link and slide MTs in that vicinity. To test this model, we generated a series of FRET biosensors of XCTK2 and importin alpha to look at their interactions in the spindle and in vitro. CyPet-XCTK2 interacts directly with importin alpha-YPet and importin beta through its tail domain, resulting in a high FRET ratio that can be reduced by the addition of the RanGTP analog RanQ69L. Surprisingly, our initial fluorescence lifetime imaging microscopy (FLIM) studies suggest there is a bias of importin alpha interaction with XCTK2 around the chromatin compared to the poles. Consistent with these results, we see an enrichment of importin alpha on the chromatin relative to the spindle and cytoplasm. Addition of a nuclear localization signal mutant of XCTK2 in our FLIM assay resulted in reduced association around chromatin and enrichment of the mutant XCTK2 near the poles, consistent with its reduced affinity to importin alpha/beta. Together these results suggest that importin alpha association may facilitate the loading of XCTK2 to the plus ends of MTs near chromatin where it could walk toward the poles. To understand how importin alpha/beta affect XCTK2 MT cross-linking and sliding, we reconstituted XCTK2 MT cross-linking and sliding in vitro and found that importin alpha/beta reduced the overall MT sliding events, consistent with the idea that the importins reduce MT association. Surprisingly, the anti-parallel MT sliding events were specifically reduced relative to the parallel MT sliding events in the presence of the importins, suggesting a bias toward parallel MT sliding that could facilitate pole formation. These results suggest that Ran regulation of spindle assembly may not be simply through the release of the importins along a gradient, but may also involve directed localization within the spindle.

Xenopus borealis egg extracts: a new system to investigate spindle variation.
M. Kitaoka1, R. Gibeaux1, R. Heald1;
1Molecular and Cell Biology, University of California, Berkeley, Berkeley, CA

Egg extracts of the African clawed frog, Xenopus laevis, have provided an instrumental in vitro cell-free system to elucidate fundamental aspects of the cell cycle, including mechanisms of spindle assembly. To study mechanisms of spindle and organelle size control, we have previously utilized a smaller, related frog, Xenopus tropicalis. Here, we investigate the Marsabit clawed frog, Xenopus borealis. While the allotetraploid X. laevis and diploid X. tropicalis are 48 million years apart, X. borealis is more closely related to X. laevis, having diverged 17 million years ago. Both X. laevis and X. borealis possess allotetraploid genomes of 36 chromosomes, although X. laevis frogs (~10 cm adult body length) are larger than X. borealis (~7 cm). In contrast, X. tropicalis frogs possess a diploid genome with 20 chromosomes and are significantly smaller (~4 cm). Scaling at the organismal level between X. laevis and X. tropicalis is accompanied by differences in the size of the egg as well as nuclei and spindles formed in egg extracts. We developed an X. borealis egg extract to provide a new system to further investigate interspecies spindle scaling and morphometric variation. As with X. laevis and X. tropicalis, spindles formed in extracts prepared from metaphase cytostatic factor (CSF) arrested X. borealis eggs appeared very similar to meiosis II spindles in vivo. CSF-arrested X. borealis formed spindles around various sources of DNA, including sperm and embryo nuclei and chromatin-coated beads, and could be cycled through interphase. Interestingly, X. borealis cycled spindles showed similar length but decreased width compared to X. laevis, and the microtubule distribution across the length of the spindle differed noticeably from both X. laevis and X. tropicalis. Mixing experiments revealed that titration of X. borealis extract with X. laevis extract did not alter spindle size, whereas addition of X. tropicalis extract caused X. borealis spindles to shrink, potentially indicating common scaling phenomena across the three species. Ongoing experiments aim to evaluate the role of known key players in spindle assembly and microtubule organization, such as the RanGTP gradient, in establishing spindle size and morphology in X. borealis extract.

CENP-E-PRC1 interaction provides a temporal cue for central spindle assembly.
Y. Liu1,2, W. Wang1,2, P. Yao1, D. Li2, X. Wang1,2, H. Wang2, X. Liu1,2, X. Yao1,2;
1Physiology, Morehouse school of Medicine, Atlanta, GA, 2Anhui Key Laboratory for Cellular Dynamics Chemical Biology, University of Science and technology of China, Hefei, China

Mitotic kinesin CENP-E plays key roles in chromosome congression and spindle checkpoint satisfaction. We have recently identified and characterized syntelin, a novel allosteric inhibitor selective for CENP-E (Ding et al., 2010. Cell Res. 20, 1386-1389; Mo et al., 2016. Nat. Chem. Biol. 12,226-232; Liu et al., 2016. J Mol Cell Biol. 8,144-156). Cells treated with syntelin progress through interphase, enter mitosis normally with a bipolar spindle and lagging chromosomes around the poles. Our optical trap analyses show that syntelin is an allosteric inhibitor which tightens CENP-E-microtubule interaction by slowing inorganic phosphate release. To delineate the role of CENP-E in reorganization of interpolar microtubules into an organized central spindle, metaphase synchronized cells were exposed to syntelin and other mitotic motor inhibitors. Syntelin does not perturb inter-polar microtubule assembly but abrogates the anti-parallel microtubule bundle formation. Real-time image shows that CENP-E inhibited

Tuesday-153
cells undergo central spindle splitting which is confirmed by transmission electron microscopic analyses. Using a syntelin affinity matrix, we identified a novel CENP-E complex containing PRC1. Interestingly, inhibition of CENP-E did not alter the interaction between CENP-E and PRC1 but perturbed temporal assembly of PRC1 to the midzone. These findings reveal a previously uncharacterized role of CENP-E motor in temporal control of central spindle assembly. Currently, we are reconstituting the central spindle sliding assay in vitro and delineate how CENP-E-PRC1 interactions establish the central spindle and promote spindle elongation using super-resolution imaging analyses.

She1 Preferentially Crosslinks Parallel Microtubules to Ensure Spindle Stability for Spindle Positioning.
Y. Zhu1, A. Tomaszewski1, P.K. Hepler1, W. Lee2;  
1Biology Department, Umass Amherst, Amherst, MA, 2Department of Biological Sciences, Dartmouth College, Hanover, NH

Dynein mediates spindle positioning in budding yeast by pulling on astral microtubules from the cell cortex. The microtubule-associated protein She1 regulates dynein activity along astral microtubules and directs spindle movements toward the bud cell. In addition to localizing to astral microtubules, She1 also targets to the spindle, but its role on the spindle remains unknown. Using function-separating alleles, live-cell spindle assays, and in vitro biochemical analyses, we show that She1 is required for the maintenance of metaphase spindle stability. She1 binds microtubules via a C-terminal microtubule-binding site and preferentially crosslinks microtubules in a parallel configuration. EM and sedimentation analyses reveal that She1 self-assembles into ring-shaped oligomers, formation of which appear to be disrupted by Ipl1/Aurora phosphorylation. In cells, She1 stabilizes interpolar microtubules, preventing spindle deformations during movement, and we show that this function is regulated by Ipl1/Aurora B phosphorylation during cell cycle progression. Our findings reveal how She1 ensures spindle integrity during spindle movement across the bud neck and suggest a potential link between regulation of spindle integrity and dynein pathway activity.

Vesicular trafficking plays a role in centriole disengagement and duplication.
S. Xie1, J. Reinecke2, K. Bahl3, N. Naslavsky1, G.C. Rogers3,4, S. Caplan1;  
1Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE, 2Steady Family Department of Pediatrics, University of Iowa Stead Family Children’s Hospital, Iowa City, IA, 3University of Arizona, The Department of Cellular and Molecular Medicine, Tucson, AZ, 4University of Arizona, University of Arizona Cancer Center, Tucson, AZ

Centrosomes, as the major microtubule-organizing centers of cells, play a crucial role in microtubule anchoring, organelle positioning, primary ciliogenesis, and cell cycle progression. At the centrosome core lie a tightly-associated or ‘engaged’ mother-daughter centriole pair. During mitotic exit, centrosomes are licensed to duplicate by the process of ‘disengagement’ when the inter-centriolar linkers that hold mother-daughter centrioles together are degraded. The degradation of such linkers usually renders the removal of pericentriolar matrix components, including Cep215/Cdk5RAP2 and
pericentrin/PCNT. This process ensures that centrosomes duplicate only once each cell cycle, which is critical for proper centrosome function. Despite the importance of Cep215 and pericentrin removal on disengagement and duplication, little is known about the mode by which they are eliminated. Herein, we explore a new mechanism involving vesicular trafficking for the removal of Cep215 from the centrosome. We show that EHD1, an ATPase and endocytic regulatory protein, is required for the transport of Cep215 from centrosomes to the spindle midbody, thus facilitating disengagement and duplication. Cep215 is transported on transferrin-containing vesicles away from centrosomes in an EHD1-dependent manner. We also show that EHD1 and Cep215 are in a complex with the distal appendage protein CP110, which is functionally involved in EHD1-mediated removal of Cep215. Our data supports a previously unknown role for vesicular trafficking in the regulation of the centrosome cycle.

The small ovary (sov) gene is essential for centrosome function and cell cycle progression during embryogenesis.
E.A. Castro¹, D.A. Lerit²;
¹Cell Biology, Emory University School of Medicine, Atlanta, GA

In the germline stem cell niche, cues for either stem cell renewal or differentiation arise both cell autonomously and from neighboring somatic niche cells. Proper orchestration of these cues is critical for germline development. Using clonal knockdown approaches, we demonstrate that the Drosophila small ovary (sov) gene, or CG14438, is differentially required in somatic and germline lineages during female germline development. Loss of sov in the niche results in massive tissue degradation, failed oogenesis, and ovarian tumors. Conversely, while sov knockdown in the germline permits oogenesis, the resulting embryos exhibit numerous defects. Consistent with a role in germline development, embryos deficient in sov produce fewer primordial germ cells. Moreover, sov mutant embryos display increased nuclear fallout, dysmorphic nuclei during metaphase/anaphase, and aneuploidy, ultimately resulting in embryonic lethality within the first few hours of embryogenesis. In the syncytial embryo, centrosomes are microtubule-organizing centers essential for error-free nuclear divisions. Further analysis confirmed that loss of sov results in centrosome disorganization, detachment, and mispositioning. Taken together, these data suggest Sov regulates centrosome function and is essential for proper cell cycle progression and embryonic viability.

Proximity labeling to define the nucleoporin-interactome at centrioles.
N. Vishnoi¹, K. Dhanasekaran¹, M.K. Khokha², P. Lusk¹;
¹Department of Cell Biology, Yale School of Medicine, New Haven, CT, ²Department of Genetics and Pediatrics, Yale School of Medicine, New Haven, CT

Nuclear pore complexes (NPCs), which control the exchange of molecules between the nucleus and cytoplasm, are massive assemblies of proteins called nucleoporins (nups). Nups also moonlight in other subcellular locations with several established connections to the mitotic apparatus (1). For example, in previous work, we showed that the inner ring nucleoporin Nup188 localizes to the bases of cilia, surrounding the mother and daughter centrioles (2). A key challenge, however, is that it remains difficult to determine a specific pericentriolar function for Nup188 outside of its established role at NPCs.
Therefore, we have undertaken a proximity-dependent biotin identification (BioID) strategy to interrogate the pericentriolar-specific interactome for Nup188. We generated stable cell lines expressing the promiscuous biotin ligase BirA or BirA-Nup188 fusion protein and validated the BirA-Nup188 specific biotin labeling of both NPCs and centrosomes by fluorescence imaging. Mass spectrometry analysis of biotinylated proteins derived from total cell extracts identified all previously reported NPC-specific interactions for Nup188, supporting the functionality of the BirA-Nup188 construct. To specifically assess pericentriolar interactions, we purified centrosomes by density-gradient centrifugation and affinity purified biotinylated proteins from these isolated fractions. We identified several pericentriolar proteins including Cep152, Cep192 and PCM1, in addition to several, potentially centriolar-specific nups. Interestingly, depletion of either Cep152 or Cep192 leads to the loss of Nup188 localization specifically at centrioles, suggesting a model in which key centriolar components recruit Nup188 to the pericentriolar material (PCM). These interactions provide a genetic framework to be able to directly probe the function of Nup188 outside of NPCs.

Activation of the centrosome’s microtubule-assembly activity by the Zika virus (ZIKV).
R.A. Buchwalter¹, J.V. Chen¹, C. Hammack², S.C. Ogden², H. Tang², T.L. Megraw²;
¹Department of Biomedical Sciences, Florida State University, Tallahassee, FL, ²Department of Biological Sciences, Florida State University, Tallahassee, FL

Recent outbreaks of the Zika virus (ZIKV) in the Americas have resulted in a public health crisis due to its links to microcephaly and additional birth defects collectively known as congenital Zika syndrome. Our lab investigates the inherited forms of microcephaly, which are due to mutations in centrosome protein-encoding genes. The centrosome, found in most animal cells, is the major microtubule-organizing center (MTOC). However, the functional link between centrosomes and the development of microcephaly remains unclear. We are investigating how ZIKV infection affects centrosome function. We found that the centrosome’s MTOC activity is elevated upon ZIKV infection. We also found a close association between the centrosome and the assembly of the viroplasm, a ER-derived compartment that is responsible for virus replication and assembly. These viroplasms have a toroid shape with the centrosome positioned in its center with a core of dense microtubules composed of both tyrosinated and acetylated tubulin. When treated with centrinone, a drug that results in centrosome elimination, viroplasm assembly is impaired. The activated centrosome appears to organize the toroid shape of the viroplasm as this structural element is lost in the infected drug-treated cells. One particular centrosomal protein is recruited at higher levels to centrosomes in ZIKV infected cells compared to uninfected cells. This protein is recruited to the centrosome in response to ZIKV, and we surmise that it is required for centrosomal activation during viral infection. We further propose that ZIKV-mediated centrosome activation is required for ZIKV viroplasm organization.

Identification of novel regulators of centriole duplication in Caenorhabditis elegans.
J. Iyer1, N. Peel2, Y. Liu3, K.F. O’Connell1;
1NIDDK, NIH, Bethesda, MD, 2Department of Biology, The College of New Jersey, Ewing, NJ

Centrosomes are organelles comprised of two centrioles (one mother and one daughter) and a surrounding pericentriolar material (PCM). The centrosome is the major microtubule-organizing center of the cell and aids in building the mitotic spindle. In quiescent cells, the mother centriole serves as a basal body for cilia assembly. Centrioles are duplicated only once per cell cycle and this involves the formation of a single daughter centriole next to each mother. Dysregulation of this process can result in aneuploidy, a hallmark of cancer cells. Therefore, it is critical that centriole duplication be tightly regulated. All the core components of the centriole duplication pathway that have been identified in C. elegans are conserved in humans. We are interested in understanding the molecular mechanisms by which proper centriole number is maintained in the cell. The kinase ZYG-1 (Plk4 in humans) is a master regulator of centriole duplication. Depleting ZYG-1 prevents centriole duplication while increasing its levels or activity causes centriole over-duplication. We are currently performing genetic suppressor screens for a hypomorphic loss-of-function zyg-1 allele (zyg-1(it25)) as well as using biochemical assays and mass spectrometry to identify novel proteins that regulate centriole duplication. Using our genetic suppressor approach, we have identified the proteins PP1, I-2, SDS-22 and CHD-1 as negative regulators of centriole duplication. We recently showed that PP1 acts as a molecular brake for centriole duplication and its activity is required to ensure that one and only one daughter centriole forms next to each mother during centriole duplication. We have also identified the chromatin remodeling protein CHD-1 as an additional negative regulator of centriole duplication. At the restrictive temperature, the loss of CHD-1 function partially rescues the embryonic lethality and centriole duplication defects of the zyg-1(it25) mutant. To complement our genetic approach, we have screened for proteins that physically interact with ZYG-1. Preliminary experiments indicate that one of the candidate proteins positively regulates centriole duplication. We also identified LIN-23, a known negative regulator of centriole duplication as a ZYG-1-interacting protein in our assay. Thus, using this approach, we can expect to identify both positive as well as negative regulators of centriole duplication. In the future, we will assay whether any of the other ZYG-1-interacting proteins regulate centriole duplication and will also determine the underlying mechanism.

Using Genome Wide CRISPR/Cas9 Screens to Elucidate How Cells Arrest Following Centrosome Amplification.
L.T. Evans1, T. Anglen1, A.J. Holland1;
1Molecular Biology and Genetics, Johns Hopkins, Baltimore, MD

Centrosomes are the main microtubule organizing centers of mammalian cells and play an important role in guiding the formation of the bipolar spindle apparatus upon which chromosome are segregated. Centrosome copy number is normally precisely controlled so that cells possess exactly two copies of the centrosome during cell division. Alterations in centrosome number reduce the fidelity of cell division by disrupting the structure of the mitotic spindle, leading to chromosome segregation errors. Extra copies of centrosomes are common in human cancer cells and are sufficient to promote genome instability and tumorigenesis in mice. Surprisingly, while centrosome amplification is frequently observed in cancer
cells, it is poorly tolerated in non-transformed cells. Our lab has performed genome wide loss-of-function screens to identify key proteins that are required to arrest the cell cycle in response to centrosome amplification. We have identified several proteins that, when knocked out, allow the continued growth of cells with extra centrosomes. We are currently examining how these proteins function to prevent the proliferation of cells with extra centrosomes. Understanding how the genes involved in this pathway ‘sense’ abnormal centrosome numbers and transmit this signal to arrest cell growth may lead to novel targets for cancer therapeutics.

Structural and functional analyses of the C. elegans Spindle-Defective Protein 2 ASH domain.
M. Murph1, S.M. Singh1, M. Schvarzstein1;
1Biology, Brooklyn College, City University of New York, Brooklyn, NY

Centrosomes are organelles that nucleate and organize microtubules in the cell. They have central roles in the formation of the bipolar spindle during the division of the spermatocytes and early embryo, and they are essential for the formation of the primary cilia and flagellum. Aberrant centrosome structure and/or function is a hallmark of cancer, and results in developmental abnormalities and ciliopathies including, polycystic kidney disease, nephronophthisis, Senior-Loken syndrome, orofaciiodigital syndrome and Bardet-Biedl syndrome. Our overall goal is to understand mechanisms of accurate centrosome inheritance during meiosis and mitosis. At the G2/prophase checkpoint of the cell cycle, centrosome maturation becomes apparent as the centrosome increases in size and pericentriolar material. Upon entry into the mitotic/meiotic division, activated centrosomes form the microtubule-organizing center (MTOC) of the bipolar spindle. Our focus here is to identify and test in vivo the role of the domains required for the normal localization and function of the centrosomal SPD- 2/CEP192 protein during mitosis/meiosis in C. elegans. The Spindle-defective protein 2, SPD-2, is a highly conserved protein with key roles in centrosome maturation and duplication. In addition, SPD-2 serves to recruit different proteins to the centrioles and to the pericentriolar material. Its numerous roles in centrosome structure and function make it an excellent target to study mechanisms of centrosome inheritance. Here we present the modeled three-dimensional structure of the ASH domain of C. elegans SPD-2 using template based modeling and its biophysical characterization. We also show localization of the SPD-2 ASH domain to the centrosome utilizing a GFP-tagged ASH construct. Using several domain mutation constructs, we present the sufficiency of specific residues for localization and function of the ASH domain. These studies not only expand our knowledge of centrosome function, but also provides a new tool for targeting proteins to the centrosome in C. elegans.

Pericentrin reduction is essential for efficient spermatogenesis.
B.J. Galletta1, J.M. Ortega1, R. Varadarajan1, K. Plevock Haase1, C.J. Fagerstrom1, N.M. Rusan1;
1Cell Biology and Physiology Center, NHLBI, Bethesda, MD

During spermiogenesis, centrioles are significantly remodeled in a process termed centriole reduction. This process includes the removal of many core centriole proteins. Previous studies in Drosophila have shown that a failure to remove the centriole protein Asterless (Asl) does not result in a defect in fertilization, but rather results in defects in embryogenesis caused by the unreduced paternal centriole (Khire et al. 2016). In this study, we find that pericentrin-like protein (PLP) is reduced prior to Asl
reduction, suggesting its removal might be a critical first step in the reduction process or be occurring for a distinct reason. To test the importance of PLP-reduction, we ectopically expressed PLP throughout spermatogenesis, which resulted in its sustained presence on the centriole. Furthermore, we found ectopic expression of PLP causes complete male infertility as a result of catastrophic failure to produce mature sperm. By investigating all stages of spermatogenesis, we determined that meiosis is unaffected by ectopic PLP expression in spermatocytes. However, significant defects appear in later stages of spermatid development, including in the attachment of the centriole to the nucleus and in the proper individualization of spermatids. Together, these data suggest that sperm centrioles must reduce PLP for reasons distinct from those for Asl. Interestingly, we found that ectopic PLP expression can lead to ectopic PCM and microtubule (MT) recruitment to basal bodies. We propose that PLP reduction is a highly regulated mechanism required to strip basal bodies of PCM and MTs for proper nuclear docking and are currently using Drosophila genetics in combination with high-resolution microscopy to test this model.

Unravelling the structural aspects of core Centriole proteins using various biophysical techniques.

P. Sankaralingam1, K.F. O'Connell1;
1National Institute of Diabetes and Digestive and Kidney Diseases, National Institutes of Health, Bethesda, MD

Centrioles are cylindrical microtubule-based organelles that aid in bipolar spindle formation and serve as basal bodies for nucleating cilia. They are characterized by a nine-fold symmetrical arrangement of microtubules at the periphery of the cylinder. Centriole duplication is tightly controlled in dividing cells. Misregulation of this process has been linked to a growing number of diseases such as cancer and microcephaly. Studies in C. elegans have identified core centriole proteins: SPD-2, ZYG-1, SAS-5, SAS-6, and SAS-4. Orthologs of these proteins have been found across genera including humans and the general theme of assembly is evolutionarily conserved with only slight variations. Although the molecular machinery has been worked out, structural details of centriole biogenesis are still obscure. The insolubility of centriolar proteins when expressed heterologously in bacteria, has hampered structural studies. In this study, we have devised improved methods for in vitro refolding of full-length ZYG-1, SAS-5, SAS-6 and SAS-4 expressed as inclusion bodies in bacteria. We subjected the full-length proteins to a variety of biophysical methods to elucidate their structural features. Circular Dichroism spectra of these proteins revealed the presence of defined secondary structural elements - SAS-6 and SAS-5 were predominantly alpha-helical, while ZYG-1 may have a mixture of both beta-sheets and alpha-helices. The in vitro refolded ZYG-1 is active, confirming that the polypeptides have attained their native conformation. The oligomeric status of these proteins was determined by size exclusion chromatography. ZYG-1 eluted as a single peak corresponding to a mean molecular mass of 994 kDa, indicating that ZYG-1 is approximately a 13mer. SAS-6 and SAS-5 eluted at the exclusion limit showing either the presence of large oligomers or that they form assemblies with an elongated morphology. SAS-4 exhibited a broad elution profile within the separation range, a feature of polydisperse ensembles. Thus, our study demonstrates that the full-length core centriolar proteins could be refolded in vitro and that they are amenable to biophysical analysis. The ability to refold these proteins ensures unhindered supply for structural investigations.

2Urology, State University of New York Upstate Medical University, Syracuse, NY, 3Biochemistry and 
Molecular Biology, State University of New York Upstate Medical University, Syracuse, NY

PLK1 mis-regulation drives chromosome segregation errors. We are testing a PLK1 scaffold, Gravin, 
during this process. In both 3-D primary prostate cancer cell cultures that are prone to Gravin-depletion 
and control prostate epithelial cells treated with a Gravin shRNA an increase in cells containing 
micronuclei was noted when compared to control cells that express Gravin. To examine whether loss of 
Gravin affected PLK1 distribution and activity we utilized Fluorescence Recovery After Photobleaching 
(FRAP) and a PLK1 activity-biosensor. Gravin-depletion resulted in an increased PLK1 mobile fraction and 
activity. Gravin-loss, and subsequent increase in PLK1 activity, resulted in the spindle pole component, 
CEP215, having increased S/T phosphorylation and disorganization. Gravin-loss led to defects in 
microtubule re-nucleation from spindle poles, decreased K-Fiber formation, chromosome misalignment, 
and subsequent micronuclei formation following mitosis completion. Murine Gravin rescued 
chromosome misalignment and micronuclei formation, but a mutant Gravin (Gravin-T766A) that cannot 
bind PLK1 could not. These findings suggest that disruption of a Gravin–PLK1 interface likely leads to 
inappropriate PLK1 activity contributing to chromosome segregation errors, micronuclei formation, and 
subsequent DNA-damage.

Genetic Analysis of a sas-6 Mutant Suggests an Instructive Role for the Mother Centriole in 
Centriole Assembly.
N. DeVaul1, G. Fabig2, T. Müller-Reichert2, K.F. O’Connell1;
1Laboratory of Biochemistry and Genetics, National Institute of Diabetes Digestive Kidney Diseases, 
Bethesda, MD, 2Experimental Center, Technische Universität Dresden, Dresden, Germany

Centrioles are nine-fold symmetric barrel-shaped structures that exist as mother-daughter pairs, and 
participate in the assembly of bipolar spindles and the formation of cilia and flagella. During S phase of 
each cell cycle, centrioles are precisely duplicated through a process that involves the formation of a 
new daughter next to each preexisting mother centriole. While the mother centriole clearly dictates 
where a new centriole will form, its role in daughter centriole formation, beyond providing spatial 
control, has been controversial. SAS-6 is a protein that forms the central scaffold of the centriole and 
recent work has shown that SAS-6 can assemble into nine-fold symmetric rings in vitro suggesting that 
daughter centrioles can self-assemble. Indeed in vivo, centrioles can form de novo without a mother 
centriole, however these centrioles are often structurally abnormal. Here we describe a missense (D9V) 
mutation in C. elegans SAS-6 that compromises the ability of centrioles to act as mothers. The SAS-
6(D9V) protein can be assembled into centrioles (D9V centrioles) which organize normal-sized 
centrosomes and spindle poles. Further, D9V centrioles possess SAS-7, a marker of mature centrioles 
and are able to form daughter centrioles from cytoplasmic pools of wild-type SAS-6 protein. Thus, in 
many respects D9V centrioles appear normal. However, in the presence of a cytoplasmic pool of SAS-
6(D9V) protein, D9V centrioles almost always fail to form daughters. In contrast, wild-type centrioles 
can readily assemble cytoplasmic SAS-6(D9V) into daughter centrioles, demonstrating that SAS-6(D9V) is
assembly competent. Together these data indicate that centriole duplication failure associated with SAS-6(D9V) arises in part from a mother centriole defect and suggest some type of molecular communication between the mother centriole and the assembling daughter. Experiments are underway to identify which step in daughter centriole assembly is defective in D9V mothers.

1Biomedical Sciences, Florida State University, Tallahassee, FL, 2Johns Hopkins, Baltimore, MD, 3Fisk University, Nashville, TN

At least sixteen centrosomal proteins have been shown to be involved in microcephaly and primordial dwarfism syndromes; however, the underlying cellular and molecular mechanisms remain poorly understood. For this study, we focused on a single disease gene in Drosophila melanogaster known as centrosomin (cnn). Cnn facilitates proper assembly of the matrix of proteins known as pericentriolar material (PCM) and is responsible for coordinating the microtubule organizing center (MTOC) activity of mitotic centrosomes. Additionally, Cnn plays a critical role in neural stem cells where it is recruited asymmetrically to the younger “daughter” centrosome and is required for correct spindle pole polarity. Cells lacking cnn, however, are capable of assembling bipolar, anastral spindles at mitosis despite the fact that the cells lack functional centrosomes. Centrioles themselves are not necessary for proper division; furthermore, certain cell types can successfully complete multiple rounds of division without the centrosome. Cell division in plants and many unicellular eukaryotes, as well as oocyte meiosis in the majority of animal species, routinely occurs without the help of centrosomes.

We hypothesize the existence of a “backup” pathway that allows cnn mutant somatic cells to faithfully undergo mitosis despite their lack of functional centrosomes. To investigate this phenomenon, we conducted a screen in Drosophila to isolate mutations on the X chromosome that are synthetically lethal with cnn. We reasoned that mutants that were viable, but whose mutations were lethal in combination with a cnn null mutation, would reveal key components of the “backup” pathway. Isolated mutants reveal a variety of functions such as kinetochore microtubule stability, spindle pole focusing, spindle microtubule size control, and other spindle microtubule integrity effects.

Characterization of aPKC-Related Signalling Pathways in Normal and Oncogene-Transformed Cells.
L. Wang1, L. McCaffrey1;
1Experimental Medicine, McGill University, Montreal, QC

Loss of epithelial homeostasis is considered a prerequisite for tumour formation, progression and developmental abnormalities. Atypical Protein Kinase C (aPKC) is required for cell polarity, proliferation and migration, and is commonly up-regulated in multiple cancer types including lymphoma, breast, prostate, pancreas and colon cancer. Partitioning defective 6 (Par6) is a regulatory element for aPKC that
regulates its localization and activity. Recent studies indicate that aPKC is required for Ras-induced transformation and carcinogenesis in many cancer types. However, our understanding of aPKC-mediated signaling pathways in normal cells and during carcinogenesis is incompletely understood particularly in 3D systems. To examine aPKC-related signalling pathways in normal and oncogene-transformed 3D cultured cells, Caco-2 cells were stably modified to express constitutively active KRAS-G12V. Non-transformed Caco2 cells form regular hollow central lumen and polarized spheroids in 3D culture. However, KRAS-transformed cells produce solid, irregular structures with disrupted cell polarity that exhibit a 3-fold increase in cyst size, which was blocked by aPKC knockdown. To examine aPKC targets in control and KRAS-transformed cells we used BioID. In addition to confirming known aPKC interacting proteins (including Pard3, Lgl2 and Pard6b) we identified 138 novel aPKC-interacting proteins. One of these is Aminopeptidase N (ANPEP), which is a widely-expressed type II membrane-bound metalloprotease. ANPEP is frequently overexpressed in diverse tumour cells, including breast, ovarian, and prostate cancer. We confirmed that ANPEP is in a complex with aPKC and Par6b, and that the PB1 domain of Par6 is necessary for association with ANPEP. We found that ANPEP co-localizes with aPKC and Par6 at the apical domain in 3D cysts. Interestingly, knockdown ANPEP in KRAS-transformed cells, cells presented significantly smaller than KRAS-transformed cells, this indicates that ANPEP associates with the apical Par complex and is required for KRAS-induced overgrowth and proliferation. Further characterization of the function and the pathway mechanisms of polarity-interacting proteins in 3D systems will give more insight to potential targets in epithelial transformation.

The lateral mobility of membrane-tethered KRAS4b revealed spatiotemporal complexity of signaling.
D. Goswami1,2,3,4, D. Chen1,2,3,4, J. Columbus1,2,3,4, T.J. Turbyville1,2,3,4;
1Frederick National Laboratory for Cancer Research, Frederick, MD, 2National Cancer Institute, Frederick, MD, 3Cancer Research Technology Program, Frederick, MD, 4Leidos Biomedical Research, Inc, Frederick, MD

RAS proteins function as GTP/GDP-dependent control switches to regulate signaling networks in cells and play a major role in human cancer. The major difference across the isoforms of RAS proteins (KRAS4a, KRAS4b, NRAS, and HRAS) lies within the C-terminus hypervariable region (HVR, aa 167-189) and its post-translational lipid modifications. One hypothesis is that the differential signaling behavior from RAS isoforms is controlled by the recruitment and organization of RAS into distinct membrane nano-domains. Association with these nano-domains is determined by RAS lipid-tethers and key residues in the HVR. However, very little is known about the molecular dynamics of membrane-tethered RAS molecules and how these dynamics influence the downstream signaling cascade within a living cell. Herein, the molecular mobility of membrane-tethered Ras variants was characterized by using single molecule tracking method that further estimated underlying mobility states. Detailed analysis of tracks revealed that KRAS4b exhibit confined mobility with three diffusive states in the active plasma membrane of living cells. This diffusion characteristic was unique to KRAS4b and influenced by both the hypervariable region and globular domain of the protein, compared to all the other RAS isoforms. Importantly, the occupancy of each diffusive states was altered for the oncogenic mutant of KRAS4b, implicating enhanced signaling activity. Our study begins to decipher the underlying principle of KRAS functionality in real time on the membrane of living cancer cells that will augment our ability to develop novel therapeutic strategies for targeting oncogenic KRAS4b.
Contract HHSN261200800001E - Funded by the National Cancer Institute
The Ras family of small GTP-binding proteins is frequently activated by mutations, including NRAS (20%), KRAS (2%), and HRAS (1%), in melanoma. In addition to mutations, Ras isoforms can also be activated by the inactivation of Ras GTPase activating proteins (RasGAPs), such as \( NF1 \), \( RASA1 \), and \( RASA2 \). In our recent study, we observed that the inactivation of \( RASA1 \) (RAS p21 protein activator 1, also called p120RasGAP) suppressed melanoma via its RasGAP activity toward the R-Ras (related RAS viral \( r-ras \) oncogene homolog) isoform. We hypothesized that, although not mutated, R-Ras is activated in melanoma through the inactivation of RasGAPs and that RasGAP/R-Ras pathway activation cooperates with BRAF activation in melanoma tumorigenesis.

In this study, we addressed the importance of R-Ras, a previously less appreciated member of the Ras family, in melanoma tumorigenesis and investigated the molecular mechanisms underlying R-Ras signaling in BRAF mutant melanoma. We observed frequent activation of R-Ras in BRAF mutant human melanoma cell lines. In addition, RNAi-mediated reduced expression of R-Ras suppressed anchorage-independent colony growth and tumor growth. Moreover, among the 3 major RAS effector pathways, reduced R-Ras expression suppressed Ral-A activation, which may explain the mechanism of Ral-A activation in BRAF mutant melanoma. Interestingly, anchorage-independent growth driven by \( RASA1 \) inactivation and subsequent R-Ras activation was suppressed by both genetic (siRNA targeting Ral-A) and pharmacological (Ral inhibitor BQU57) inhibition of Ral-A. To further investigate the impact of \( RASA1 \) loss, and thus R-Ras activation, on BRAF mutant melanoma development \textit{in vivo} we generated a \( RASA1^{+/\footnote{1}} \); BRAF \( ^{CA/CA}_L \); Tyr-CreERT2 mouse model in which treatment with 4OHT results in the expression of constitutively activated mutant BRAF and the deletion of \( RASA1 \) in melanocytic lineage cells. Preliminary analysis shows hyperpigmentation of the ear, tail, and foot pad in \( RASA1^{1/\footnote{1}} \) BRAF \( ^{CA/CA}_L \) mice compared to \( RASA1^{1/\footnote{1}} \) BRAF \( ^{CA/CA}_L \) littermates and the development of melanoma in \( RASA1 \) mutant mice. This study demonstrates the importance of the \( RASA1/R-Ras/Ral-A \) signaling pathway in BRAF mutant melanoma and supports the possible combinatorial treatment strategy targeting both the BRAF/MAPK and Ral signaling pathways.

The alteration of the epidermal growth factor receptor (EGFR)-driven signaling network is a characteristic feature of non-small cell lung cancer (NSCLC), and inhibition of EGFR represents a treatment strategy. However, EGFR-targeted interventions have been largely ineffective. Aberrant
subcellular translocation and distribution of EGFR represent a major yet underappreciated NSCLC development mechanism. These include the translocation of EGFR to non-canonical sub-cellular locations including the nucleus and mitochondria. Mapping the relationship between the subcellular interactome of EGFR and NSCLC can yield a fundamental understanding of the mechanisms governing tumor progression and therapeutic resistance, leading to alternative treatment strategies. In this study, we employed isobaric mass tags (iTRAQ)-based quantitative proteomics approach to identify subcellular proteins that interact with EGFR in the highly invasive CL1–5 NSCLC cells. The resulting MS/MS spectra were analyzed using the UniProtKB/Swiss-Prot sequence database with the MASCOT algorithm. The search results were further evaluated using the TPP software (version 4.1) with stringent criteria regarding protein probability (>0.90) and at least two peptide hits for one protein identification. Using such an analysis, we identified 58, 79, and 67 EGFR-interacting proteins in the cytosol, mitochondria, and nucleus, respectively. To deduce the potential biological processes involving subcellular EGFR interactome, the EGFR-interacting proteins identified in the iTRAQ experiment were uploaded into DAVID v6.7 and analyzed for enrichment of categories belonging to biological processes. The proteins of direct interactions with mitochondrial EGFR are correlated with biological process of metabolism and mitochondrion organization. The EGFR-interacting proteins in nucleus are exclusively related to process of RNA processing/splicing. We have confirmed a number of these interactions. These data indicated that EGFR at the different subcellular locations elicits distinctly different signaling. Variations in the subcellular translocation and distribution of EGFR within NSCLC cells could also serve as an additional molecular signature for therapeutic choice, as those variations could have a dramatic impact on therapeutic efficacy.

Quantitative analysis of calcium signaling to identify specific pathways that promote drug resistance in neuroblastoma.
I.A. Espinoza-Fuenzalida¹, I. Lange¹, D.L. Koomoa¹;¹The Daniel K Inouye School of Pharmacy, University of Hawaii at Hilo, Hilo, HI

Neuroblastoma (NB) is the most common extra-cranial solid tumor and the second most common pediatric tumor in children. The range of clinical outcomes in NB is broad, from spontaneous regression to aggressive tumors, and poor outcome is often due to disseminated disease and the development of multi-drug resistance (DR). The mechanisms whereby NB cells switch to a DR phenotype remain relatively unknown. Calcium is a well-known second messenger with a crucial role in cell viability, cell differentiation, and cell proliferation. Intracellular calcium levels are tightly controlled through calcium signaling at the plasma membrane, as well as the endoplasmic reticulum (ER) and mitochondria, which serve as calcium reservoirs. However, many of these calcium signaling pathways are deregulated in cancerous cells, resulting in uncontrolled growth, increased metastatic potential, increased survival signaling, resistance to cell death and DR. We hypothesize that altered calcium-related pathways, including calcium signaling between subcellular compartments, can exacerbate cell survival or reduce cell apoptosis leading to the DR phenotype in NB cells. MYCN-amplified, drug-sensitive (SKNBe1) or drug-resistant (SKNBe2(c)) cell lines were tested using Western blot, cell survival assays, ratio-metric Fura-2-AM calcium measurements, and confocal microscopy when exposed to anti-cancer drugs. Several anti-cancer drugs (doxorubicin, etoposide, vincristine and cisplatin) alter cell survival and expression levels of calcium-signaling-related proteins. Intracellular calcium levels of drug-sensitive (DS) or DR cells were measured in a confocal microscope using fluorescent dyes or genetically encoded calcium indicators specifically targeted to the ER or mitochondria. To distinguish the sources of intracellular
calcium, we have developed analytical protocols of signal co-localization to obtain Pearson’s correlation coefficients (PCC) to discriminate between compartments. Using a microperfusion system, transient applications of anti-cancer drugs induce rapid changes in intracellular calcium levels. These new findings suggest that this methodology can clearly differentiate specific calcium-related signaling that may be involved in the switch to a more aggressive DR phenotype, and reveal novel targets for the development of more effective treatments for high-risk NB patients.

HBx-induced Ca²⁺ aberrancy in hepatocellular carcinoma.
Y. Lin¹, P. Tsai¹, F. Tsai¹2;
¹Department of Pharmacology, College of Medicine, Taipei, Taiwan, ²Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan

Chronic infection of hepatitis B virus (HBV) is the leading cause of hepatocellular carcinoma (HCC), but how HBV viral proteins induce cancer initiation and progression remains unknown. Previous researches revealed that one of the viral proteins, HBx, induced liver cancer in mouse models. Further investigations also indicated that HBx regulated intracellular Ca²⁺ to promote the replication of HBV and the death of hepatocytes. However, how such HBx-related acute events are linked to the development of HCC remains elusive. We therefore studied how HBx regulated intracellular Ca²⁺ signaling and its functional significance in HCC. We firstly detected [Ca²⁺] in cytosol, endoplasmic reticulum (ER) and mitochondria of HBx-expressing hepatocyte or HCC cell lines, using live-cell fluorescence Ca²⁺ imaging. We noticed that cells expressing HBx had universally decreased [Ca²⁺] in cytosol, ER and mitochondria in different cell lines, indicating that HBx might decrease the internal Ca²⁺ storage and subsequently reduce intracellular Ca²⁺ signals in affected hepatocytes or HCC cells. We further studied the mechanism how HBx decreased intracellular Ca²⁺ in HCC cells, through examining whether or not HBx changed Ca²⁺ flows between intracellular compartments. By manipulating Ca²⁺ pump activities and extracellular Ca²⁺ levels, we noticed that HBx increased Ca²⁺ excretion from cytosol to the extracellular space. Interestingly, neither the Ca²⁺ release from ER to cytosol nor the store-operated Ca²⁺ entry (SOCE) was directly affected by HBx. Therefore, the plasma membrane Ca²⁺-ATPase (PMCA), Na⁺-Ca²⁺ exchanger (NCX) or other Ca²⁺ extrusion systems may be potential HBx targets. We are currently working on (1) how HBx mechanistically suppresses Ca²⁺ excretion, and (2) whether or not HBx-induced Ca²⁺ alterations are linked to the initiation and progression of HCC. These approaches will probably resolve the mystery of HBx, leading to the improvement of current HBV treatment and HCC prevention.

Long noncoding RNA HOTAIR and miR-203 regulate tumorigenesis in renal cell carcinoma by targeting the epithelial-to-mesenchymal transition pathway.
P. Dasgupta¹, P. Kulkarni¹, S. Majid¹, V. Shahryari¹, Y. Hashimoto¹, N.S. Bhat¹, M. Shiina¹, G. Deng¹, S. Saini¹, S. Yamamura¹, Y. Tanaka¹, R. Dahiya¹;
¹Urology, University of California San Francisco and VA Medical Center, San Francisco, CA

Objective: Long non-coding RNAs (lncRNAs) and miRNAs are known to be involved in gene regulation in several cancers, but their regulatory mechanisms are far from clear. Several studies show that HOTAIR, an lncRNA, is highly expressed, whereas miR-203 has low levels of expression in various types of cancer, however the role of HOTAIR in renal cell carcinoma (RCC) remains poorly understood. We hypothesized
that lncRNA HOTAIR and miR-203 interaction may be crucial for renal cell carcinoma (RCC) proliferation, invasion, and tumorigenesis. Thus, the focus of the present study was to investigate the role of oncogenic lncRNA HOTAIR and its regulatory miRNA miR-203 in renal cancer using in vitro and in vivo models.

Experimental Design: Human renal cancer cell lines (ACHN and Caki-1), normal renal epithelial cells HK-2 and tumor tissues were used for this study. Expression levels of HOTAIR and miR203 were evaluated by quantitative real-time PCR and their interaction was confirmed by luciferase assay. Cells were transiently transfected with HOTAIR siRNA (25nM) and miR-203 mimic (10nM) for 72 hours and used for functional studies. Statistical analysis was performed to determine the clinical significance of HOTAIR and miR-203 in kidney cancer patients. The biological role of miR-203 and its interaction with HOTAIR was investigated using cell lines and nude mouse models.

Results: HOTAIR expression in RCC cell-lines and clinical specimens was observed to be higher and that of miR-203 lower when compared to normal cells and tissues. Overexpression of miR-203 altered the cell cycle, inhibited epithelial-to-mesenchymal transition (EMT) and decreased proliferation with induction of epithelial marker proteins, PTEN, p21, p27 and decreased pAKT. Luciferase assay confirmed direct binding of miR-203 to HOTAIR. Knockdown of HOTAIR reduced cell migration, invasion, and induced apoptosis, mimicking the effects of miR-203 overexpression. Administration of miR-203 mimic to established tumors in nude mice significantly suppressed tumor growth compared to controls. Statistical analysis using patient samples showed that both HOTAIR and miR-203 may serve as diagnostic and prognostic biomarkers for renal cell carcinoma.

Conclusion: Our results demonstrate that miR-203 overexpression inhibits RCC progression through HOTAIR knockdown and reversal of epithelial-to-mesenchymal transition. These studies show that HOTAIR and miR-203 may be useful in RCC diagnostics and therapeutics.

Influence of breast cancer drivers on mammary gland architecture.

V. Srivastava\(^1\), C. van der Putten\(^1\), J. Garbe\(^1,2\), J.L. Hu\(^1\), M.A. LaBarge\(^3\), Z.J. Gartner\(^1\);  
\(^1\)Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA, \(^2\)Life Science Division, Lawrence Berkeley National Laboratories, Berkeley, CA, \(^3\)Population Sciences, City of Hope National Medical Center, Duarte, CA

Though many putative drivers of breast cancer have been identified, there is limited understanding of the mechanisms by which they promote cancer progression at the level of tissue structure. Specifically, their impact on the transition from in situ to invasive cancers is largely unknown. In the normal breast, the milk-secreting luminal cells (LEPs) are surrounded by the contractile myoepithelial cells (MEPs). This bilayered architecture constitutes a tumor suppressive microenvironment for transformed luminal cells, and its systemic breakdown is the hallmark of progression to invasive cancers.

We recently demonstrated that the tissue architecture is maintained by a balance of interfacial tensions between LEPs, MEPs, and their extracellular matrix (ECM). Specifically, the unique ability of MEPs to strongly interact with the ECM is central to their capacity to maintain tissue architecture through self-organization. Consequently, we hypothesize that physical changes to the interfacial properties of LEPs and MEPs upon oncogenic activation can cause architectural disruption, thereby promoting the progression to invasive cancers. While changes in the physical properties of both tumor cells and surrounding matrix during cancer progression have been reported, a direct mechanistic link between oncogenes, altered interfacial mechanics, and a breakdown in tissue architecture has not been made.

To this end, we are characterizing the influence of putative breast cancer driver genes on the self-organizing capacity of the mammary gland. Starting with primary human mammary epithelial cells from
healthy human donors, we are systematically analyzing the self-organization, biophysical properties, and transcriptional dynamics of these cells expressing defined combinations of driver genes for fixed periods of time. For example, we found that LEPs expressing a mutant form of PIK3CA fail to self-organize with MEPs, likely due to PIK3CA activation-induced changes to cellular mechanics. In contrast, the expression of cyclin D1, another common oncogene which does not have a major role in cytoskeletal regulation, does not have a significant impact the tissue self-organization.

Collectively, by quantitatively linking cancer-driver expression, biophysical changes in cell and tissue mechanics, and the associated transcriptional changes, we aim to determine the molecular underpinnings of tissue architectural disruption in breast cancer.

MiR-133a function in the pathogenesis of dedifferentiated liposarcoma.
1Medicine, Ohio State University, Columbus, OH, 2Veterinary Clinical Sciences, Ohio State University, Columbus, OH, 3Surgical Oncology, Ohio State University, Columbus, OH, 4Arthur G. James Comprehensive Cancer Center, Columbus, OH, 5Pathology and Laboratory Services, Ohio State University, Columbus, OH, 6Cancer Biology and Genetics, Ohio State University, Columbus, OH

Objective: Sarcomas are malignant heterogeneous tumors of mesenchymal derivation. Dedifferentiated liposarcoma (DDLPS) exhibits aggressive biological behavior with an 80% local recurrence rate and metastasis in approximately 20% of patients. Our laboratory characterized a unique miRNA expression signature associated with human DDLPS tissue. The objective of this study is to characterize the biological and molecular consequences of miR-133a in DDLPS.

Methods: Taqman real-time PCR was used to evaluate expression levels of myomiRs in human DDLPS tissue, normal fat tissue, and available human DDLPS cell lines. To evaluate the effects of miR-133a expression on DDLPS cell line behavior in vitro, cells were stably transduced with miR-133a vector or empty lentiviral vector and the effects on cell cycle, proliferation, apoptosis, and migration were assessed. DDLPS cells were injected subcutaneously in mice to form xenograft tumors. Agilent Seahorse Bioanalyzer system was used to assess metabolism in vitro and ex vivo from sectioned xenografts. We performed an in silico search for predicted targets of miR-133a using target prediction databases and compared these target genes to known genes that are highly expressed in human DDLPS tissue.

Results: The expression levels of myomiRs were significantly decreased in human DDLPS tissue compared to normal human fat as well as in human DDLPS cell lines compared to a human preadipocyte cell lines. Overexpression of miR-133a decreased cell proliferation, decreased glycolysis, and increased spare respiratory capacity. There was no significant effect on cell cycle, apoptosis, migration, or in vivo tumor growth. Oxidative respiration was increased in xenograft tissue formed from cells overexpressing miR-133a. Using in silico target gene analysis, we identified 18 potential targets of miR-133a.

Conclusions: We have demonstrated that enforced expression of miR-133a decreased proliferation and metabolism in human DDLPS cells. We have identified putative gene targets of miR-133a and are currently dissecting the molecular mechanism by which miR-133a may mediate proliferation and metabolism in DDLPS cell lines. Taken together, these results suggest that miR-133a regulates metabolism and proliferation, and its dysregulation might contribute to the oncogenic phenotype of DDLPS.

BRCA1 regulation of miRNA expression in breast cancer.
L. Delgado-Cruzata1, L. Duran1;
1Sciences, John Jay College, City University of New York, New York, NY

Hereditary mutations in BRCA1 are a well-known susceptibility factor in breast cancer. Women with one defective copy of this protein end up with increased chances to acquire breast cancer. Partial disruption of the function of this protein is enough to cause cancer susceptibility. There are several functions attributed to BRCA1 that explain its role in carcinogenesis. Some studies have found that BRCA1 can be a transcription factor and others suggest it is a protein involved in DNA double strand repair. Additional work suggests BRCA1 acts through regulating DNA methylation by biding to DNA methyltransferase-1. Other effects of BRCA1 epigenetic regulation have been less explored. Here we proposed to study the effect of partial depletion of BRCA1 in the breast cancer cell line MCF7. We treated the cells with limited amounts of siRNA (5nM) targeting BRCA1 and determine the levels of expression by qRT-PCR. Our results showed that the mRNA levels of BRCA1 decreased by 40% (BRCA1 mRNA expression = 58.62% ± 3.16%). In the cells where BRCA1 was partially expressed, levels of DNMT1 and DNMT3B were slightly decreased by 20% and 10%, respectively (DNMT1 mRNA expression = 82.30% ± 6.10% and DNMT3B mRNA expression = 90.91% ± 9.01%). We will determine how the partial loss of BRCA1 affects the levels of miRNAs in the cell, by examining miRNA expression using the Human miRNA CodeSet from NanoString. We will later confirm the positive hits by qRT-PCR. These findings will greatly increase our understanding of BRCA1 function and the role it plays in susceptibility to breast cancer.

A Genome-Wide miRNA Screen to Identify Regulators of Tetraploid Proliferation.
M.A. Vittoria1, E. Shenk1, K.P. O’Rourke2, A.F. Bolgioni3, S. Lim1, V. Kacprzak1, R.J. Quinton1, N.J. Ganem1,3; 1Department of Pharmacology Experimental Therapeutics, Boston University School of Medicine, Boston, MA, 2Department of Cancer Biology Genetics, Memorial Sloan Kettering Cancer Center, New York, NY, 3Department of Medicine, Division of Hematology, Boston University School of Medicine, Boston, MA

Tetraploid cells, commonly generated by errors in cell division, are genomically unstable and well known to promote tumorigenesis. Recent studies indicate that ~40% of solid tumors undergo a whole-genome doubling event during tumor development. This suggests that tetraploidy, which promotes aggressive and invasive phenotypes, plays a significant role in shaping the evolution of tumors. To combat the pro-oncogenic effects of tetraploidy, it was recently discovered that tetraploid cells activate the Hippo tumor suppressor pathway and stabilize p53 to restrict their growth. To successfully proliferate and become oncogenic, tetraploid cells must therefore overcome this G1 cell cycle arrest; however, how tetraploid cells circumvent this arrest remains poorly understood. We hypothesized that overexpression of specific miRNAs, which are small non-coding RNAs that are commonly deregulated in various human malignancies, may enable the proliferation of tetraploid cells. We performed a comprehensive, gain-of-function genome-wide screen to identify miRNAs that promote the proliferation of arrested tetraploid cells. Our screen identified ~20 miRNAs whose expression significantly promoted tetraploid proliferation. The vast majority of these miRNAs promote tetraploid growth by enhancing growth factor signaling (e.g. miR-191-3p); however, we also identified several miRNAs that disable the p53-p21 pathway (e.g. miR-523-3p), and a single miRNA (miR-24-3p) that inactivates the Hippo pathway, in part
via downregulation of the tumor suppressor gene NF2. Collectively, our data reveal several new avenues through which tetraploid cells may regain the proliferative capacity necessary to drive tumorigenesis.

Evolution of genetic instability through single-hit mutations.
M.C. Coelho¹, A.W. Murray¹;
¹MCB, Harvard University, Cambridge, MA

Genetic instability, defined as an increase in the mutation rate, accelerates evolutionary adaptation. Repeatedly selecting for antibiotic resistance selects for genetically unstable mutants in E. coli. Genetic instability is universal in cancer and is thought to arise primarily from the inactivation or removal of both copies of genes whose products function in DNA metabolism and cell cycle regulation.

We evolved and characterized genetic instability in diploid strains of the budding yeast, Saccharomyces cerevisiae, by selecting for the sequential inactivation of three independent growth suppressor genes, yeast analogs of tumor suppressor genes. Our selection produced clones with increased point mutation, mitotic recombination, and chromosome loss rates. Whole genome sequencing and genetic segregation analysis identified candidate, heterozygous mutations and when these were engineered, individually, into the ancestral, genetically stable diploid strain, they induced genetic instability. Conversely, restoring the wild-type allele in the evolved clone reduced genetic instability. 20% of the genes we found have homologs implicated in human cancer, they include essential genes and genes not previously implicated in genetic instability, they are enriched for genes which function in transport, protein quality control, and DNA metabolism, and they differ from genes found in previous screens for genetic instability.

We conclude that single genetic events can cause genetic instability in diploid yeast cells, and propose that similar, single-hit, mutations may initiate genetic instability in cancer.

Stereotyped p53 binding tuned by chromatin accessibility.
J. Stewart-Ornstein¹, A. Hafner¹, G. Lahav¹;
¹Systems Biology, Harvard Medical School, Boston, MA

Differential regulation of transcription factors give cell types their identity. Many transcription factors are ubiquitously expressed yet nonetheless regulate specific targets in different cellular contexts. The degree to which the differential activities represent different transcription factor binding or more downstream regulation of their activity at the promoter or system wide level is unclear. We focused on the tumor suppressing transcription factor p53 and compared in vitro binding to in vivo ChIPseq data. We observe that while a position weight matrix/motif predicts p53 binding in vitro well, in vivo the p53 motif is only weakly associated with binding suggesting other cellular factors modulate binding. To explore if in vivo regulators of p53 binding could vary across cell lines leading to different p53 dependent phenotypes we used ChIPseq to compare p53 binding across 13 cell lines. Interestingly, we observe quite uniform p53 binding, with only ~5% of p53 binding sites varying substantially across cell lines. The binding of p53 to these ‘variable’ binding sites was lineage specific with, for example, p53 associating with several novel ER regulated target genes in an ER+ breast cancer line. Indeed, in this cell line ER binding was a significant predictor of adjacent p53 binding. We wondered to what extent these interactions represented direct regulation or indirect control through chromatin accessibility. Using
ATACseq we found that chromatin accessibility was a strong predictor of p53 binding and that when controlling for accessibility all other factors tested (e.g. ER or Myc binding) were not significant. These results show the limited diversity of p53 binding across cell lines and identify the key role of chromatin regulation in regulating cell type specific p53 dna binding.

E6 Proteins from Diverse High-Risk HPV Types Differ in their Target Specificities.
M. Thomas\(^1\), M.P. Myers\(^2\), P. Massimi\(^3\), C. Guarnaccia\(^3\), L. Banks\(^1\);
\(^1\)Tumour Virology, ICGEB, Trieste, Italy, \(^2\)Protein Networks, ICGEB, Trieste, Italy, \(^3\)Biotechnology Development, ICGEB, Trieste, Italy

At least twelve HPV types have been defined as definitely carcinogenic in humans, and a further thirteen types as probably or possibly carcinogenic. All of these have PDZ-binding motifs (PBM)s on the extreme C-terminus of the E6 oncoprotein.

Using an unbiased proteomic approach we have previously shown that each of these E6 PBM}s has a particular set of preferred cellular targets, and that increased oncogenic potential of the virus appears to correlate with increased functional flexibility of the PBM, and preferred selection of a subset of PDZ domain-containing target proteins. We also identified the ZO2 protein as a novel E6 target that is stabilised, rather than degraded, in the presence of HPV E6. We have now identified another cellular protein, bound through a different motif, that also appears to be stabilised by binding the E6 proteins from certain HPV types. It is becoming clear that the outcome of any infection is the result of interplay between the lineage of the infected cell and the precise type of HPV infecting it. Accordingly we have now extended our studies to look at how the target protein repertoire of these PBM}s might change under different growth conditions, and in cells from different origins. In addition we have found that certain non-PDZ-containing proteins are also targeted by this region of E6, apparently in a phosphorylation-dependent manner.

IDENTIFICATION OF CANDIDATE GENES ASSOCIATED WITH TRIPLE NEGATIVE BREAST CANCER.
A. Player\(^1\), N. Abraham\(^1\), K. Burrell\(^1\), L. Nunez\(^1\), A. Williams\(^1\), T. Williams\(^1\), S. Kwende\(^1\), W. Walls\(^1\);
\(^1\)Biology, Texas Southern University, Houston, TX

Triple negative breast cancer (TNBC) is a heterogeneous disease. Although the disease is defined as a single subtype, patients (or cell lines) within the group can be very different. Microarray analyses of TNBC samples show that at least five different subclasses exist within the subtype. One of the subclasses has been defined as enriched for immune-related genes. For the current project we identified TNBC cell lines and clinical patient microarray datasets from Gene Expression Omnibus (GEO). The TNBC cell line datasets were separated into two groups based on low or high expression of immune-related genes. Unsupervised bioinformatics-analysis of the microarray datasets was performed and a larger list of differentially expressed genes were selected. Following further comparison to clinical patient samples and experimental validation, six candidate genes were ultimately selected. The six candidate genes included IL32, GATA3, MYBL1, ETS1, TMEM158 and PTX3. The candidate genes demonstrated differential gene expression in approximately 60% of TNBC patient samples compared to other TNBC, normal, luminal A, luminal B and Her2 patient samples. This study outlines the approach utilized to select the final list of candidate genes. At this point, it is unclear as to the clinical utility of the six genes
either individually or jointly. The first approach is to confirm the use of the genes to further characterize TNBC heterogeneity.

TGF-beta determines the pro-migratory potential of bFGF signaling in medulloblastoma.
K. Santhana Kumar1, A. Neve1, A. Guerreiro Stucklin2,3,4, C.M. Kuzan-Fischer2,4, J. Rushing5, M.D. Taylor2,3,4, D. Tripolitsioti1, L. Behrmann1, D. Kirschenbaum5, M.A. Grotzer4, M. Baumgartner1; 1Oncology, University Children's Hospital Zürich, Zürich, Switzerland, 2Department of Laboratory Medicine and Pathobiology, The Hospital for Sick Children, Toronto, Canada, 3The Division of Haematology/Oncology, The Hospital for Sick Children, Toronto, Canada, 4Department of Surgery, The Hospital for Sick Children, Toronto, Canada, 5Institute of Neuropathology, University Hospital Zürich, Zürich, Switzerland

The mechanistic understanding of how tumor cell dissemination is controlled by microenvironment-derived cues is still incomplete. In this study, we investigated the integration of microenvironment-derived growth factor signaling and how this affects cancer cell migration and invasion. We developed a phenotype-based screening approach1 to identify mechanisms and regulators of cell migration/invasion in the pediatric brain tumor medulloblastoma (MB), the most common malignant brain tumor in children. The combination of this approach with validations in organotypic cerebellum slice culture2 and an orthotopic PDX model allowed us to determine at the molecular, cellular and tissue levels how tumor cells integrate parallel signals from different, microenvironment-induced pathways.

We identified tumor growth factor beta (TGF-b) function as a key determinant of pro-migratory basic fibroblast growth factor (bFGF) signaling in MB. We demonstrate that bFGF promotes migration/invasion through FGF receptor substrate 2 (FRS2), and that at low bFGF concentrations, TGF-b antagonizes FRS2 activation through Rho kinase (ROCK) and Extracellular Regulated Kinase (ERK1/2). Latter prevents activating FRS2 tyrosine phosphorylation only in the context of non-canonical TGF-b signaling via contractility-dependent relocalization of ERK1/2. Conversely, at high bFGF concentrations where FRS2 activation is blocked by negative feedback through ERK1/2, TGF-b restores FRS2 activation and enables migration/invasion. Thus, by controlling FRS2 function through coinciding ERK1/2 and ROCK activation, TGF-b determines the pro-migratory response of the tumor cells to the variable abundance of bFGF in the microenvironment.

This study identified FRS2 as a coincidence detector that integrates variably abundant microenvironmental cues to control pro-migratory cell functions, and it exemplifies a novel paradigm of rheostat regulation of growth factor signaling.

**Illuminating the role of neurogenic regulator REST in Medulloblastoma dissemination.**  
K. Callegari¹, T.H. Dobson², J.B. Bravo¹, S. Shaikh¹, V. Gopalakrishnan¹;  
¹Experimental Pediatrics, UTHealth Sciences Center/MD Anderson, Houston, TX

Perturbed developmental signaling is characteristic of the pediatric brain tumor Medulloblastoma (MB). In fact, MB is subgrouped by activation of various molecular pathways including sonic hedgehog (SHH) and wingless (WNT) signaling, with two other less defined subgroups named group 3 and group 4. Across all subgroups, patients with metastasis display increased levels of the protein, RE-1 silencing transcription factor (REST). Consistent with this, an increased incidence of leptomeningeal dissemination is observed in a novel transgenic mouse model expressing REST in the cells of origin of SHH MB, cerebellar progenitor cells. We demonstrate here that elevated REST results in an abnormal cytoarchitecture in the postnatal cerebellum. Further analysis of these defects revealed REST-dependent dysregulation of the CXCR4 signaling pathway, a cascade known to play a role in proper cerebellar lamination. The activation of CXCR4 is an established marker of negative prognosis in MB patients. Consistent with this, when we elevated REST in the tumor environment, there was a concomitant increase of CXCR4 signaling and tumor cell migration. Our findings suggest that REST-dependent activation of CXCR4 contributes to the aggressive tumor behavior displayed by subgroups of MB patients and open the discussion to treatment options targeting the REST complex in REST-high tumors.

**Optimized Isolation of Plasma Extracellular Vesicles for Use as Potential Biomarkers in Patients with Glioblastoma.**  
L.M. Cumba Garcia¹, T.E. Peterson², A.J. Johnson³, I.F. Parney⁴;  
¹Immunology, Mayo Clinic Graduate School of Biomedical Sciences, Rochester, MN, ²Neurologic Surgery, Mayo Clinic, Rochester, MN, ³Immunology/Neurology, Mayo Clinic, Rochester, MN, ⁴Neurologic Surgery/Immunology, Mayo Clinic, Rochester, MN

Glioblastoma (GBM) is the most common brain tumor and is nearly universally fatal within five years despite aggressive treatment. Tissue histopathology is required for definitive diagnosis. Imaging alone is inadequate to distinguish tumor progression from treatment-related inflammatory pseudoprogression, particularly following immunotherapy. Therefore, there is a need for non-invasive diagnostic alternatives. GBM’s release extracellular vesicles (EV’s) including exosomes (<100nm) and microvesicles (100nm–1000nm). GBM EV’s in plasma may have biological effects including mediating immunosuppression and could serve as liquid biopsies as they contain signature tumor-associated antigen immunosuppressive protein profiles. However, plasma EV isolation techniques have not been optimized. Here, we present a simple technique to isolate plasma EV’s from grade 2, 3 and 4 glioma patients (n=21) with new or recurrent tumors that are isocitrate dehydrogenase (IDH) mutant or wild type (WT), and normal donors (n=19) using a two-step ultracentrifugation protocol. After ultracentrifugation using a sucrose gradient (90 minutes at 100,000 x g), nanotracker (NanoSight) analysis revealed that glioma patients with tumors that are IDH WT (n=7) have smaller particle size (13.04 ± 5.660) (P<0.05), but increase plasma EV concentration (-1.993X1011 ± 9.207X1010) (P<0.05) compared to normal donors. Further ultracentrifugation (16 hours at 100,000 x g) concentrated EV’s efficiently for additional analysis, but resulted in EV aggregation that skewed nanotracker results. Western blot analysis of isolated plasma EVs confirmed exosome markers CD63 and HSP70 in both
glioma patients and healthy donors. Interestingly, a higher expression of the immunosuppressive molecule programmed death-ligand 1 (PD-L1) was observed in glioma patients in comparison to healthy donors. Cytokine array analysis showed higher concentration of the Th1 cytokine IFN-γ in plasma EV's from normal donors in comparison to plasma EV's from glioma patients (34.50 ± 9.856) (Ps0.05). These findings suggest that a simple two-step ultracentrifugation protocol efficiently isolates plasma EVs with distinct differences between glioma patients and normal donors that could be used as a non-invasive biomarker.

Emerging role of a sulfhydryl oxidase in glioma cell behavior.
R. Dutt1, C. Thorpe1, D.S. Galileo2;
1Department of Chemistry and Biochemistry, University of Delaware, Newark, DE, 2Department of Biological Sciences, University of Delaware, Newark, DE

Quiescin Sulfhydryl Oxidase 1 (QSOX1) is a flavo-enzyme that catalyzes the oxidation of free thiols to generate disulfide bonds with the reduction of molecular oxygen to hydrogen peroxide. QSOX1 has been reported to be upregulated in a number of cancers including breast, prostate, pancreatic and certain brain cancers. Overexpression of QSOX1 has been correlated with aggressive cancers and poor patient prognosis. Gliomas are primary brain tumors that occur mostly in adults. Glioblastoma Multiforme (GBM) is a stage IV glioma that is very aggressive and has been practically impossible to treat successfully. GBM cells invade normal brain tissue very quickly and, thus, escape surgery to lead to an often more aggressive recurrence. There is a continuing need to understand the mechanism of GBM cell migration and invasion. Here we investigate the function of QSOX1 in human gliomas. We lentivirally introduced shRNA to knockdown QSOX1 in a human GBM cell line, T98G. These QSOX1 knockdown cells showed decreased cell migration in vitro as demonstrated by a quantitative Super Scratch assay. We also used the embryonic chick brain xenograft model to demonstrate glioma cell invasion in vivo. Therefore, reduced QSOX1 expression leads to decreased glioma cell migration and invasion both in vitro and in vivo, respectively.

Biological self-organization is when a process or a biological multicellular structure forms at the macroscopic level as a result of interactions among lower-level components, i.e., individual cells. Interactions among the individual components only utilize local information. Cancer growth is mostly understood as random. The role that stereotypical structures may have in tumor growth has not been carefully considered. During the study of both rodent and human brain tumors we determined the existence of multicellular structures which we named oncostreams. Oncostreams are elongated cells 5-20 cells wide and of variable length. Oncostreams express proteins that are typical of brain tumors, i.e., GFAP, nestin, twist, MMP2, retinoblastoma, olig2, amongst others. The density of immunocytochemically distinct proteins varies between oncostream and non-oncostream glioma cells.
The function of oncostreams was explored utilizing cell biological, molecular, and mathematical modeling experiments. Oncostreams mediate glioma invasion, as they form tight fingers of parallel elongated cells that push into surrounding normal brain. Oncostreams can also serve as preferential highways for the movement of glioma cells throughout the brain. Injection of slowly moving human brain glioma stem cells into rapidly streaming rodent glioma cells results in the alignment of the human glioma cells to the oncostreams, and their fast distribution throughout the tumor along these structures. Oncostreams may also limit immune cells’ entry into gliomas as they appear to be excluded from these structures. To test the hypothesis that oncostreams are formed solely from interactions between individual glioma cells, we built a series of agent-based mathematical models. These allowed us to discover that only elongated cells form structures resembling oncostreams. Circular cells never do so. The length:width ratio of the elongated oncostream-forming cells is not significantly different from the ratio measured in vivo. Finally, to understand whether oncostreams differ molecularly from surrounding glioma cells, we dissected oncostreams and surrounding glioma tissue using laser scanning microdissection, RNA-Seq and bioinformatics. The set of gene expression patterns differs significantly between the two areas, thus enabling us to identify the molecular individuality of oncostreams. Network analysis has identified fyn and STAT-1 as highly connected nodes. Deletion studies are now allowing us to demonstrate that fyn appears to play a role in oncostream formation and malignant tumors’ phenotype. In conclusion, we demonstrate that oncostreams are a novel cancer structure with individual molecular makeup and function, and have an important role in determining the phenotype of malignant brain gliomas.

Mechanisms Involved in Microglia Stimulation of Glioblastoma Invasion.
S.J. Coniglio1, M. Patel1, D. Patel1, D. Habib1, J. Merritt1, J.E. Segall2, U. Rath2;
1NJCM, Kean University, UNION, NJ, 2Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

Glioblastoma multiforme (GBM) is one of the deadliest human cancers with a median survival rate of 12 months post diagnosis. One of the major hallmarks of GBM is its highly infiltrative nature which makes advanced tumors nearly impossible to fully resect. Therefore increasing our knowledge of the mechanism GBM cells use to invade normal brain is of critical importance in designing novel therapies. We recently showed that tumor associated microglia stimulate GBM cell invasion and this process is mediated by CSF-1R signaling. This finding is consistent with the great body of literature that supports a role for myeloid cells in invasion and metastasis of a variety of cancers regardless of cellular origin. In this study, we seek to identify factors that are upregulated in GBM-stimulated microglia as well as uncover potential signaling mechanisms that promote GBM invasion. We assayed cDNA and protein from microglia treated with conditioned media from the murine GBM cell line GL261, and discovered that the EGFR ligand amphiregulin (AREG) and the chemokine CCL3 (MIP1a) are significantly induced. Using RNA interference, we show that microglia depleted of AREG cannot promote invasion of GL261 cells into matrigel-coated invasion chambers as effectively as controls. In addition, an AREG blocking antibody strongly attenuates the ability of THP1 macrophages to activate human GBM cell line U87 invasion. We have also demonstrated that novel small molecule CCR1 specific antagonists also inhibit the ability of microglia to stimulate microglia-stimulated glioblastoma. Interestingly, the ability of microglia to fully stimulate GBM cell invasion requires cell-cell contact. Three dimensional spheroid invasion assays confirm the extensive cell-cell contacts that occur between invasive GL261 and U87 cells and microglia. We have identified the tyrosine kinase receptor EphB2 as a key mediator of microglia activation of invasion. Microglia and other macrophage cell lines were found to express abundant levels
of Ephrin-B1, the principal ligand for EphB2. Consistent with the observation that juxtacrine interactions are critical, microglia are unable to stimulate invasion of EphB2-depleted U87 GBM cells. Taken together, we observe in two models of GBM that CSF-1 secreted by tumor cells reprogram microglia and macrophages to stimulate GBM invasion via several mechanisms including AREG/EGFR, CCL3/CCR1 and Ephrin-B/EphB2.

**Downregulation of ASCT2 (alanine-serine/cysteine transporter 2 / SLC1A5) in human cancer.**  
A. Oliveira¹, P. Soares-da-Silva¹,²;  
¹Phyzat Biopharmaceuticals, Porto, Portugal, ²Center for Drug Discovery and Innovative Medicines, MedInUP, Porto, Portugal

ASCT2 (alanine-serine/cysteine transporter 2 / SLC1A5) is highly expressed in cancer cells to support their continuous growth and proliferation and is a promising pathological marker for predicting a worse outcome in certain types of cancer (Semin Cancer Biol 15:254-266,2005). The present study examined the effect of ASCT2/SLC1A5 gene down regulation by RNA interference on the expression and function of the transporter in human cancer cells. Target sites within ASCT2 gene (NM_001145144) were selected from the respective human mRNA sequences. Nucleotide homology searching was performed against nonredundant and dbEST using BLAST via online connection to NCBI. The commercial siRNA SI00079730 that targets the human ASCT2 mRNA sequence and negative control siRNA commercial sequences NC-SI03650318 and NC-SI03650325 (Qiagen) were tested. Cells (human liver adenocarcinoma SK-HEP-1, human fibrosarcoma HT-1080 and human bladder carcinoma T24) were cultured for 48 h (in RPMI and DMEM-hg, respectively). ASCT2 mRNA and protein expression, inward transport of [14C]-L-alanine, and effects of siRNA anti-ASCT2 upon [14C]-L-alanine uptake were analyzed. Antibodies raised against ASCT2 and GAPDH were used, and images were obtained by scanning at both 700 nm and 800 nm, with an Odyssey Infrared Imaging System (LI-COR Biosciences). For RT-PCR, total RNA was converted to cDNA and qPCR analysis was made in the StepOnePlus instrument (Applied Biosystems). Primers for ASCT2 and for the endogenous control gene GAPDH were used. All cell types expressed ASCT2 mRNA and protein. The abundance of ASCT2 mRNA differed among the tumor cell lines, being more intense in HT-1080, followed by SK-HEP-1 and T24 cells. The abundance of ASCT2 protein followed the same trend. The sodium-dependent inward transport of non-saturating concentrations (0.25 μM) of [14C]-L-alanine, the preferred substrate of ASCT2, was linear with time for up to 10 min of incubation. In order to determine the kinetics of the transporter, cells were incubated for 1 min with [14C]-L-alanine (0.25 μM) in the absence or in the presence of increasing concentrations of unlabelled substrate L-alanine (1 to 3 mM). The kinetic parameters of [14C]-L-alanine uptake (Km in mM; Vmax in nmol/mg protein/min) were determined by non-linear analysis of the specific analysis of inhibition curve for L-alanine and are as follows: SK-HEP-1, Km=0.221±0.023, Vmax=6.746±0.570; T24, Km=0.225±0.015, Vmax=8.799±0.103. Transfection with siRNA against ASCT2 gene, but not the negative control siRNAs, reduced the [14C]-L-alanine accumulation in all cancer cell lines. In conclusion, anti-ASCT2 siRNA decreased [14C]-L-alanine uptake, possibly by downregulation of ASCT2 expression and function.

Over-Expression of the βII Isotype of Tubulin and Especially Its Localization in Cell Nuclei Correlates with Poorer Outcomes in Colorectal Cancer.

K. Ruksha¹, A. Mezheyeuski², A. Nerovnya³, T. Bich³, G. Tur⁴, J. Gorgun⁵, R.F. Luduena⁶, A. Portyanko¹,²;
¹N.N. Alexandrov National Cancer Centre of Belarus, Minsk, Belarus, ²Immunology, Genetics and Pathology, Uppsala University, Uppsala, Sweden, ³Pathology, Belarusian State Medical University, Minsk, Belarus, ⁴Minsk City Clinical Oncologic Dispensary, Minsk, Belarus, ⁵Gastroenterology and Nutrition, Belarusian Medical Academy of Post-Graduate Education, Minsk, Belarus, ⁶Biochemistry, University of Texas Health San Antonio, San Antonio, TX

Tubulin, the subunit protein of microtubules, is a heterodimer of α and β subunits, each of which exists as isotypes differing in amino acid sequence and encoded by different genes, with the differences being highly conserved in evolution. Specific isotypes of tubulin have associations with cancer that are still not well understood. Previous studies noted that the βII-tubulin isotype is expressed in a number of transformed cells where the normal tissues do not express βII (Yeh, & Ludueña, Cell Motil. Cytoskeleton 57: 96, 2004). Even more interesting, in many of these tumors, βII is found in cell nuclei in non-microtubule form (Walss et al. Cell Motil. Cytoskeleton 42: 274, 1999). The association of βII expression and its nuclear localization with cancer progression has been noted to be more frequent in cancers but its potential clinical significance has not been addressed. Here we report a study with patients with colorectal cancer. We have previously reported that, while normal colon expresses little or no βII or βIII, inflamed colon expresses βIII while cancerous colon expresses both βII and βIII (Portyanko et al. Virchows Arch 454:541, 2009; Portyanko et al. J. Crohn's & Colitis 10, Suppl. 1: S102, 2016). We have found that patients whose tumors over-express βII-tubulin have a greatly decreased life expectancy, compared to patients whose tumors do not express βII-tubulin. We have also found life expectancy is even shorter in those patients with nuclear βII. These results are consistent with a model whereby, as a cancer progresses, it begins to over-express βII and then to localize it in the cell nuclei and therefore that βII expression and localization could be a useful prognostic marker. We have also observed that otherwise normal colon epithelial cells adjacent to the tumor contain nuclear βII. This observation could decrease the probability of a false negative biopsy. Our results suggest that expression of βII and its localization to the nucleus in non-microtubule form may be important for cancer cell growth and proliferation, and may be part of an as yet unknown signaling pathway. Our results raise the following mechanistic and pharmacological questions: 1) How does transformation lead to expression and nuclear localization of βII? 2) What does nuclear βII do for the cancer cell? 3) How does a cancer cell stimulate nearby cells to express βII? 4) Is the currently accepted paradigm that anti-tubulin drugs work by freezing microtubule dynamics sufficient or do we need a new set of drugs to target tubulin in non-microtubule form?

It has been shown that cell stiffness could be used as a marker for cancer progression and metastatic potential. Furthermore, changes in cytoskeletal architecture induced by stress (anti-cancer drugs or fluid shear stress in the circulatory system during metastatic processes) were shown to significantly influence biomechanical features of cancer cells. In this study, we were focused on cell stiffness changes in separated CD90-positive cells from tumour tissue of head and neck squamous cell cancer patients and prostatic cell lines PNT1A. 22Rv1, LNCaP, and PC-3 after exposure to antineoplastic drugs docetaxel and cisplatin.

Primary cell lines were prepared from tumour tissue obtained at surgery. For separation of CD90-positive subpopulations derived from primary cell line magnetic particles were used. Atomic-force microscopy (AFM), wound healing assay, and gene expression followed by cytostatic treatment was used.

AFM was performed on in sum 68 LNCaP, 42 PC-3, 20 22Rv1, and 64 PNT1A non-treated cells. Young’s modulus was 1153±52 kPa for PNT1A, 671±52 kPa for 22Rv1, 997±52 kPa for LNCaP and 1210±52 kPa for PC-3. The Young’s modulus of primary tumor’ 22Rv1 was significantly different from those obtained for other cell lines (both non-tumor and metastatic, p<0.005 in all cases). On the other hand, exposure of cells to cytostatic treatment increased the cell stiffness of all studied cell lines significantly. Regarding CD90+ head and neck cancer, cell stiffness of tumour cells derived from patients with stage of lymph node metastasis N0-1 was significantly higher than cell stiffness of CD90-positive tumour cells derived from patients with stage N2-3. Results indicate that changes of cell stiffness could be promising predictor of metastatic and/or aggressive behaviour of various cancers.

Oncosomes as a Biomarker for Quantifying Metastatic Cancer Dynamics in Real-Time.
H.S. Leong1,2, K. Deng3, Y. Kim1,2;
1Urology, Mayo Clinic, Rochester, MN, 2Surgery, Western University, London, ON

INTRODUCTION AND OBJECTIVES: Tumor cells acquire qualities that enable them to succeed at key steps of the metastatic cascade, but very little is known about how individual cells accomplish these feats in a challenging hemodynamically active environment. Using intravital imaging, we observe that oncosome release is a key event during cancer cell extravasation in various prostate cancer cell lines. Oncosomes are large cell fragments released by cancer cells at various stages of cancer progression. Having observed their release in vivo during cancer cell extravasation, we sought to determine at what other
Stages of metastasis oncosomes were released. METHODS: Using PC-3, LnCAP, Du145 cells, intravenous injection into the chorioallantoic membrane (CAM) of chick embryos, a gold standard of visualizing cancer cell extravasation, was employed and confocal resonance scanning microscopy was used to visualize the release of oncosomes and other smaller extracellular vesicles in vivo. Blood at various timepoints was also collected to enumerate the number of CD9+ve and STEAP1+ve oncosomes released by extravasating cells. Primary tumors were also formed and blood collected in the same manner to ascertain the extent of oncosome release in vivo. RESULTS: At the key step of extravasation, arrested cancer cells release oncosomes into the microcirculation which are observed to exhibit a diameter >900 nm and expressing surface antigens found on the surrogate prostate cancer cell such as CD9 and STEAP1. We explored the abundance and biophysical characteristics (size diameter range) of extracellular vesicles (EVs) released during the metastatic cascade and found that oncosomes are not consistently released by primary tumors or metastases and that these large cancer cell fragments are specifically released by actively extravasating cancer cells. CONCLUSIONS: Circulating oncosome levels in patient plasma are a novel biomarker or “liquid biopsy” for actively metastasizing cells in the body, representing a powerful tool for monitoring metastatic cancer dynamics. We show that oncosome biogenesis is a specific byproduct of extravasating cells and not by primary tumors or metastatic deposits even in the presence of pro-apoptotic or pro-necroptotic stimuli. Our findings in plasma samples from patients on first-line treatment for metastatic prostate cancer support the concept of oncosomes as a promising biomarker for monitoring cancer metastasis dynamics in realtime, a novel "liquid biopsy" for metastatic prostate cancer treatment response.

Single CTC isolation and Analysis of PCa CTCs Using Celsee™ PREP SingleCell system.
A. Ahmed1, V.P. Sharma2, W. Chow2, P. Gogoi2, K. Handique2, E. Keller1;
1University of Michigan, Department of Urology, Ann Arbor, MI; 2Applications Research and Development, Celsee Diagnostics, Plymouth, MI

Prostate cancer (PCa) is the second most common cancer in American men accounting for an estimated 180,890 new cases and about 26,120 deaths in 2016 (Siegel, Miller, & Jemal, 2016). PCa metastasis is responsible for the vast majority of PCa-related deaths (Kelly & Yin, 2008). Circulating tumor cells (CTCs) are considered the focal points of the metastatic cascade. Recently, our understanding of cancer heterogeneity indicates that metastasis is a complex problem consisting of heterogeneous populations residing within the tumor. Due to lack of a sensitive technology, the majority of studies on PCa metastasis have focused on CTC enumeration and cell signaling of bulk cells. With the advent of the microfluidic technology it has now become possible to capture rare cell populations from peripheral circulation. However, isolating rare cells in a single cell format with high efficiency has been a long-standing challenge. In this study, we will present evidence that PCa CTCs can be isolated from peripheral blood of mice that have C4-B PCa cells xenografts, using the Celsee PREP CTC enrichment method. Following this, cells are captured onto a Celsee SingleCell chip and single CTCs are isolated using Celsee single cell retriever for downstream analysis such as single cell expression and morphology analysis. The Celsee SingleCell chip is fabricated with an optically compatible polymer and consists of 256,000 nano wells which captures cells with high efficiency in less than an hour. The Celsee single cell retriever allows precision movements over nano-meter distance and isolates single cell from the chip while maintaining cell morphology and viability. The overall objective of this study is to demonstrate the capability of the Celsee PREP technology to isolate single CTCs most likely undergo transformation to metastasize in the peripheral blood from the site of injection. The isolated CTCs may further be used for any high resolution molecular analysis.

Overexpression of VRK1 promotes mammary epithelial cell proliferation in three-dimensional culture, slows cell migration and induces a partial mesenchymal to epithelial transition (MET) phenotype.
A.M. Mon1, P. Traktman1;
1Department of Biochemistry, Medical University of South Carolina, Charleston, SC

Vaccinia-related kinase 1 (VRK1) is a nuclear serine/threonine kinase that shows elevated expression in highly proliferative tissues, tumors and several cancer cell lines. Mice engrafted with VRK1-depleted MDA-MB-231 cells develop smaller primary tumors and fewer, if any, distal metastases to the lung and brain than seen with control cells (Molitor & Traktman, 2013). In contrast, VRK1 overexpression has been associated with poor clinical outcome in ER+ breast cancer patients. Here, we describe the impact of overexpressing VRK1 (or, as a control, 3XF-kinase dead-VRK1) on MCF10A cells using stable cell lines generated by lentiviral transduction. RNA microarray analysis of control vs 3XF-VRK1 monolayers revealed altered expression of several genes associated with cell migration, cell-cell and cell-substratum adhesion. In a series of follow-up studies, we determined that VRK1 overexpression significantly delays cell spreading, sheet migration, filopodia formation and transwell invasion. 3XF-VRK1 cells show reduced accumulation of the mesenchymal marker vimentin and increased accumulation of the epithelial cell-cell adhesion markers E-cadherin, and claudin-1. Strikingly, 3XF-VRK1 overexpression is also associated with reduced levels of the transcriptional repressors snail, slug, and twist, which regulate E-cadherin and claudin-1 expression. Because these findings suggest that VRK1 overexpression augments the epithelial properties of MCF10A cells, we also studied 3D matrigel cultures, in which cells proliferate and form spherical epithelial sheets surrounding hollow lumens (acinus). When we examined VRK1-overexpressing cells in 3D culture, we observed that initial acinus growth was accelerated relative to control cells. When acini were pulsed with BrdU, we found that constitutive VRK1 overexpression led to an increase in the S-phase population at days 4 and 5. By days 7 and 12, however, the vast majority of cells were in G0/G1 in all cell lines. VRK1 overexpression clearly promotes initial acinus growth, but does not block the later stages of acinar maturation, which are characterized by a cessation of cell proliferation and the apoptosis of luminal cells that are not participating in cell:cell or cell:matrix interactions. In sum, we have shown that VRK1 overexpression promotes MCF10A proliferation in 3D culture, and retards cell spreading, migration and invasion in 2D culture. By doing so, VRK1 may play a role in promoting the mesenchymal-to-epithelial transition involved in cancer cell colonization and metastatic spread, perhaps by regulating the transcription repressors snail, slug, and twist1.

The effects of bisphenol (BPA) and BPA structural analogs on metastasis of the MCF-7 breast cancer cell line.
J. Lachowicz1, S. Parikh1, C. Leahy2, A. Kopera2, E. Frees2, J. Saunders2, A. Goldstein1, R. Roberts1,2;
1Biochemistry Molecular Biology Program, Ursinus College, Collegeville, PA, 2Biology Department, Ursinus College, Collegeville, PA

Bisphenols are plasticizers that share a similar structure to estrogen and are, therefore, classified as estrogen disrupting compounds. When bisphenols are present, they can bind to estrogen receptors and signal both classical and non-classical pathways to elicit a cellular response. The natural hormone
estrogen is known to modify enzyme function and elicit cell proliferation of certain cell types, including breast cancer cells. Similar effects, including an increase in metastasis, are seen in breast cancer cells exposed to bisphenol A. This is partly achieved through the hyper-production and excretion of lysosomal proteases known as cathepsins. Although many plastic-producing companies have removed bisphenol A from the manufacturing process, it is often being replaced with similar structural analogs. Through the use of cathepsin-specific fluorescence activity assays and transwell migration assays, we have found that BPA structural analogs (BPF and BPS) also modify cathepsin activity and cell metastasis of the MCF-7 line of human breast cancer cells.

Role of mDia2 at Adherens Junctions in Epithelial Ovarian Cancer.
Y. Zhang, K.M. Eisenmann;
1Biochemistry and Cancer Biology, University of Toledo, Toledo, OH

Epithelial ovarian cancer (EOC) cells disseminate within the peritoneal cavity, in part, via the peritoneal fluid as single cells, clusters, or spheroids. Initial single cell egress from a tumor mass involves the disruption of cell-cell adhesions in a process commonly known as epithelial-mesenchymal transition (EMT). In epithelial cells, adherens junctions (AJs) are characterized by homotypic linkage of E-cadherins on the plasma membranes of adjacent cells. AJs are anchored to the intracellular actin cytoskeletal network through a complex involving E-cadherin, p120 catenin, β-catenin, and αE-catenin. However the specific players involved in the interaction between the junctional E-cadherin complex and the underlying junctional actin is complex and remains unclear. Recent evidence indicates that the actin-nucleating family of mammalian Diaphanous-related (mDia) formins plays a key role in epithelial cell AJ formation and maintenance. Binding of αE-catenin to linear F-actin inhibits association of the branched-actin nucleator Arp2/3, while favoring linear F-actin bundling. Our previous published work specifically implicated mDia2 and not mDia1 as a downstream effector of RhoA in maintaining EOC spheroids. Loss of mDia2 was associated with spheroid invasive egress. Our current work indicates that mDia2 has a role at adherens junctions in EOC cells and human embryonic kidney (HEK) 293 cells through its association with αE-catenin and β-catenin. Both inhibition of mDia2 activity and depletion of mDia2 in EOC cells leads to disruption of cell-cell junctions, supporting the necessity of mDia2 for the stability of the junctional E-cadherin/catenin complex. Further experiments will be performed to determine the impact of mDia2 depletion compared to mDia2 agonism on AJ formation and stability.

Melanoma cell malignancy does not correlate with migratory rates in three different highly metastatic cell lines.
A.M. Pasapera-Limon, T. Amos, C.M. Waterman, M.A. Baird;
1Cell Biology, NHLBI-NIH, Bethesda, MD, 2Chantilly High School, Chantilly, VA

Malignant melanoma is characterized by its ability to metastasize to different organs, and is responsible for 90% of skin cancer mortality. Metastasis requires cancer cell migration from the primary tumor to blood and lymph vessels, where the cells become disseminated to and populate distant organs. Cell migration is a complex process that requires dynamic remodeling of the cytoskeletal and integrin-based focal adhesions (FAs). However, it is unclear whether metastatic potential correlates directly with cell migration behavior or cytoskeletal and FA phenotype. To test this, we examined cell migration and the
cytoskeleton and FAs in 3 different human melanoma cell lines that differ in their metastatic potential: the highly metastatic Lu 1205, A375 cells with an intermediate metastatic potential, and less metastatic SK-mel-28 cells. Cell motility was evaluated by time-lapse phase contrast microscopy in wound healing assays over 48 hours, and cell velocities were measured using kymograph analysis. We found that SK-mel-28 cells migrated 2 times faster than Lu1205 and A375 cells. To see if cytoskeleton and FA organization related to the migratory behaviors, we performed immunofluorescence analysis using antibodies to myosin IIA and paxillin as an FA marker and stained the actin filaments with Alexa 565 phalliodin. Fluorescence images showed that SK-mel-28 cells presented small focal adhesions and dense, well-organized myosin IIA ribbons on a cortical actin meshwork, while A375 and Lu 1205 cells had larger focal adhesions and myosin IIA filaments organized into peripheral arcs and thick actin stress fibers. We then used polyacrylamide gel electrophoresis and western blot to analyze the FAK signaling pathway across the 3 cell lines. This showed that Lu 1205 cells presented highest phosphorylation of FAK on tyrosine 397 (p-FAK), while SK-mel-28 had the least p-FAK in comparison. Since higher p-FAK correlates with strong integrin binding to the ECM, it is likely Lu 1205 cells exert higher integrin activation in their large FAs, which could correlate with slower FA turnover and slower migration. In contrast, in SK-mel-28 cells, lower p-FAK, small focal adhesions and well organized myosin likely result in the observed fast motility. However, because the slow-migrating Lu 1205 cell line has a higher metastatic potential than the fast-migrating SK-mel-28, our results suggest that there is no correlation between metastatic potential and in vitro motility rate and corresponding cytoskeletal and adhesion phenotype.

Role of AMPK isoforms during breast cancer cell migration.
C.D. Williams1, M.M. Fox1;
1Biology, Wingate University, Wingate, NC

AMP-dependent kinase (AMPK) has made its way to the forefront of cancer biology following a 2005 retrospective study showing that diabetic patients have a reduced incidence of cancer when following a treatment regimen consisting of metformin therapy, a biguanide pharmaceutical that is a known AMPK activator. As a master metabolic regulator, AMPK serves to suppress energy expenditures under nutritional stress and instead tilt signaling pathways towards catabolic processes to restore energy levels. In a cancer cell setting, it has been shown that AMPK activation will reduce cell growth, halt cell cycle progression, and even promote apoptosis under appropriate conditions. This has resulted in a widespread acceptance that AMPK functions to suppress tumor growth and should be targeted for therapeutic opportunities. Upon closer examination of AMPK signaling pathways, however, a paradox surfaces showing that AMPK’s efforts to restore energy levels may also enhance survival mechanisms – in both normal and cancer cells - through angiogenesis, autophagy, and migration/invasion. This study investigated the potential role for AMPKα1 and -α2 isoforms in regulating MDA-MB-231 breast cancer cell migration. A wound healing assay was performed by plating cells to confluence, establishing a “wound” using a pipet tip, and imaging the rate of wound closure periodically over the course of 24 hours. Results indicate that MDA-MB-231 cells exhibited a baseline wound closure rate of 41.4 ± 9.9% under standard culture conditions. When the AMPKα isoforms were activated with metformin, there was a significant dose-dependent increase in wound closure with values of 76.2 ± 3.2% (p=3.2x10^6) with 2.5mM metformin and 85.5 ± 4.6% (p=1.4x10^-7) with 5mM metformin. This migratory effect was ablated when AMPK was inhibited with compound c and wound closure values were reduced to 18.7 ± 3.2% (p=1.2x10^4) and 15.8 ± 4.2% (p=3.7x10^-5), respectively. The experiment was also repeated using siRNA oligos targeting AMPKα1 or AMPKα2 to determine whether this phenotype was isoform specific. Results showed partial knockdown of each AMPKα isoform (ranging from 50-75% ablation at the protein
level) but did not demonstrate any influence on migratory behaviors. Lastly, the localization of phosphorylated AMPKα protein was evaluated by performing immunofluorescence on cells fixed during the wound healing process. Staining reveals that activated AMPK localizes to the leading edge of the migratory cells, suggesting a possible linkage between cytoskeletal rearrangement and AMPK signaling. Overall, it is seen that AMPK activation promotes migration in MDA-MB-231 breast cancer cells and should be further explored to better understand this adverse survival phenotype prior to clinical use.

Cholangiocarcinoma (CCA), a biliary duct cancer, is highly prevalent in northeastern area of Thailand. The prognosis of CCA is poor with short survival time, therefore new therapeutic targets for CCA treatment is required. The secreted glycoprotein galectin-3-binding protein (LGALS3BP) is found to be overexpressed in serum and tissue of cancer patients, and it has been reported to have both positive and negative influences on cancer prognosis. However, the expression and roles of LGALS3BP on CCA are still unknown. We found that the expression levels of LGALS3BP protein were upregulated in CCA cell lines compare to human cholangiocyte cells. Role of LGALS3BP in two CCA cell lines, KKU-M213 and HuCCA-1 was examined using lentiviral shRNA. Knockdown LGALS3BP decreased CCA cell proliferation and survival. Surprisingly, we found that knockdown LGALS3BP increased migration and invasion abilities of both of CCA cell lines. The expression levels of LGALS3BP partners (CD82, CD9, β1 integrin and galectin-3) were not altered in knockdown LGALS3BP cells. Moreover, knockdown LGALS3BP decreased Akt (Ser473) and however increased p70S6K (Thr389) phosphorylation. These results indicate that the decreasing of cell proliferation and survival in knockdown LGALS3BP CCA cells might be mediated through inhibition of Akt activation. In contrast, increasing of cell migration and invasion after LGALS3BP suppression might be partly mediated by activation of p70S6K. Herein, we demonstrated for the first time about the dual effects of LGALS3BP on CCA phenotypes. Our finding highlights the precaution of using LGALS3BP as therapeutic target or prognostic biomarker for CCA.

**Thy-1/CD90 induces metastatic breast cancer cell migration.**
M. Brenet\(^1\), S. Martinez\(^1\), A.F. Quest\(^1\), L. Leyton\(^1\);
\(^1\)Cellular Communication Laboratory. Advanced Center for Chronic Diseases (ACCDiS). Center for Molecular Studies of the Cell (CEMC), Institute of Biomedical Sciences. Faculty of Medicine., University of Chile, Santiago, Chile

Cell migration is essential for the development and homeostasis of multicellular organisms, tissue repair and regeneration, and contributes significantly to disease states, such as tumor cell metastasis. Previous studies have shown that Thymus cell antigen 1 (Thy-1/CD90), a cell adhesion molecule of activated endothelial cells, mediates the adhesion of melanoma cells to the endothelium through interactions...
with integrins in cancer cells. However, a role for Thy-1 in the migration of breast cancer cells remains undefined. Here, we studied whether Thy-1 may participate in the migration of metastatic human breast cancer MDA-MB-231 cells. We determined the migration of cells in a wounded monolayer stimulated by Thy-1. We observed that Thy-1 induced a rapid increase in ATP release, focal adhesion formation and cell migration in MDA-MB-231 cells. In the presence of Apyrase, Thy-1-induced cell migration was decreased, suggesting that ATP is required for migration of breast cancer cells. Moreover, blockers of the P2X7 purinergic receptor also decreased cell migration. Thus, our results reveal that ATP signaling via P2X7 receptors is required for Thy-1 induced migration of breast cancer cells. These findings suggest that purinergic receptors may represent an attractive therapeutic target to prevent breast cancer metastasis.

1Pharmacology Physiology, Drexel University, Philadelphia, PA, 2Lankenau Institute for Medical Research, Wynnewood, PA, 3The Wistar Cancer Center Molecular Screening, Wistar Institute, Philadelphia, PA

Pancreatic ductal adenocarcinoma (PDAC) has become the third-leading cause of cancer death in the United States. Most patients present with advanced metastatic disease that is resistant to conventional therapies, which is in part due to a unique tumor microenvironment (TME). The PDAC TME includes a dense desmoplastic stroma comprised of heterogeneous cellular and fibrotic components that exert both pro- and anti-tumorigenic effects. These phenotypes are mediated through intercellular crosstalk and interaction with the extracellular matrix. CX3CL1 is a chemokine known to play an important role in extravasation, homing and distal establishment of breast and prostate cancer cells through its receptor CX3CR1. Furthermore, previous results show that PDAC perineural locoregional invasion within the pancreas is driven by CX3CR1:CX3CL1 traction. However, it remains unknown if this signaling axis contributes to other elements of PDAC tumor primary development and maintenance or its metastasis to distal sites. We hypothesize that CX3CR1 signaling is a driving force of growth, survival, dissemination and metastatic progression through TME interaction. Here we demonstrate CX3CL1:CX3CR1 signaling regulating cancer cell mobility and proliferation. Our data suggest that CX3CL1 contributes to cancer cell motility, and inhibition of the CX3CR1 receptor by selective small molecule antagonists diminishes cell migration and viability in contact-independent cultures, in part through loss of phosphorylation of AKT. Interestingly, log phase 2D cell viability remained unaffected by CX3CR1 inhibition, suggesting a particular role for CX3CL1 in the three-dimensional organization and progression of PDAC tumors through TME cell-cell interaction and/or signaling. Our findings suggest that CX3CR1 inhibition may serve as a viable therapeutic intervention for PDAC.

Differential Expression of miRNAs and EMT-Related Targets in Cutaneous Squamous Cell Carcinoma Tissues.

C.S. Pulford$^{1,2}$, M.R. Montgomery$^{2,3}$, C.K. Uppalapati$^1$, A.S. Pascual$^2$, E.E. Hull$^2$, K.J. Leyva$^1$;

$^1$Department of Microbiology Immunology, AZCOM, Midwestern University, Glendale, AZ; $^2$Biomedical Sciences Program, Midwestern University, Glendale, AZ; $^3$Department of Nutritional Sciences, Oklahoma State University, Stillwater, OK

Cutaneous Squamous Cell Carcinoma (cSCC) is a common form of skin cancer predominantly induced by exposure to UV radiation (sunlight), with most cases remaining localized at the site of initiation. As cSCC is commonly treated by surgical excision, the amount of research investigating how cSCC can progress from a relatively benign state to becoming invasive, and potentially metastatic, is sparse. Metastasis of tumor cells is mediated by a process known as epithelial-to-mesenchymal transition (EMT). During EMT, epithelial cells undergo a dedifferentiation process whereby they transition to a highly mobile and invasive mesenchymal cell type with metastatic capacities. Although numerous factors have been identified as influencing the EMT process in a variety of cancers, we chose to examine the role of miRNAs. miRNAs are small, non-coding RNA species that are known to epigenetically regulate a host of genes within a given cell type. We hypothesized that miRNAs are differentially expressed between normal vs. cSCC tissue and that these differences in expression contribute to the progression of cSCC. To test this hypothesis, we compared the expression pattern of ten miRNAs (miR-21, -31, -34a, -125b, -181, -199a, -200b, -200c, -204, and -1246) between fresh primary tumor samples and fresh adjacent normal tissue (ANT) collected from patients diagnosed with either cSCC, SCC in situ, or invasive SCC. Total RNA was isolated from each of the samples and qPCR was performed to determine the expression level of each miRNA relative to control. Of the ten miRNAs tested, two were significantly upregulated (miR-21 and miR-31) in the patient cSCC samples compared to ANT. We then examined the expression of miR-21 and miR-31 targeted EMT markers via qPCR and/or Western blot from RNA and protein isolated from both cSCC and ANT tissues. TGF-β1 and TGF-βR2 mRNA were significantly increased relative to normal tissue, suggesting EMT may be being initiated in the cancerous tissue. mRNA expression of E-cadherin was significantly increased in cSCC as well, and protein expression of phosphorylated E-cadherin was also significantly higher, potentially indicating increased E-cadherin-mediated signaling in the cancerous cells, although this remains to be verified experimentally. Further work investigating the function of these differentially-expressed miRNAs will elucidate the role miRNAs are playing in the progression of cSCC.

DDR1 regulates tumor dormancy by balancing p38/ERK signaling.

J.S. Di Martino$^1$, C. Mondal$^1$, J. Aguirre-Ghiso$^1$, J.J. Bravo-Cordero$^1$;

$^1$Hematology Oncology, Icahn school of medicine at Mount Sinai, New York, NY

Background: Metastasis is the primary cause of death in cancer patients. However, metastatic manifestation can takes years after primary tumor removal. This delay in metastatic growth is a consequence of tumor dormancy, a reversible growth arrest that can be regulated by the interaction of disseminated tumor cells (DTCs) with the environments they encounter, through balancing p38/ERK (quiescence/proliferative) signals. Tumor cells interact with collagen through integrins, DDRs, GPVI and LAIR-1 receptors. The collagen receptor Discoidin Domain Receptor 1 (DDR1) is part of a dormancy
signature established in ER+ breast tumors; however its role in tumor dormancy is not well understood. Here, we investigate the role of DDR1 in tumor dormancy.

Methods: We used breast cancer cell lines and a well-described dormancy model of head and neck squamous cell carcinoma (HNSCC) to study the role of DDR1 in tumor dormancy. To analyze the status of p38/ERK signaling pathways at the single cell level we used recently developed p38 and ERK biosensors to study the activation of these signaling nodes in vivo by using intravital multiphoton microscopy.

Results: We have determined that DDR1 is overexpressed at both RNA and protein levels in breast cancer and HNSCC dormant cells when compared with their proliferative counterparts. We demonstrated that the downregulation of DDR1 induces proliferation of dormant cells in vivo: in chicken embryo CAMs and in nude mice, by balancing p38/ERK signaling. Finally, we utilized p38 and ERK biosensors to identify where proliferative and dormant cells reside in vivo.

Conclusion. We demonstrated that DDR1 expression maintains quiescence of tumor cells and prevents metastasis formation through the regulation of p38/ERK signaling.

The role of srGAP1 in regulating cancer cell motility and invasion.
C. Mondal¹, J.S. Di Martino¹, J.J. Bravo-Cordero¹;
¹Medicine, Icahn School of Medicine at Mount Sinai, New York, New York, United States

The Rho family of small GTPases, which regulates actin cytoskeleton organization, contributes to many key cellular functions, including cell motility, polarity, and vesicle trafficking. Activation and deactivation of Rho GTPases is regulated by guanine nucleotide exchange factors (GEFs), GTPase-activating proteins (GAPs), and guanine nucleotide dissociation inhibitors (GDIs). In pathological processes, such as cancer, regulators of Rho GTPases are often mutated and overexpressed; however, their contribution to disease progression is relatively unknown.

The Slit-Robo GAP (srGAP) family was initially identified as Robo-interacting proteins that regulate neuronal cell migration. We find that srGAP1, an F-BAR domain containing protein, is expressed in mesenchymal, triple-negative breast cancer cells, but not in ER+ non-migratory breast cancer cells. srGAP1 localizes to both lamellipodia and invasive protrusions (invadopodia and linear invadosomes), which are F-actin rich structures that degrade the extracellular matrix. siRNA-mediated depletion of srGAP1 expression results in an increase in 2D and 3D cell motility on collagen I fibrils and in collagen I plugs, respectively, as well as an increase in matrix degradation on collagen I fibrils.

To analyze the effects of srGAP1 on tumor cell dissemination in vivo, we have developed an intravital imaging platform that allows us to analyze disseminated tumor cell (DTC) behavior and measure single-cell motility parameters, such as protrusion formation, in sites of dissemination (e.g. the lymph nodes). We aim to utilize intravital multiphoton imaging to further understand srGAP1 effects on DTC seeding, motility, and metastasis formation.

1Biomedical Sciences, Midwestern University, Glendale, AZ

Background: The SW13 cancer cell line has two naturally occurring, well-defined and epigenetically distinct cell subtypes. The SW13(Vim-) has a phenotype that resembles typical epithelial tumors and displays increased growth and proliferation with a low level of invasiveness. The SW13(Vim+) subtype has mesenchymal-like phenotype that is commonly associated with invasive and metastatic epithelial cancers. The phenotype of the SW13(Vim-) cell subtype can be driven toward the SW13(Vim+) phenotype when treated with histone deacetylase inhibitors. This SW13 cell line model is used to study the epigenetic phenotypic differences in primary tumor versus metastatic cells. Gene chip data obtained from the SW13 subtypes documents differential expression of genes involved in cholesterol, sphingolipid, and GPI-anchored protein metabolism, all of which are essential components of lipid rafts.

Hypothesis: As genes affecting the synthesis of all components of lipid rafts are differentially expressed in the SW13 subtypes, we hypothesize that 1) lipid raft protein composition is distinctly different between the two SW13 cell subtypes and that 2) differences in the composition of lipid rafts may play a role in the unique oncogenic phenotypes of the two subtypes.

Methods: Utilizing low-temperature detergent-resistant lipid raft isolation techniques, western blotting, and mass spectrometry, we investigated protein composition differences between the two SW13 cell subtypes. Cholesterol assays were used to assess the distribution and total cholesterol content of each SW13 subtype to evaluate the impact of the differentially expressed cholesterol genes detected in gene chip data obtained from the subtypes. Cholesterol depletion techniques utilizing cyclodextrin for acute disruption and simvastatin for chronic disruption have been used to perturb lipid rafts and observe their role in the unique oncogenic phenotypes of the SW13 cell subtypes.

Results: Preliminary results in cholesterol assays confirm differential cholesterol levels in the two SW13 cell subtypes. Western blot analysis suggests differential protein composition of lipid rafts, several of which are confirmed cancer biomarkers, isolated from each SW13 subtype. Ongoing experiments are measuring the metastatic capacity in the SW13(Vim+) after lipid raft and cholesterol perturbations.

Conclusions: Results may detail a mechanism in which cholesterol perturbations are capable of decreasing metastasis, improving the outcome of patients with epithelial cancers. Specifically, this data may provide a mechanism by which treatment with statin drugs has led t

Cancer Therapy: Targeting the Tumor Microenvironment

SIRPA-inhibited, marrow-derived macrophages engorge, accumulate, and differentiate in antibody-targeted regression of solid tumors.
C. Alvey1, D.E. Discher1;
1Pharmacology, University of Pennsylvania, Philadelphia, PA

Marrow-derived macrophages are highly phagocytic, but whether they can also traffic into solid tumors and engulf tumor cells is questionable, given the well-known limitations of tumor-associated macrophages (TAMs). Here, SIRPα on macrophages from mouse and human marrow was inhibited to
block recognition of its CD47 ligand, a ‘marker of self’ on all other cells. These macrophages were then systemically injected into mice with fluorescent human tumors that had been antibody targeted. Within days, the tumors regressed, and fluorescence analyses showed that the more the SIRPα-inhibited macrophages engulfed, the more they accumulated within regressing tumors. Human marrow-derived macrophages engorged on the human tumors, while TAMs were minimally phagocytic, even toward CD47-knockdown tumors. Past studies have opsonized tumors in situ with antibody and/or relied on mouse TAMs but have not injected SIRPα-inhibited cells; also, unlike past injections of anti-CD47, blood parameters remained normal here. Consistent with tumor-selective engorge-and-accumulate processes in vivo, phagocytosis in vitro inhibited macrophage migration through micropores that mimic features of dense 3D tissue. Accumulation of SIRPα-inhibited macrophages in tumors favored tumor regression for 1-2 weeks, but donor macrophages quickly differentiated toward non-phagocytic, high-SIRPα TAMs. Analyses of macrophages on soft (like marrow) or stiff (like solid tumors) collagenous gels demonstrated a stiffness-driven, retinoic acid-modulated upregulation of SIRPα and a mechanosensitive nuclear marker, lamin-A. Mechanosensitive differentiation was also evident in vivo and likely limited the anti-tumor effects, as confirmed by re-initiation of tumor regression by fresh injections of SIRPα-inhibited macrophages. Macrophage motility, phagocytosis, and differentiation in vivo are thus coupled.

Extracellular matrix-binding peptide conjugation to immune checkpoint blockades enhances anti-tumor efficacy and reduces adverse events.
J. Ishihara1,2, K. Fukunaga3, A. Ishihara1, H.M. Larsson2, L. Potin1,2, P. Hosseinchi1, M. Swartz1, J.A. Hubbell1,2;
1Institute for Molecular Engineering, The university of Chicago, Chicago, IL, 2Institute of Bioengineering, Ecole Polytechnique Fédérale de Lausanne, Lausanne, Switzerland, 3Department of Bioengineering, Tokyo Institute of Technology, Kanagawa, Japan

Therapy using anti-CTLA4 and anti-PD-1/PD-L1 antibodies (Abs) has exhibited considerable anti-tumor effects, but instances of severe side-effects have been previously reported. We hypothesized that conjugation of an extracellular matrix (ECM)-binding peptide derived from placenta growth factor-2 (PIGF-2123-144) to anti-CTLA4 and anti-PD-L1 Abs would accomplish localized immune checkpoint blockade therapy, minimizing the Abs’ systemic exposure. Here, we show that enhanced tissue retention and lower Ab concentrations in the blood plasma resulted from PIGF-2123-144 conjugation when the Abs were administered peri-tumorally compared to wild-type (wt) Abs administered by the same route at the same dose. This resulted in decreases in TNFa and IFNg concentrations in the serum and a decrease in liver tissue damage, as was assessed both biochemically and histologically. These results indicate lower systemic side-effects. Particularly, we show that PIGF-2123-144 conjugation reduced the risks of checkpoint blockade-induced auto-immune diabetes in the male non-obese diabetic (NOD) mouse. Remarkably, wt anti-PD-L1 induced type 1 diabetes in 100% of male NOD mice, while our matrix-binding variant did not induce type 1 diabetes in any mice. Because diabetes induced by PD-1/PD-L1-inhibition has been reported in the clinic, this strongly supports the idea that PIGF-2123-144-conjugation to Abs could reduce treatment-related adverse events. This observation with localized PIGF-2123-144-Abs could be an important breakthrough in treating patients who have discontinued checkpoint blockade therapy due to the associated side-effects, as well as those who are not amenable to systemic chemotherapy. In addition, we show that PIGF-2123-144 anti-CTLA4 and -anti-PD-L1 Abs treatment exhibited significantly higher anti-tumor activity compared to wild-type forms in three cancer models: B16F10 melanoma, Tyr:Cre-ER+/LSL-BrafV600E/Ptenfl/fl inducible autochthonous melanoma, and MMTV-PyMT breast.
cancer. Importantly, local injections of Plgf-2123-144-Combination Abs increased the number of activated CD8+ and CD4+ T cells within the tumor, resulting in growth suppression of both the distant tumor and re-challenged tumor. This data suggests the feasibility of treating patients with oligometastatic tumors by administration of Plgf-2123-144-Combination Abs into one available metastasis. Our data suggest that local injection of Plgf-2123-144-Combination Abs efficiently activates tumor-antigen-specific T cells while maintaining systemic immune homeostasis by avoiding influence on non-tumor antigen specific T cells. This simple approach of using engineered ECM-binding Abs may hold potential for clinical translation of locally-delivered immune checkpoint blockade as a cancer therapeutic.

Extracellular matrix-binding form of anti-Cd40 agonistic antibody reduces systemic damages and increases anti-tumor efficacy.
A. Ishihara1, J. Ishihara2, K. Fukunaga1,2, J.A. Hubbell1;
1Institute for Molecular Engineering, University of Chicago, Chicago, IL, 2Department of Bioengineering, Tokyo Institute of Technology, Yokohama, Japan

Anti-Cd40 agonistic antibody maturates antigen-presenting cells, showing considerable anti-tumor effects, but previous studies have reported severe side-effects. We hypothesized that peri-tumoral injections of extracellular matrix (ECM)-super affinity peptide conjugated anti-Cd40 antibody would accomplish local immune therapy via antigen presenting cell maturation around the tumor. Here, we conjugated an ECM binding peptide: placenta growth factor-2 (Plgf-2123-144), to anti-Cd40 antibody and observed a decrease in concentrations in blood plasma. This reduces cytokine concentration in the serum and liver tissue damages, indicating lower systemic side-effects. Plgf-2123-144-Cd40 antibody administration exhibit significantly higher anti-tumor efficacy compared to its wild-type form in B16F10 mouse melanoma model. Importantly, Plgf-2123-144-anti-Cd40 treatment slowed growth of B16F10, at low dosages where wild-type anti-Cd40 antibody had no effect. Plgf-2123-144-Cd40 antibody administration activates CD8+ T cells (defined as PD-1+ and CD62L-Cd44+) in both tumor and tumor-draining lymph nodes as much as its wild-type form. Plgf-2123-144-Cd40 antibody, but not wild-type form, increased maturated dendritic cells (defined as % CD80+CD70+ of CD11c+) within tumor. Plgf-2123-144-Cd40 antibody but not wt Cd40 antibody increased mature B cells (defined as % MHCIIhigh CD80+ of B220+ cells) in tumor and tumor-draining lymph node. Plgf-2123-144-Cd40 antibody but not wt Cd40 antibody increased plasmablasts (defined as % Blimp I of B220+ cells) in tumor-draining lymph node. Also, Plgf-2123-144-Cd40 antibody but not wt Cd40 antibody increased mature CD11b cells (defined as % MHCIIhigh CD80+ of B220+ cells) in tumor-draining lymph node. Finally, the activation of immune cells efficiently suppresses the growth of a distant tumor when Plgf-2123-144-Cd40 antibody was injected peri-tumorally to one tumor. This ECM-binding Cd40 antibody may be useful to achieve effective cancer local immunotherapy avoiding its systemic side-effect.

NMK-057, a novel triazole derived γ-secretase inhibitor attenuates Notch mediated-EMT and stemness in triple negative breast cancer cells by inducing autophagic cell death.

A. Das1,2, P. Mukherjee1, N.M. Kumar3, A. Ganguli2, D. Ghoshdastidar2, B. Basu5, U. Chatterji3, S. Banerjee6, D. Kumar4, G. Chakrabarti2;

1Biotechnology, National Institute of Technology, Sikkim, Ravangla, India, 2Biotechnology, Calcutta University, kolkata, India, 3Zoology, Calcutta University, kolkata, India, 4Chemistry, Birla Institute of Technology and Science, Pilani, Rajasthan, India, 5Amity Institute of Biotechnology, Amity University, Noida, UP, India, 6Cancer Research Unit, VA Medical Center, Kansas City, MO

Autophagy plays a dual role in cancer depending on its role in the survival or death of cancer cells. The relationship between autophagy and Notch signaling is not clear and only a few reports have come across in highly reputed journals in last one year. Notch signaling is reported to be deregulated in several malignancies including breast and the enzyme γ-secretase plays important role in the activation and nuclear translocation of Notch intracellular domain (NICD). Hence pharmacological inhibition of γ-secretase might lead to the subsequent inhibition of Notch signaling in cancer cells. But whether inhibition of γ-secretase triggers autophagy is an interesting topic of investigation and not reported in detail. In search of novel γ-secretase inhibitors (GSIs), we screened a series of triazole-based compounds, for their potential to bind γ-secretase and we observed that 3-(3′,5′-Trimehtoxyphenyl)-5-(N-methyl-3′-indolyl)-1,2,4-triazole compound (also known as NMK-T-057) can bind to γ-secretase complex. Very interestingly, NMK-T-057 was found to inhibit proleiferation, colony forming ability, and motility in various triple negative breast cancer cells such as MDA-MB-231, MDA-MB-468, 4T1 and also MCF-7, with negligible cytotoxicity towards non-cancerous MCF-10A, and PBMC. NMK-T-057 also showed limited toxicity in Swiss albino mice, as determined by measuring the hematological and clinical parameters. Moreover NMK-T-057 treatment resulted in the reprogramming of the EMT process in TNBCs, accompanied by the drastic reduction of CD44high/CD24low population. NMK-T-057 also inhibited the spheroid forming ability of TNBCs and reduced the stem cell enriched side population. It was also observed that in NMK-T-057 treated cells, Notch-1 and its downstream targets such as Hes-1 and pAkt were significantly down regulated. The in silico study revealing the affinity of NMK-T-057 towards γ-secretase, was further validated by fluorescence based γ-secretase activity assay, which confirmed the inhibition of γ-secretase activity in NMK-T-057 treated TNBC cells. Very interestingly, we observed that NMK-T-057 induces significant autophagic responses in TNBCs and administration of the autophagy inhibitor 3-MA, attenuates NMK-T-057 induced cell death. Similar results were observed on the treatment of TNBC cells with commercially available γ-secretase inhibitor DAPT. Thus we might conclude that NMK-T-057 could be potential drug candidate against breast cancer, which can trigger autophagy mediated cell death in breast cancer cells by inhibiting the γ-secretase –mediated activation of Notch-signaling.

Saad\textsuperscript{1};

\textsuperscript{1}Hematology and Hemotherapy Center-University of Campinas, Campinas, Brazil, \textsuperscript{2}Universidade São Francisco, Bragança Paulista, Brazil, \textsuperscript{3}Dipartimento di Biotecnologie, Chimica e Farmacia, Università degli Studi di Siena, Siena, Italy

Src kinase family (SFK) is a family of non-receptor tyrosine kinases that includes nine members, which are aberrantly expressed and/or activated in diverse bone marrow malignancies, as acute myeloid leukemia (AML), a heterogeneous neoplasm with high incidence in older person. The better understanding of molecular targets that participate in the disease pathogenesis has led to new drug development and novel therapeutic strategies. In this concern, the aim of this study was to investigate the role of hematopoietic cell kinase (HCK), the unique SFK member restricted expressed in hematopoietic cells. We found that HCK is overexpressed in hematopoietic stem cell (HSC) isolated from total bone marrow of AML patients. Therefore, we did an effort to develop a selective inhibitor for HCK (iHCK). Using the iHCK, we evaluated its effects on cell growth and death as well as on regulation of the oncogenic pathways MAPK and PI3K, which usually is superexpressed in hematological neoplasm. The iHCK treatment significantly decreased cell growth and induced apoptosis in myeloid leukemic cell lines and in primary AML patient’s cells without changing in healthy donors HSC survival or death. Similar results were found in a 3D culture system (bioscaffold) that works as an optimal microenvironment: after iHCK treatment and culture into a bioscaffold for 7 days, primary AML patient’s cells showed an decreased proliferation when compared to healthy donors HSC. We also induced leukemia in mice using human leukemic cells. After the confirmation of the leukemia development, the mice were treated with iHCK. As occurred in vitro assays, the in vivo treatment with iHCK led to a decrease phosphorylation of ERK, AKT and P70S6K proteins in leukemic mice compared to untreated mice. These results demonstrated a reduced activation of MAPK/ERK and PI3K/AKT pathways in leukemic cells after HCK pharmacological inhibition. We also analyzed the combinatory effects of iHCK with Cytarabine or 5-Azacitidine, both drugs that are actually used in chemotherapy. The combinatory treatment of iHCK and Cytarabine or iHCK and 5-Azacitidine demonstrated additive effects relative to either drug alone on the reduction of cell growth and death, with increased BAX (pro-apoptotic) and reduced BCL-XL (anti-apoptotic) protein levels. In conclusion, the selective HCK inhibitor has an antiproliferative activity in leukemic cells without alter cell death and survival of normal HSC. Besides, iHCK treatment was able to abolish the activation of MAPK/ERK and PI3K/AKT pathways. Our results indicate that this compound only acts onto cells with higher HCK expression and activity, as occurs in leukemia, and could be useful for a novel AML treatment, mainly in combination with other chemotherapy drug.

Programmed death ligand 1 (PD-L1), Immune-Checkpoint Blockade with Combination Therapy in Syngeneic Colon Carcinoma Model.
W.H. Ka1;
1WJ RD Center, WOOJUNBSC, Suwon, South Korea

Cancer cells sometimes find ways to use these checkpoints to avoid being attacked by the immune system. But drugs that target these checkpoints hold a lot of promise as cancer treatments. Combination therapy is becoming more and more general in the treatment of oncological diseases. Now that safety and clinical activity has been demonstrated in the monotherapy setting, the field is moving in the direction of testing novel combinations. The aim of the study was to explore the role of programmed death ligand 1 (PD-L1) and the antitumor effect of anti- cytotoxic T-lymphocyte–associated antigen-4 (CTLA-4), Lymphocyte-activation gene-3 (LAG-3) and mucin-domain containing-3 (TIM-3) combination therapy in Colon Carcinoma. In this in vivo trial combination the standard immunotherapeutic treatment; the PD-L1 regulatory antibody and a CTLA-4, LAG-3 and TIM-3 antibody will be tested in Syngeneic Colon Carcinoma model. Monoclonal antibodies that target either PD-L1 or combination can block this binding and boost the immune response against cancer cells. These drugs have shown a great deal of promise in treating certain cancers.

HDAC6/DHPS signaling drives hypusination and nuclear export of eIF5A to promote TGFbeta-induced EMT and associates with a novel SOX2 signature to predict decreased breast cancer patient survival.
L. Kutscher1, Y. Adamian1, K. Meade1, K. Bhakta1, R. Gueth1, J.A. Kelber1;
1Biology, California State University Northridge, Northridge, CA

Progression of solid tumors to a metastatic stage accounts for over 90% of cancer mortality. Thus, it is critical to identify therapeutic strategies that target both primary and metastatic tumors. Epithelial-mesenchymal transition (EMT) negatively correlates with therapy response, contributing to intratumoral heterogeneity and systemic dissemination in breast cancer. We previously reported that pseudopodium-enriched atypical kinase one (PEAK1) promotes breast cancer cell EMT and metastasis by potentiating fibronectin - transforming growth factor beta (TGFβ) signaling cross-talk. Since eukaryotic initiation factor five A (eIF5A), a unique translation factor that is activated by post-translational hypusination, is required for PEAK1 expression, we hypothesized that TGFβ may directly regulate eIF5A activity as a novel means of promoting EMT, and that targeting this pathway may inhibit or reverse metastatic progression. In this regard, we provide evidence of an active eIF5A-EMT program in undifferentiated breast cancer tissue. Notably, blockade of eIF5A hypusination (via deoxyhypusine synthase, DHPS, inhibition) reduces PEAK1 translation, cell viability and TGFβ-induced EMT. Conversely, we demonstrate that TGFβ induces post-translational hypusination of eIF5A in metastatic breast cancer cells. TGFβ is known to activate histone deacetylase six (HDAC6) and HDAC6 was independently reported to promote eIF5A deacetylation and nuclear export, supporting its translation activity. When delivered in combination, HDAC6 and DHPS inhibitors synergize to sequester eIF5A to the nucleus, suppress eIF5A-dependent translation and potently kill metastatic breast cancer cells. To identify candidate pathways downstream of the eIF5A/PEAK1 axis during EMT, we generated a Cytoscape interactome using eIF5A signaling and PEAK1-induced EMT genes as search terms. All interactome component genes were then
analyzed across two breast cancer patient studies available on the Cancer Bio Portal. Interestingly, SOX2, PIK3CA and EIF4A2 were the interactome nodes that exhibited copy number amplifications among patients harboring genomic alterations in the initial interactome search genes, and SOX2 amplification significantly and independently associated with decreased patient survival (p = 0.0476). Taken together, our results establish a novel signaling pathway by which TGFβ stimulates HDAC6 and DHPS function to activate cytoplasmic elf5A and promote EMT and survival in breast cancer cells. This work also identifies new therapeutic reagents and strategies that may improve cancer patient survival.

Cordycepin induces human lung cancer cell apoptosis by inhibiting nitric oxide mediated ERK/Slug signaling pathway.
S. Kang¹, I. Jang¹;
¹Division of Bioconvergence, Korea Basic Science Institute, Daejeon, South Korea

Nitric oxide (NO) is an important signaling molecule and a component of the inflammatory cascade. Besides, it is also involved in tumorigenesis. Aberrant upregulation and activation of the ERK cascade by NO often leads to tumor cell development. However, the role of ERK inactivation induced by the negative regulation of NO during apoptosis is not completely understood. In this study, treatment of A549 and PC9 human lung adenocarcinoma cell lines with cordycepin led to a reduction in their viability. Analysis of the effect of cordycepin treatment on ERK/Slug signaling activity in the A549 cell line revealed that LPS-induced inflammatory microenvironments could stimulate the expression of TNF-α, CCL5, IL-1β, IL-6, IL-8 and upregulate NO, phospho-ERK (p-ERK), and Slug expression. In addition, constitutive expression of NO was observed. Cordycepin inhibited LPS-induced stimulation of iNOS, NO, p-ERK, and Slug expression. L-NAME, an inhibitor of NOS, inhibited p-ERK and Slug expression. It was also found that cordycepin-mediated inhibition of ERK downregulated Slug, whereas overexpression of ERK led to an upregulation of Slug levels in the cordycepin-treated A549 cells. Inhibition of Slug by siRNA induced Bax and caspase-3, leading to cordycepin-induced apoptosis. Cordycepin-mediated inhibition of ERK led to a reduction in phospho-GSK3β (p-GSK3β) and Slug levels, whereas LiCl, an inhibitor of GSK3β, upregulated p-GSK3β and Slug. Overall, the results obtained indicate that cordycepin inhibits the ERK/Slug signaling pathway through the activation of GSK3β which, in turn, upregulates Bax, leading to apoptosis of the lung cancer cells.

Life is a continuous cycle of the cells, composed of beginning, surviving and death. Cells keep dividing, differentiate and form somatic cells; and soon organism is formed. These somatic cells at some point can be turn into cancer cells and share characteristics of stem cells. The processes during these periods are important for the identifying the tendency to abnormality in somatic cells and transformation to the cancer cells. Cancer progenitor cells are the challenging concept not only arise, development and recurrence of the cancer but also sharing the characteristics of embryonic developmental stages. To control emergence and progress of the cancer, mechanisms take part in the surviving become significant, especially EMT and inflammation. EMT occurs in both embryonic developmental stages and cancer progression and molecular basis of this process can be the therapeutic target for cure. For the promising agents in cellular and molecular targeted therapy, this study was conducted in cancer, somatic and embryonic stem cells; compares similarities and differences in central signalling pathways EMT, MAPK and inflammation via gene profiling and protein expression. For cancer cell mouse squamous lung cancer cells (SqLCs), for somatic cells mouse skin fibroblast cells (MSF) and for embryonic stem cell mouse embryonic stem cells (mESCs) were used. Three signalling pathways were compared at the gene expression level with EMT, MAPK and inflammation related genes in mESC, SqLC and MSF. With immunofluorescence staining protein level of ERK 1/2, vimentin and twist. We selected four to five most significant fold changes of RT-PCR results in each panel. ERK ½ protein expression in SqLCs and MSFs were similar while mESCs were less intensity. In addition, while ERK 1/2 protein expression was rich in nuclear region of MSFs, SqLCs had leaky in nucleus. Likely the gene expression, Vimentin protein expression was the highest in MSF and the least in SqLCs. Differently, MSF had significant vimentin fibrils. Twist expression, on the other hand, has similar intensity in SqLCs and mESCs while MSF had higher. Twist was expressed more in dividing cells into MSF cells. Mostly SqLC had expression into cytoplasm (no protein in nucleus), whereas mESC into the nucleus. These results show that the molecular basis of the EMT and inflammation supported by the MAPK signalling pathway were similar in SqLCs and mESCs while MSF relatively altered, therefore the molecules can be the potential driving force for therapeutic target.

Mechanical properties of extracellular matrices surrounding cancer cells is critical for the cancer progression and survivability. Increase of the matrix stiffness make the cancer cells much more sensitive to drug-resistance. However, the underlying molecular relationship between matrix stiffening and anti-cancer drug resistance remains largely unknown. In this study, we report that the level of tubulin acetylation depending on the matrix stiffness is important for regulation of drug resistance during chemotherapy. Aggressive breast cancer cell lines cultured in a stiff substrate became more sensitive to anti-cancer drugs such as cisplatin or eribulin than on soft one, whereas expression of stem cell marker genes profoundly increased in cells cultured on the soft substrate. We also found that the cancer cells cultured in the stiff matrix rapidly upregulated the level of tubulin acetylation in prior to the onset of cell death upon the treatment of anti-cancer agents. However, in the case of cells resistance to anti-cancer drugs, treatment with anti-cancer drugs did not increase the tubulin acetylation. Interestingly, disruption of a-tubulin acetyltransferase gene, ATAT1 by CRISPR/Cas9 system reduced the death of breast cancer cells upon treatment of anti-cancer drugs. Moreover, recovery of tubulin acetylation by overexpression of ATAT1 or treatment of HDAC6 inhibitor, tubacin in drug resistance cell reduced the expression of stem cell marker genes and increased the cell death. Taken together, our results indicate that level of tubulin acetylation under variety of mechanical cancer microenvironment is critical for the regulation of drug sensitivity in chemotherapy.

Therapeutic Effect of FCH domain only 1 shRNA in K-ras¹⁰¹¹ Mice.  
S. Park¹, A. Lee², K. Cho³, Q. Tran¹, H. Lee¹, Y. Hong¹, H. Cho¹, M. Kim¹, J. Park¹, K. Kim⁴, M. Cho², J. Park¹;  
¹Department of Pharmacology and Medical Science, Chungnam National University, Daejeon, Korea, South, ²Research Institute for Veterinary Science and College of Veterinary Medicine, Seoul National University, Seoul, Korea, South, ³Department of Pathology, Jonhs Hopkins University, Baltimore, MD, ⁴Department of Applied Chemistry, Kyung Hee University, Yongin, Korea, South

The FCH domain only 1(FCHO1) protein is associated with early working proteins at the surface clathrin assembly as key coat nucleators in a previous study. However, the possible involvement of FCHO1 protein in cancer is not clear. In this study, we provide evidence that FCHO1 regulates mitotic proteins by global proteomics. In addition, we aimed to demonstrate the therapeutic effect of FCHO1 protein down-regulation, especially lung cancer. Lenti-viral shRNA is a biocompatible carrier used for aerosol gene delivery. Repeated aerosol delivery of lenti-viral FCHO1 shRNA was performed to 8-week-old female K-ras¹⁰¹¹ mice twice a week for 4 weeks in a nose-only exposure chamber. Aerosol delivery of lenti-viral FCHO1 shRNA inhibits lung cancer in K-ras¹⁰¹¹ mice compared to control and scramble control groups. In addition, FCHO1 siRNA led to the cell death caused by cell division failure in A549 cell. Therefore, Down-regulation of FCHO1 significantly suppresses lung cancer in vitro and in vivo.

A New Targeting Agent that Specifically Binds to Breast Cancer Cells?

Targeted therapy is one of the major improvements for treating cancer. Targeted molecular imaging agents (TMIAs) can be applied for more effective diagnosis of primary and metastatic tumors by locating and illuminating cell types of interest bearing the molecular marker that allows targeting. To be an effective TMIA, a molecule must exhibit binding affinity and specificity for the desired cell type. Purpose: To evaluate a new molecular imaging agent that targets specifically to breast cancer cells. Methods: A newly developed TMIA which we have named M1 consists of a fluorescent dye (Cy5.5) conjugated to a peptide found to bind to keratin 1 of breast cancer (BrCa) (Soudy et al, 2017). Results: M1 binding was studied via in vitro models using the BrCa cell line MDA-MB-231. MDA-MB_231 cells were observed to stain well with the M1 stain exhibiting internalized localization within vesicles. Visualization of M1 staining was achieved via confocal fluorescent microscopy. The M1 staining of MDA-MB-231 was more significant than control cancer lines such as lung and prostate cancer lines. M1 was reported to display specificity toward tumors over healthy breast tissue and greater binding specifically to BrCa. Conclusion: The M1 TMIA holds great potential as a cancer imaging agent. Characterizing the binding and processing of M1 in BrCa cells should aid in our understanding of the interaction of TMIAs like M1 with cancer cells and hopefully lead to better treatment of cancer patients and improved clinical outcomes.

GLE regulates stemness properties in Inflammatory Breast Cancer cells via STAT3 regulation.

M.M. Martinez-Montemayor, P. Lopez, V. Rivera-Amill, Y. Yamamura, T.J. Rios; 1Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR, 2Basic Sciences, Ponce Health Sciences University, Ponce, PR

Inflammatory Breast Cancer (IBC) is the most lethal and aggressive type of breast cancer where patients have a 43% higher risk of death when compared to non-IBC. It accounts for 5% of all breast cancer cases in the U.S., with a five year survival rate of 20-50% when treated with chemotherapy. IBC is associated with a deprived outcome and an elevated risk of recurrence and metastasis compared with non-inflammatory locally advanced breast cancer. IBC cells contain a high cancer stem cell (CSC) composition, which display the CD44+/CD24− surface marker phenotype, and contribute to metastasis, recurrence and drug resistance. It has been demonstrated that the signal transducer and activator of transcription 3 (STAT3) is involved in oncogenesis and takes part in mediating the effects of maintaining a stem cell phenotype. A recent study reported that CD44+ tumor-initiating breast cancer cells had preferential activation of STAT3, suggesting that STAT3 may be a potential therapeutic target in breast cancer. Our data indicates that Ganoderma lucidum extract (GLE) decreases STAT3 activation in the IBC cell model SUM-149. A constitutively active mutant of STAT3 (cSTAT) was developed in order to determine the role of STAT3 in SUM-149 cells. Therefore, we tested the hypothesis that GLE decreases stem cell properties in IBC cells via STAT3 regulation. Our preliminary flow cytometry results show that cSTAT cells have a larger population of CD44+/CD24− cells compared to wild type (wt) SUM-149 cells. Importantly, our results demonstrate that GLE treatment significantly decreases the CD44+/CD24− cell population in cSTAT cells. To further analyze if GLE is decreasing stem cell properties, we performed
western blot analysis of stem cell-related transcription factors (Nanog, Oct4, and Sox2), which have a strong correlation with the CSCs phenotype. Our data demonstrates an increased expression of these proteins in cSTAT cells compared to wt SUM-149 cells. Interestingly, our results show that GLE decreases the expression of these transcription factors in both cSTAT and wt SUM-149 cells. Our results suggest that GLE is decreasing stemness properties in SUM-149 cells regulated by STAT3. We highlight the effectiveness of GLE in decreasing stem cell properties and identified STAT3 as a potential IBC target for therapy. CTLA-4 in cancer cells transmits high forces via the bond to CD80.
S. Park1, Y. Shi1, Y. Joo1, L. Lin1, B. Kim2, D. Reich2, T. Ha2, L. Lu1, Y. Chen1;
1Department of Mechanical Engineering, Johns Hopkins University, Baltimore, MD, 2Henry A. Rowland Department of Physics and Astronomy, Johns Hopkins University, Baltimore, MD, 3Division of Biological Sciences, University of California San Diego, San Diego, CA, 4Thomas C. Jenkins Department of Biophysics, Johns Hopkins University, Baltimore, MD

Cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) is abundantly expressed on regulatory T cells and responsible for immune suppression. We examined two breast cancer cell lines, MDA-MB-231 (human) and EO771 (mouse), and found that the expression of CTLA-4 is significantly higher than their respective normal counterparts, MCF10A and EPH4-EV cells. The observation suggests that CTLA-4 by cancer cells might play a role in immune suppression. Immune suppression might be achieved by transendocytosis of CD80/CD86, or triggering signaling pathways that inhibit antigen presenting cells (APCs), or T cell activation, or both. We hypothesize that mechanical forces transmitted through CTLA-4/CD80 bond are involved in mediating either transendocytosis or immune suppression signaling. To test our hypothesis, we measured the forces between CTLA-4 and CD80 using DNA-based tension gauge tether (TGT) and the micropillar method. The TGT measurement results showed that EO771 and MDA-MB-231 cells exert higher pulling forces via the CTLA-4/CD80 bond, in the range between 12 pN and 54 pN, compared to the control EPH4-EV and MCF10A cells. Interestingly, micropillar measurement showed MDA-MB231 cells could transmit significantly higher (more than 2-fold) traction forces via CTLA4/CD80 bond, compared the bond between integrin and the RGD motif in ECM proteins. This finding implies mechanical forces might be significant in immunosuppression of breast cancer cells. Furthermore, it was observed that CTLA-4 co-localizes with phosphorylated myosin in cancer cells. In summary, our study provides a possible force-dependent mechanistic model responsible for immune suppression in breast cancer.

Therapeutic strategies for osteosarcoma stem cells by regulating adipocyte differentiation based on actin dynamics.

H. Nobusue¹, N. Takahashi¹, H. Kunitomi¹, E. Sugihara¹, T. Shimizu², N. Onishi³, S. Iwai-Yamaguchi³, H. Saya¹;
¹Division of Gene Regulation, Institute for Advanced Medical Research, Keio University School of Medicine, Tokyo, Japan, ²School of Pharmacy and Pharmaceutical Sciences, Hoshi University, Tokyo, Japan

Cancer stem cells (CSCs) are a subset of tumor cells that are responsible for initiating and maintaining the disease. In the clinical point of view, the most important characteristics of CSCs include their resistance to various therapeutic interventions. However, the underlying mechanisms of the resistance remain unclear. To address this question, we established a mouse osteosarcoma (OS) model by overexpressing c‐MYC in bone marrow stromal cells derived from Ink4a/Arf (−/−) mice. These OS cells were composed of two distinctly different clones: highly tumorigenic cells (termed AX cells), similar to bipotent‐committed osteochondral progenitor cells, and low tumorigenic tripotent cells (termed AO cells), similar to mesenchymal stem cells. We found that the loss of adipogenic potential is an essential event for AO cells to become AX‐like tumorigenic cells. Although AO cells are not found tumorigenic as far as they maintain the adipogenic differentiation potential, AO cells are found to be highly resistant to chemotherapeutic agents such as Adriamycin. Then, AO cells survived after the chemotherapy eventually change to AX‐like cells by losing their adipogenic differentiation potential to become tumorigenic. Therefore, our understanding of regulatory mechanisms of adipocyte differentiation would contribute to control OS tumorigenesis. We have recently found a novel regulatory mechanism of adipocyte differentiation. Regulation of the transcriptional coactivator MKL1 (megakaryoblastic leukemia 1) by actin cytoskeleton dynamics drives adipocyte differentiation mediated by peroxisome proliferator‐activated receptor (PPARγ), a master transcriptional regulator of adipogenesis. We found that disruption of actin stress fibers through the inactivation of RhoA‐ROCK signaling induces the rapid increase in monomeric G‐actin, leading to the interaction of G‐actin with MKL1, which prevents nuclear translocation of MKL1 and allows expression of PPARγ followed by adipogenic differentiation. Our findings thus provide new mechanistic insight into the relation between the actin dynamics and transcriptional regulation during cellular differentiation. Based on this discovery, we attempted to induce adipocyte differentiation in OS stem cells by treatment with ROCK inhibitors. ROCK inhibitors induced adipocyte differentiation of OS stem cells and significantly suppressed their in vitro growth and in vivo tumorigenesis. Our findings suggest that induction of trans‐differentiation of cancer stem cells by regulating actin cytoskeleton dynamics is a potential approach for some tumor types.

Inhibition of IL‐8 uptake by breast cancer cells suppresses vasculogenic mimicry.

A.R. Aikins¹², M. Kim¹, B. Raymundo ¹, C.W. Klm¹;
¹Biotechnology, Korea University, Seoul, United States, ²Biochemistry, Cell and Molecular Biology, University of Ghana, Accra, United States

Highly aggressive cancer cells have been found to act as endothelial cells by forming capillary‐like networks for blood supply to the developing tumor in a process known as vasculogenic mimicry (VM). This implies that interventions targeting angiogenesis‐endothelial cell based vasculature – may not be

Tuesday-197
completely effective at disrupting the growth of the tumor. The aim of the study was to investigate the effect of transgelin knockdown on VM in vitro, and on the expression of angiogenesis-related markers during VM. The formation of VM was accompanied by the expression of CD34 as revealed by flow cytometry and immunocytochemistry. Silencing of transgelin by siRNA suppressed VM but did not affect the expression of angiogenesis-related markers such as VEGFR2, CD34, VE-cadherin and IL-8 as shown by flow cytometry, immunocytochemistry analyses and RT-PCR. Suppression of vasculogenic mimicry by transgelin downregulation however, led to increased levels of IL-8 in the culture supernatant. Blocking the IL8 receptor, CXCR2, also inhibited VM and led to increased levels of IL-8, confirming that IL-8 uptake is associated with VM. Findings from these studies highlight the need for more work to elucidate the molecular mechanisms involved in vasculogenic mimicry that will eventually help in the development of improved interventions that do not only target angiogenesis, but the entire vasculature, for a more effective therapy.

Investigating mitotic kinesins as therapeutic targets for triple negative breast cancer.
F. Cindy1, C. Marquis1, L. Wood1, C.J. Anker2, A.K. Howe3, J.E. Clayton4, J. Stumpff4;
1Molecular Physiology and Biophysics, University of Vermont, Burlington, VT, 2Division of Radiation Oncology, University of Vermont, Burlington, VT, 3Pharmacology, University of Vermont, Burlington, VT, 4BioTek Instruments, Inc., Winooski, VT

Patients with triple negative breast cancer (TNBC) display a particularly high risk for metastatic spread and disease recurrence, and 5-year overall survival rates associated with regional (85%) and distant (25%) metastases are lower than those for locally controlled tumors (99%). TNBC, molecularly defined by the absence of estrogen receptor, progesterone receptor and overexpressed human epidermal growth factor receptor 2 (Her2), accounts for ~15% of all breast cancers and poses significant treatment challenges. There are currently no targeted therapies available for TNBC, leaving cytotoxic agents as the primary systemic option. TNBC cells exhibit two common features not found in normal cells that we predict can be exploited for novel treatments: (1) they display high levels of chromosome instability, and (2) they exhibit significant changes in the expression of genes that regulate mitotic spindle function. Mitotic spindle integrity is dependent on a balance of mechanical forces generated by molecular motor proteins and microtubule dynamics. We hypothesize that changes in the expression of mitotic spindle proteins within TNBC cells reduces spindle integrity by disrupting this normal force balance, making the tumor cells more susceptible than normal cells to inhibition of spindle force regulators, such as kinesins. We are testing this “fragile spindle” model by assessing the effects of inhibiting five different kinesin motor proteins in cell models for three TNBC subtypes (basal-like 1, basal-like 2, and mesenchymal), as well as normal breast epithelial cells. Our results indicate that inhibition of Kif18A significantly slows the growth of TNBC cells but not normal cells. This slow growth is correlated with a mitotic delay and the formation of abnormal spindle structures. Taken together, our results support Kif18A as a promising target to specifically limit the growth of TNBC cells with low toxicity to other cell types.

Telomerase inhibitors TMPyP4 and Thymoquinone decreased cell proliferation and induced cell death in NSCLC cell line LC-HK2, modifying the pattern of focal adhesion.
A.M. Garnique1, P. Rezende-Teixeira1, G.M. Machado-Santelli1;
1Cell and Development Biology, University of Sao Paulo, Sao Paulo, Brazil

The telomere is a repetitive double-strand sequence of DNA that protects the chromosomes ends. Its length is maintained by telomerase, whose expression is low or absent in somatic cells but is present in most cancer cells. As the cell continues to divide, telomeres shorten and undergo a process called telomeres dysfunction. This DNA breaks activate p53, a tumor suppressor that induces cell senescence, or other checkpoint responses depending on the cell type. G-quadruplexes are structures formed at the ends of the telomere, this structure is rich in guanines and are stabilized by molecules that bind to specific sites by Hoogsten-base paring. TMPyP4 and Thymoquinone are small that bind to the G-quadruplexes helping to form and to stabilize them. They have drawn attention for their role as telomerase inhibitors. The aim of this study was to evaluate the effects of telomerase inhibitors on cellular proliferation, senescence and death. Two cell lines LC-HK2 (Non-Small Cell Lung Cancer) and RPE-1 (hTERT) were treated with TMPyP4 (5 μM) and Thymoquinone (10 and 40 μM) (telomerase inhibitors) for 72 and 120 h. Both inhibitors were effective in decreased telomerase activity (TelO TAGGG Telomerase PCR ELISA assay). TMPyP4 increased the percentage of cells with membrane damage associated with cell death induction as evidenced by the zombie green assay and decreased the frequency of cells in S-phase (evaluated by EdU incorporation). Alterations in cell morphology and in the pattern of microtubules and microfilaments organization were more evident when cells were treated over longer periods (10 days). TMPyP4 changed the cell adhesion ability decreasing the number of attached cells and modified the pattern of focal adhesion, confirmed by slowdown of vimentin and vinculin mRNA expression in the qRT-PCR assay. Thymoquinone acted in a dose-dependent manner, and differently from TMPyP4, increased the frequency of senescent cells in the β-Galactosidase assay. It induced to cell cycle arrest in the G1 phase observed in the analysis by flow cytometry. In conclusion, the effects of both telomerase inhibitors on tumor cell line and non-tumoral cells were similar, despite the differences between them.

A "Trojan Horse" strategy to target lysosomes in cancer mediated by acidotropic nanomedicine. Z. Yang1, X. Zhang1, M. Feng1, C. Wang1;
1School of Pharmaceutical Sciences, Sun Yat-sen University, Guangzhou, China

Lysosomes are acidic catabolic organelles in which intracellular wastes and foreign materials are degraded and recycled by various lysosomal enzymes. As a destination of several cellular pathways including endocytosis and autophagy, lysosomal dysfunction could perturb cell homeostasis, resulting in apoptotic or necrotic cell death. Therefore, it seems a promising strategy to destabilize the lysosomes in cancer cells using nanomedicines which are readily taken up into lysosomal compartments via endocytosis. However, it remains a challenge to specifically deliver lysosomal-targeting nanomedicine to the tumors while ignoring the normal tissues, since lysosomes are present in almost all the mammalian cells. In our work, we developed one acidotropic nanomedicine (PAC/HA) which preferentially accumulated in the acidic tumor than in normal tissues. Subsequently, PAC/HA overloaded in tumor cells induced lysosomal alkalinization and autophagy blockage accompanying with lysosomal membrane

Tuesday-199
permeabilization (LMP) and oxidative stress, and thereby triggered the cell death. All the in vitro and in vivo data demonstrated the tumor-acidity-selective cytotoxicity of PAC/HA. Hence, this facile strategy offers an opportunity to target lysosomes via our well-defined acidotropic nanomedicine in the treatment of cancer.

Pharmacological effect of three tryptophan analogues with HDAC inhibitory activity in MDA-MB-231 triple negative breast cancer cells.
E. Mera-Jiménez¹, C.R. Trejo-Muñoz¹, G. Gutiérrez-Iglesias¹, T. Mancilla-Percino¹,²; ¹POSGRADO, INSTITUTO POLITECNICO NACIONAL. ESCUELA SUPERIOR DE MEDICINA, MEXICO, Mexico, ²QUIMICA, CENTRO DE ESTUDIOS AVANZADOS DEL IPN, MEXICO, Mexico

The mechanisms leading to epigenetic modifications such as acetylation and deacetylation of histones by the enzymatic activity of HAT and HDAC, play an important role in regulating gene transcription. It has been shown that many diseases, particularly cancer is caused when epigenetic regulation mechanisms is aberrant. Breast cancer is unhealthy therefore epigenetic mechanisms of deregulation emerging pathology associated with aging and lifestyles. The subtype of breast cancer triple negative (TNBC), named for the absence of receptors for estrogen, progesterone and HER2 / neu is characterized as the most aggressive, and not respond to trastuzumab and endocrine therapies. As TNBC cells overexpressing HDAC8 in our working group have been designed and synthesized three analogues of tryptophan with inhibitory activity HDAC8. So the objective of this work was to determine the degree of inhibition of HDAC8 inducing analogs FTrpa tryptophan, and Trp1 FTrpc; the antiproliferative effect and morphological changes that induce each of these compounds on the MDA-MB-231 cells TNBC.

Methodology: The degree of inhibition of HDAC8 was performed using a commercial kit from SIGMA-ALDRICH. To indirectly determine the number of surviving cells to treatment with each of the analogues of tryptophan the proliferation of TNBC cells was quantified by the colorimetric MTT assay in MDA-MB-231 seeded in 96 wells, incubated at 37 ° C and 5% CO2 DMEM F12 medium, 10% FBS (100uL / well) to a 90% confluence, were added 100uL / well of each compound at 8 different concentrations were 0310-10 mM, DMEM F12 medium was used as a positive control and 10 mM TSA HDACi, as negative control. And the evaluation of cellular morphological changes were made by Giemsa staining. Our results show that FTrpa, and Trp1 FTrpc compounds had the ability to inhibit the activity of HDAC8 being Trp1 the most effective. All three compounds had the ability to inhibit proliferation of MDA-MB-231 being the most TNBC powerful Trp1. They also had the ability to induce the death of MDA-MB-231 cells TNBC. In conclusion Trp1 compound has a greater chance of success as an antitumor agent in TNBC.

Experimental therapeutics of orthotopic colon cancer models.
J. Lopez¹, G. Fracia¹, P. Valenzuela¹, K. Parra¹;
¹Biology, University of Texas at El Paso, El Paso, TX

To the potential impact on colon cancer growth of different low-dose chemotherapy regimens, including combinations with the angiogenesis inhibitor bevacizumab, we generated orthotopic models of the human HT29 cancer cell line in immunodeficient mice. HT29 cells were transfected to express GFP (Green Fluorescent Protein), luciferase or human chorionic gonadotropin (hCG), and subsequently injected intracaecally or intrasplenically into female mice. Tumors were subsequently monitored via
Prostate cancer (PCa) is one of the most common cancers in American men. While initial resection and radiation therapy is usually successful, recurrence is common. Upon recurrence, PCa patients are often treated with androgen deprivation therapy (ADT), which impairs proliferative signaling through the androgen receptor (AR). Despite ADT treatment, many cancers eventually recur as hormone treatment refractory cancers. These castration resistant prostate cancers are uniformly lethal. In some cases, such ADT insensitive tumors may display neuroendocrine characteristics. These cancers are termed neuroendocrine prostate cancer (NEPC) and are particularly aggressive. Clinical evidence suggests that incidence of the NEPC phenotype is increasing concurrently with increasing use of potent new ADT medications, such as abiraterone and enzalutamide.

We aim to understand the effects of prenylation on ADT-related neuroendocrine differentiation of PCa. Prenylation is a post translational modification in which proteins are modified by the addition of a farnesyl or geranylgeranyl group derived from mevalonate via the isoprenoid pathway. Prenylated proteins have roles in cancer development, metastasis, cytoskeletal regulation, and differentiation. Here, we investigated digeranyl bisphosphonate (DGBP) as a potential modulator of neuroendocrine differentiation. This compound inhibits the synthesis of geranylgeranyl pyrophosphate and thus reduces the geranylgeranylation of regulatory proteins, including members of the Rho family. We found that DGBP reduces PCa progression and metastasis in both in vitro and xenograft models. Reporter assays and Western blotting suggest that short term DGBP treatment of PCa cells reduces AR activity, but not protein levels. Fluorescence microscopy revealed this is due to reduced nuclear localization of the AR protein. In the context of long term treatment, however, it appears that DGBP can restrict unfavorable changes toward the NEPC phenotype in both steroid-reduced and ADT induced cell culture models of prostate cancer, while also reducing AR expression. We conclude that geranylgeranylation of downstream proteins is required for both PCa progression and AR nuclear translocation, and inhibition of this process may enhance patient responses.

In vitro antitumor activity of new quaternary hydroxypyridine-based phosphonium salts.
A. Iksanova1, R.R. Gabbasova1, T. Kupriyanova1, A. Akhunzyanov1, M. Pugachev1, N. Shtyrlin1, K. Balakin1, Y. Shtyrlin1; 1Scientific and Educational Center of Pharmaceutics, Kazan (Volga region) Federal University, Kazan, Russia

Cancer is one of the leading causes of morbidity and mortality worldwide, with approximately 5.4 million deaths in 2017, and, therefore, novel approaches are required for improvement of cancer therapies. Phosphonium salts are one of promising classes of compounds with antitumor activity, which show great promise for the diagnosis and treatment of neoplasms. Some phosphonium salts have been reported to show anti-proliferative activity in several cancer cell lines and a xenograft model of ovarian cancer based on their ability to disrupt mitochondrial ultrastructure and alter cellular lipid content. Studies of phosphonium salts as contrast agents for diagnostic imaging have elucidated two key points concerning the selectivity of this class of compounds: 1) these agents are capable of preferentially accumulating within tumor cells, 2) phosphonium cation itself does not impart cytotoxicity. In this study, we assessed the effects of new quaternary phosphonium salts based on 3-hydroxypiridine and 4-deoxyxypyrdoxine on OVCAR-4 ovarian cancer cells. In particular, the following phosphonium salts were studied: 3-hydroxy-2-[tris(p-tolyl)phosphoniomethyl] pyridinium dichloride, 3-hydroxy-2,6-bis-[tris(p-tolyl)phosphoniomethyl] pyridinium dichloride, 3-acetoxy-2,4-dimethyl-5-[tris(p-tolyl)phosphoniomethyl] pyridine chloride. Anti-cancer activity and cytotoxicity of these compounds were evaluated in vitro. Cell proliferation and viability after treatment with the tested compounds was assessed by colony formation and MTT assays. The effects of compounds on apoptosis and cell cycle were determined by flow cytometry using Annexin V FITC/PI and PI staining, respectively. Effects of compounds on mitochondrial membrane potential and intracellular reactive oxygen species were determined using TMRE and DCFHA staining. Western blot analysis was used to assess changes in the expression of Bcl-xL, Bax and caspase-3 apoptotic proteins. Treatment of ovarian adenocarcinoma cells OVCAR-4 with the studied compounds led to expressed inhibition of growth and induced cell cycle arrest in G1-phase. 3-Hydroxypyridine derivatives induced apoptosis via hyperexpression of BAX and caspase-3, while 4-hydroxypyridine derivative induced cell death partly via ROS generation and caspase-3 hyperexpression. These results indicate that the studied hydroxypyridine-based phosphonium salts may be promising therapeutic agents for the treatment of ovarian cancer.

Tunneling Nanotubes, a Novel Mode of Tumor Cell-Macrophage Communication in Tumor Cell Invasion.
S.J. Hanna1, K. McCoy-Simandle1, E. Leung1, J.S. Condeelis1, D. Cox1; 1Anatomy and Structural Biology, Albert Einstein College of Medicine, Bronx, NY

The interaction between tumor cells and macrophages is crucial in promoting tumor invasion and metastasis. These two cell types are engaged in a mutual interaction in which tumor-associated macrophages produce epidermal growth factor (EGF) to activate tumor cells. In turn, tumor cells produce colony-stimulating factor-1 (CSF-1) that stimulates macrophages. The tumor cell - macrophage
pairs formed in response to this paracrine signaling are then attracted toward blood vessels under an endothelial cell produced HGF gradient. This mutual signaling interaction leads to the co-migration and invasion of both cell types as imaged both in vitro and in vivo. Recent studies have revealed an additional novel mechanism of intercellular communication between macrophages that can transmit signals over long distances through membranous actin-based tunneling nanotubes (TNTs). Our data demonstrates that heterotypic TNTs form between macrophages and tumor cells in co-culture. This novel interaction induced changes in tumor cell morphology consistent with a more invasive phenotype which was dependent on EGF-EGFR signaling. Moreover, the presence of these heterotypic TNTs was important for tumor cell invasion in an in vitro 3D invasion assay. Furthermore, reduction of M-Sec (TNFAIP2) in macrophages, a protein involved in TNT formation, inhibited tumor cell elongation and blocked the ability of tumor cells to invade. Using a modified 1D assay that mimics macrophage-dependent tumor cell streaming observed in vivo, we show a significant increase in long distance directional migration of tumor cells towards an endothelial-coated bead in a TNT dependent manner. We also employed an in vivo zebrafish model that recreates macrophage mediated tumor cell invasion in a more physiological fashion. The presence of macrophages increased tumor spread from the injection site, number of metastatic foci, and the distance of metastatic spread in a macrophage TNT-dependent manner. Overall, our studies support a role for TNTs as a novel means of interaction between tumor cells and macrophages that may lead to tumor progression and metastasis.

Substratum stiffness and tumor dormancy.
A.A. Anlas¹, C.M. Nelson¹²; ¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Molecular Biology, Princeton University, Princeton, NJ

About 90% of cancer-related deaths are due to the spread of cancer cells to secondary sites in a process called metastasis. Current treatments can effectively remove or shrink the primary tumor and slow down the growth of metastatic recurrences, however, they are only temporary. Breast cancer has a high risk of recurrence that can develop over the course of decades due to “dormant” tumor cells that, at one time, disseminated from the primary tumor to secondary sites. Although it is known that breast cancer cells preferentially metastasize to the lung, brain, bone marrow and liver, the nature of physical and biochemical interactions between disseminated cancer cells and their local microenvironment is not known. Here we investigated whether the physical microenvironment, specifically host tissue stiffness, affects the propensity of disseminated tumor cells to become dormant at secondary sites. Given that substratum stiffness affects cell phenotype, motility, adhesive properties, and proliferative behavior, it is likely to also regulate some of the mechanisms that trigger dormancy. Breast cancer cells were cultured on “soft” (E~130 Pa) or “stiff” (E~4020 Pa) polyacrylamide gels that mimic the stiffness of the normal and tumorigenic mouse mammary gland respectively. We found that tamoxifen and 5-fluorouracil induce cell dormancy in estrogen receptor-positive breast cancer cells that were cultured on soft or stiff substrata as determined by the immunofluorescence of Ki67. Quantifying the transcript levels of CD44, Nanog, and ILK in tamoxifen-treated breast cancer cells revealed upregulation in the expression of cancer stem cell markers. Our data suggest that tamoxifen and 5-fluorouracil might contribute to chemoresistance by inducing dormancy and stemness. Elucidating the respective roles of dormancy and stemness in chemoresistance and defining the characteristics of a microenvironment that harbors chemoresistant metastases could pave the way for more effective cancer treatments.

Interplay between mechanotransduction and force generation underlies mitosis in three-dimensional microenvironments.
S. Nam\(^1\), V.K. Gupta\(^1\), H. Lee\(^1\), C. Davis\(^2\), O. Chaudhuri\(^1\);
\(^1\)Mechanical Engineering, Stanford University, Stanford, CA, \(^2\)Mechanical Engineering, University of Maryland, College Park, WA

Cell division underlies the development of humans from embryo to full-grown adult, regenerative processes such as wound healing, and diseases such as cancer. The process of cell division requires extensive morphological changes, including elongation along the mitotic axis, critical for proper segregation of chromosomes and other intracellular materials and guiding orientation of daughter cells. In physiological tissues such as packed epithelial monolayers or growing tumor spheroids, cells are surrounded by adjacent cells and extracellular matrix (ECM), which mechanically constrain the growth and morphological changes required for mitosis. While much is known about the intracellular aspects of mammalian cell division, how the mechanical aspects of the microenvironment regulate cell cycle progression, and how cells overcome mechanical constraints to undergo mitosis, remain unknown. Here, we investigated cell division in viscoelastic hydrogels, which served as three-dimensionally confining microenvironments. We found that hydrogel stress relaxation, related to hydrogel viscosity, regulates cell cycle progression of tumor cells. In fast relaxing, or highly viscous, matrices, cells proliferated extensively to form large spheroids, while in slow relaxing, or more elastic, matrices, cells were less proliferative and mostly arrested in the G1/G0 phase of the cell cycle. Mechanistically, mechanical stress imposed by the surrounding microenvironment against cell growth regulated PI3K and p27 activation to control cell cycle progression. Next, we examined the mechanics of how cells undergoing cell cycle progression are able to divide in the mechanically confining viscoelastic microenvironments. We found that dividing cells generate substantial protrusive forces that deform the microenvironment along the mitotic axis, clearing space for mitotic elongation to proceed. These forces result from interpolar spindle elongation and lateral contraction of the actomyosin ring, which drives expansion along the mitotic axis through the Poisson effect. Together, these results reveal the mechanical interactions that occur between cells and their microenvironments, which sense mechanical properties of the microenvironment to control cell cycle progression and then enable cell division to occur in mechanically confining microenvironments.

Early stage breast cancer spheroids mechanically remodel the microenvironment more significantly compared to their normal and metastatic counterparts.
N. Yam\(^1\), D. Maity\(^1\), Y. Chen\(^1\);
\(^1\)Mechanical Engineering, Johns Hopkins University, Baltimore, MD

It is known that cancer cells remodel the tumor microenvironment in terms of the extracellular matrix (ECM) fiber density, organization, and stiffness by facilitating activation of mechanosensitive pathways in favor of tumor progression. However, how cancer cells remodel the microenvironment dynamically has yet to be characterized. We establish a 3D model system where spheroids of breast epithelial cells of increased malignancy [Eph4-EV (normal), 67NR (early-stage), and 4T1 (metastatic)] are embedded and cultured in thick collagen gel at 5\(\times\)10\(^4\) cells per spheroid, in mimicry of the physiological conditions in
vivo. The dynamic interaction between the spheroids and their microenvironment was recorded using time-lapse microscopy. The remodeling of the tumor microenvironment was then quantified in terms of changes in collagen density, fiber alignment, and porosity around the spheroid over time. We also used traction force microscopy to measure the mechanical forces exerted by the spheroids in 3D. 67NR cells remodeled the ECM such that they become more porous (~2.1% increase), more aligned (~8-fold increase), and denser (~17% increase) compared to EPH4-EV. It was also observed that 67NR cells generated higher forces compared to EPH4-EV. We also noticed that cancer spheroids incapable of generating relatively high mechanical forces were not capable of remodeling the ECM. Quite intriguingly, we observed that 4T1 cells invaded the collagen within 24hrs of getting embedded in collagen, while 67NR cells showed bulk spheroid behavior and hence dramatically modulated the collagen. Our findings provide a direct connection between force generation, dynamic ECM remodeling, and tumor progression.

Meaningful connections: Homotypic cell-cell interactions in pancreatic ductal adenocarcinoma’s desmoplastic stroma.

J.C. Gardiner1, R. Francescone1, J. Franco-Barraza1, E. Cukierman1;

1Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA

Pancreatic ductal adenocarcinoma (PDAC) is a devastating disease with a 7% 5 year survival rate. PDAC is mediated via complex interactions between tumor cells and the surrounding stroma, known as desmoplasia, that mainly includes cancer-associated fibroblasts (CAFs) and the dense extracellular matrix (ECM) they produce, as well as infiltrating nerves and immune cells. Desmoplasia is important to PDAC development as it 1) comprises over 70% of the cancer mass, 2) facilitates tumor-stromal interactions, and 3) imparts both pro- and anti-tumorigenic effects. Thus, elucidating how cell-cell interactions contribute to the adverse effects of desmoplasia is imperative. Comparing normal fibroblast vs. CAF gene expressions revealed increased mRNA and protein levels of the neural extracellular laminin-related glycoprotein netrin G1 (NG1) in CAFs, while its receptor, NG1 ligand 1 (NGL1) was detected in both tumor cells and CAFs. Interaction of these proteins was sufficient to establish a synapse between homotypic and heterotypic cell types. Strikingly, CRISPR-Cas9 knock out of either NG1 or NGL1 in CAFs significantly altered the CAF secretion profile, thereby suggesting that NG1/NGL1 expression in CAFs, and their engagement, may have important roles in stromal maintenance that can contribute to the pro- and anti-tumorigenic effects. While heterotypic CAF-PDAC cell interactions were found to be NG1-dependent and essential for PDAC cell survival under starvation, the role of homotypic CAF-CAF interactions in this process remains unknown. Therefore, the goal of this project is to 1) elucidate the NG1/NGL1 signaling transduction cascade within CAFs and 2) determine how this signaling contributes to cell-cell interactions effects on the tumor microenvironment. Taken together, the work done in this project will help elucidate how phenotypic changes to the stroma affect heterotypic cell-cell interactions that are necessary for PDAC survival.

Age-related gene expression and cancer susceptibility in luminal epithelial cells is driven by a microenvironment made from myoepithelial cells.
M. Miyano1, R. Sayaman1, M.A. LaBarge1,2;
1Population Sciences, City of Hope, Duarte, CA, 2Biological Systems and Engineering, Lawrence Berkeley National Laboratory, Berkeley, CA

Luminal epithelial cells in breast gradually alter expression of proteins and genes with age, appearing to lose lineage-specificity by acquiring myoepithelial-like characteristics. We hypothesize that the luminal lineage is particularly sensitive to microenvironment changes, and age-related microenvironment changes cause altered luminal cell phenotypes. To evaluate the effects of different microenvironments on the fidelity of luminal and myoepithelial gene expression via epigenetic regulation, we generated a set of lineage-specific probes for genes that are controlled through DNA methylation. Primary luminal cells cultured in conditions that favor myoepithelial survival caused reprogramming at the level of gene methylation and expression towards a more myoepithelial-like state. Primary myoepithelial and luminal cells were used to recreate bilayers, providing cues necessary to maintain luminal cells in culture without losing lineage-specific gene expression. Isogenic stromal fibroblast co-cultures were unable to maintain the luminal phenotype. Mixed-age luminal-myoeipithelial bilayers revealed that luminal cells adopt transcription and methylation patterns consistent with the chronological age of the myoepithelial cells. We provide evidence that the luminal epithelial phenotype is exquisitely sensitive to microenvironment conditions, and that states of aging are cell non-autonomously communicated through microenvironment cues over at least one cell diameter in human breast tissue.

Tumor heterogeneity is a major obstacle in the development of effective cancer treatment. Resistant clones, which may only make up a small fraction of the total cell mass, persist and expand to lethal tumors following treatment. Suitable models and technologies are lacking that allow eavesdropping on tumor cell-cell communication and facilitate quantification of the emergent behavior resulting from this cooperation.

We have developed a rigorous and reproducible model of tumor cell cooperation that demonstrates active maintenance of tumor heterogeneity and coordinated regulation of cell migration. Two subclones from the U87MG glioblastoma cell line were each created by expansion from a single, randomly picked cell. Both clones displayed a unique pattern of cytogenetic abnormalities as well as differential activation of key signal phosphoproteins. Clone A had a significantly slower growth rate (1.5 fold) compared to clone B. This prompted us to question why the slower growing clone was not outcompeted by the more aggressively growing clone.

Combining clones A and B in a 1:1 mixed-clone culture resulted in the temporary synchronization of growth rates, increasing the growth rate for clone A and restraining growth for clone B. In long-term cell culture (>100 days), clone A was maintained at a constant fraction of around 5% of the total cell number. The rate of cell migration out of 3D spheroids was comparable between both clones when
spheroids were monoclonal. However, in spheroids composed of 1:1 clonal mixes of clone A and B the migration of clone B cells was abolished by the presence of clone A. Thus, our model shows multiple layers of cooperation: (a) persistence of a slow growing clone, (b) slowed growth of a fast growing clone, and (c) inhibition of migration of the fast growing clone. Paradoxically, this indicates the slow growing clone as the driver of this interclonal cooperation.

We found high phosphorylation of Stat3 Ser727 in clone A, but not clone B or the original U87MG cell line. In a wound healing assay, inhibition of Stat3 phosphorylation using Napabucasin had no effect on cell migration in monoclonal cultures. However, the constraining effect of clone A on the migration speed of clone B was significantly exacerbated when Stat3 was inhibited in 1:1 mixed-clone cultures. This straightforward and highly reproducible in-vitro model of tumor cell-cell cooperation provides a unique opportunity to study the mechanisms underpinning interclonal communication. Our model is easily scalable to allow future screening of compounds that disrupt clonal cooperation and may thus help provide a new approach to treat cancer by eliminating driver clones that actively maintain tumor homeostasis and cause driver sub-populations to persist.

Desmoplasia meets nerves in pancreatic cancer progression.
D. Barbosa Vendramini Costa1, R.A. Francescone1, N. Shah1, T. Luong1, C. Matullo2, G. Rall2, K. Campbell2, E. Cukierman1;
1Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA, 2Blood Cell and Development, Fox Chase Cancer Center, Philadelphia, PA

Pancreatic ductal adenocarcinoma (PDAC) is recognized as one of the most deadly types of cancer, with a 5-year survival of less than 8%. One of the major features of PDAC is the rich fibrous stroma, known as desmoplasia, characterized by the expansion of cancer associated fibroblasts (CAFs) and their extracellular matrix (ECM). In this hypoxic and immunosuppressive environment, an uncommon phenomenon takes place: neoneurogenesis, or de novo innervation, which is associated with PDAC "perineural invasion" and accentuated neuropathy. The expansion of nerves, together with desmoplasia, is related to poor prognosis in PDAC. Although there is an established neurotropic role for CAF and PDAC, the relationship between these cells and neural cells within PDAC microenvironment is complex and poorly understood. Recently our lab identified the ectopic expression of the neural pre-synaptic protein NetrinG1 (NG1) in CAFs and of its binding partner NetrinG1 ligand (NGL1) in PDAC cells in samples from PDAC patients, which led us to ask if NG1-NGL1 were involved in this complex network between CAFs, PDAC and neural cells. To better understand this connection, we generated CRISPR/CAS9 mediated knockout (KO) of NG1 or NGL1 in CAFs and co-cultured them with neurons from E16 embryonic hippocampus, in a 3D culturing system, using CAFs-derived extracellular matrix as the substrate. Preliminary data indicates that neurons had increased survival when co-cultured with wild type CAFs under stressful conditions, compared with neurons cultured alone or in the presence of NG1 KO CAFs, suggesting that CAFs supports neuron survival in a NG1-NGL1 dependent way. Moreover, we observed that neurons and CAFs establish heterotypic interactions and that there is a material flow between these cells. Interestingly, the flow from neurons to CAFs was disrupted either when NG1 in the neurons and NGL1 in the CAFs were inhibited, suggesting a “pre-synaptic role” for NG1 and a “post-synaptic role” for NGL1. Additional studies will confirm these observations. Finally, we correlated the levels of NG1-NGL1, neoneurogenesis and desmoplasia at different time points in samples from a murine spontaneous PDAC model and in samples from PDAC patients, in order to establish the relationship between NG1-NGL1 expression and PDAC progression, and perhaps uncovering two new putative targets for clinical interventions or diagnostics.

Desmoplastic expression of NetrinG1 fuels pancreatic cancer growth and promotes metastasis through nutritional supply and immunosuppression.
R.A. Francescone1, J. Wagner2, D. Barbosa Vendramini Costa1, J. Franco-Barraza1, L. Gabitova2, D. Rollins1, T. Luong1, N. Shah1, S. Gupta3, R. Thapa1, D. Restifo2, S. Balachandran3, W. Kruger2, W.S. El-Diery3, I. Astsaturov3, E. Cukierman3;
1Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA, 2Molecular Therapeutics Program, Fox Chase Cancer Center, Philadelphia, PA, 3Blood Cell Development and Function, Fox Chase Cancer Center, Philadelphia, PA

Pancreatic ductal adenocarcinoma (PDAC) is a devastating disease, with a dismal 5-year survival rate of <8%. A specific PDAC characteristic is desmoplasia; which consists of the expansion of activated stellate cells, known as cancer associated fibroblasts (CAFs), and the active deposition and remodeling of their extracellular matrix. PDAC’s desmoplasia results in a microenvironment that contains collapsed blood vessels and is immunosuppressive to both cytotoxic T and natural killer (NK) cells. Cell-cell interactions between PDAC, CAFs and immune cells, within the desmoplastic milieu, are not fully understood. In this study, we uncovered the ectopic expressions of NetrinG1 (NG1), a neural pre-synaptic protein, in CAFs, and of NG1’s post-synaptic binding partner, NetrinG1 ligand (NGL1), in PDAC cells. Using a multi-cellular 3D culturing system, we observed that heterotypic CAF-to-PDAC cell-cell interactions, via NG1/NGL1 engagement, are critical for providing survival advantages to nutrient deprived PDAC cells and for CAFs to protect PDAC from NK cell-driven elimination. Mechanistically, we uncovered that PDAC starvation is overcome by NG1 expressing CAFs that provide nutrition via material transfer, based on an intact glutamine/glutamate cycle. Further, CRISPR/CAS9 mediated knockout of NG1, in CAFs, significantly reduced the production of both immunosuppressive cytokines, such as IL-6, IL-8, and TGF-β and pro-tumorigenic factors, such as GM-CSF and CCL20. Moreover, loss of NG1 from CAFs resulted in anti-tumor NK cell activation. Excitingly, results were confirmed in an orthotopic PDAC mouse model in which ablation of NGL1, in syngeneic mouse PDAC cells, significantly halted tumor growth and metastasis. Translationally, in a cohort of surgically resected samples from PDAC patients, we questioned if stromal NG1 and tumoral NGL1 expressions correlated with our recently established outcome predictive stromal signature. This study proposes a possible novel desmoplastic immune cell checkpoint and added means to influence tumor-stromal interactions.

Secretory IgM exacerbates tumor progression by inducing accumulations of MDSCs in mice.
C.A. Tang1, S. Chang1, A. Hashimoto1, Y. Chen1, C. Kang2, A.R. Mato3, J.R. Del Valle2, D.I. Gabrilovich1, C.A. Hu1;
1Translational Tumor Immunology, The Wistar institute, Philadelphia, PA, 2Chemistry, University of South Florida, Tampa, FL, 3Center for CLL, University of Pennsylvania, Philadelphia, United States

We generated and characterized an antigen-specific MD4/εμ-TCL1 CLL mouse model. B cells from young MD4/εμ-TCL1 mice harbor a monoclonal B cell receptor (BCR) against hen egg lysozyme (HEL) and secrete IgM against HEL. Surprisingly, all CLL cells developed in older MD4/εμ-TCL1 mice fail to recognize HEL, but they still respond to goat F(ab’2) anti-mouse IgM by activating robust BCR signaling, suggesting that MD4/εμ-TCL1 CLL cells reactivate a parental Ig gene allele to produce non-HEL-specific BCR and
secretory IgM (slgM). Compared with age-matched Eμ-TCL1 mice, MD4/Eμ-TCL1 mice survive significantly shorter, produce high levels of slgM, and generate significantly increased granulocytic and monocytic myeloid cells in the peripheral blood, spleens and bone marrow. We demonstrated that these granulocytic and monocytic myeloid cells purified from the spleens of MD4/Eμ-TCL1 mice can suppress the proliferation of CD8+ T cells in an antigen-dependent manner, qualifying these cells as myeloid-derived suppressor cells (MDSCs). To test the hypothesis that slgM may account for the accumulation of MDSCs, we crossed μS-/− mice, which can only produce membrane-bound BCR but not slgM, with Eμ-TCL1 mice. The μS-/−/Eμ-TCL1 mice develop significantly lower numbers of MDSCs, and survive significantly longer than Eμ-TCL1 mice. In XBP-1-deficient B or CLL cells, the synthesis of slgM is significantly downregulated. To test whether targeting XBP-1 in CLL cells can reduce the production of slgM and lead to decreased MDSCs, we crossed B cell-specific XBP-1KO mice with MD4/Eμ-TCL1 mice. The resultant XBP-1KO/MD4/Eμ-TCL1 mice indeed produce significantly reduced amounts of slgM and decreased numbers of MDSCs. In addition, pharmacological inhibition of XBP-1s also leads to compromised immunosuppressive functions of MDSCs, suggesting the therapeutic potential of targeting XBP-1s in inhibiting immunosuppressive functions of MDSCs. To test whether slgM also plays a role in regulating MDSCs in solid tumors, we implanted μS-/− mice with Lewis lung carcinoma, and showed that the function of MDSCs in suppressing anti-tumor T cells is abrogated by the absence of slgM, resulting in the slower growth of the lung cancer. These results clearly demonstrate that slgM produced by B cells can upregulate the functions of MDSCs in tumor-bearing mice to aggravate cancer progression.

A Systems Model of Human Metastatic Melanoma from Invasion to Colonization Identifies Tenascin-C as a Driver of Resistance and Emergence.
A. Bradshaw1,2, J. Grahovac3, A. Clark1, L.G. Griffith4, A. Wells1,2;
1Cellular and Molecular Pathology, University of Pittsburgh, Pittsburgh, PA, 2Veterans Administration, Pittsburgh VA Health System, Pittsburgh, PA, 3National Cancer Institute, Belgrade, Serbia, 4Biological Engineering, Massachusetts Institute of Technology, Boston, MA

The lethal progression of metastatic melanoma is driven by refractory micrometastases. These small tumors are generally chemoresistant, and under growth arrest. Dormancy confers drug resistance and secures eventual ectopic emergence. Limited information is known in regard to drivers of metastatic emergence. Human tissue biopsies indicate that metastatic melanoma harnesses the tumor microenvironment (TME) to develop a drug resistant niche, at which point durable therapeutic responses are rare. While genetically engineered mouse models have been instrumental in identifying the impacts of melanoma driver mutations, the study of cell programs governing early ectopic seeding, survival, and emergence have been constrained by inherent complexity. To address this we have developed the first all-human microphysiological systems (MPS) model of metastatic melanoma to study key events from dissemination to colonization. Using the MPS, an all-human organotypic skin organ has been connected via microfluidic circulation to a functional 3D human liver organoid to model critical changes in the primary and ectopic TMEs. Pathophysiologic changes in the TME occur early in primary melanoma which is marked by increased expression of the ECM protein, Tenascin-C (TNC). The presence of TNC in melanoma tumors is correlated to increased malignancy and poor patient prognosis. Invasive outgrowth of melanoma tumor spheroids is increased by melanoma derived TNC, and by stimulatory epidermal growth factor (EGF) and inflammatory ligand lipopolysaccharide. However, invasive outgrowth appears to be more readily influenced by cancer associated fibroblasts (CAFs). CAFs are the primary source of cancer ECM within primary and ectopic TMEs, and are hypothesized to create a tumor

Tuesday-209
permissive ECM for outgrowth and promote tumor survival via secretion of TNC which contains intrinsic low affinity, anti-adhesive, EGF-like repeats. Preliminary studies in the MPS using high TNC expressing metastatic melanomas indicate that TNC is key to driving vertical invasion into collagen matrices. Strategies will be aimed at targeting stromal and cancer cells producing TNC to limit outgrowth and invasion within the TMEs.

Collagen Increases Proliferation and Drug Resistance of Papillary Thyroid Cancer Cells Harboring BRAFV600E Mutations.
L.J. MacDonald¹, A. Sharabura¹, J. Jenkins¹, B. Anderson¹, B. LeBoeuf¹;
¹Department of Biology, Hendrix College, Conway, AR

Thyroid cancer is the most common endocrine cancer, and incidence is increasing worldwide. Thyroid cancer can be classified as either well-differentiated or poorly differentiated. Of well-differentiated thyroid cancers, papillary thyroid cancer is most common, and is associated with activating BRAF mutations. While our understanding of the genetic basis for thyroid cancer is fairly extensive, less is known about how the tumor microenvironment alters tumorigenic characteristics of thyroid tumor cells. Recently, Jolly et al. reported that papillary thyroid tumors derived from cells harboring activating BRAF<sup>V600E</sup> mutations and PTEN deletions are enriched with fibrillar collagen which is associated with decreased survival. In this study, we investigated whether growth on collagen enhanced tumorigenic characteristics of papillary thyroid cancer cell lines with BRAF<sup>V600E</sup> mutations. Three distinct cell lines derived from mouse papillary thyroid cancer tumors were grown in the presence and absence of collagen and assessed for increased proliferation, increased sensitivity to apoptosis, morphological changes indicative of epithelial to mesenchymal transition, and increased drug resistance. Interestingly, our results suggest that growth on collagen contributes to a more mesenchymal morphology, increased proliferation, and decreased sensitivity to chemotherapy drugs. Additionally, our results suggest that collagen increases resistance to apoptosis in an AKT-dependent manner. These and other results implicate an important role for collagen in the progression of thyroid cancer.

Evaluating the overexpression of mitotic checkpoint silencing protein TRIP13 in human breast cancer cell lines in 2D and 3D cell culture models.
M. Moenk¹, s. liu¹;
¹Biological Sciences, University of Toledo, Toledo, OH

Breast cancer is the most prevalent cancer afflicting women worldwide, and is responsible for hundreds of thousands of deaths each year. Several studies have linked overexpression of the TRIP13 gene with breast cancers with poor prognosis, and a variety of other cancer types. TRIP13 is one of many members of the AAA-ATPase family, which collectively have diverse roles in cells that include signal transduction, regulation of gene expression, and protein degradation. Our lab recently established that TRIP13 plays a major role in silencing the mitotic checkpoint, a regulatory mechanism that ensures proper attachment of chromosomes to the mitotic spindle during cell division. Premature silencing of the checkpoint can lead to chromosomal instability (CIN) and aneuploidy, hallmark facilitators of tumorigenesis. Although TRIP13 overexpression has also been correlated with CIN in clinical samples, there is not yet any direct evidence of a causative influence of TRIP13 overexpression on either CIN or tumor development. In the
current study, we sought to investigate the effects of TRIP13 overexpression in human mammary epithelial cells (MCF-10A) as well as in established breast cancer cell lines representing major subtypes of breast cancer: MCF-7 (Luminal A), ZR75-30 (Luminal B), MDA-MB-231 (Basal). All cell lines were engineered with inducible (doxycycline) control over TRIP13 expression. Although TRIP13 overexpression attenuated cell proliferation in all three of the breast cancer cell lines, it almost completely arrested cell proliferation in the non-tumorigenic MCF-10A cells. Flow cytometric analyses of the MCF-10A cells further revealed that TRIP13 overexpression increased G0/G1 cells while reduced cells progressing into S-phase. This was accompanied by a slight increase in CIN, as measured by FISH probing of chromosomes 8 and 12. In addition, when both MCF-7 and MCF-10A cells were plated in a 3D spheroid culture, TRIP13 overexpression noticeably reduced the circularity and compactness of the spheroids in both groups, but only the MCF-10A spheroids exhibited a decrease in total cell viability. These findings suggested that TRIP13 overexpression itself is insufficient to trigger CIN and tumorigenesis, however it is likely to synergize with other genetic or epigenetic alterations in driving the survival and uncontrolled proliferation of precancerous cells. Future work will determine how TRIP13 overexpression might specifically be advantageous for cancer cells, and whether such activities are required for the transition to metastasis.

Mechanical control of nuclear blebbing and micronuclei in hepatocellular carcinoma cells.
K. Mandal¹, R.G. Wells², P.A. Janmey³;
¹Institute for Medicine and Engineering, University of Pennsylvania, Philadelphia, PA, ²Departments of Medicine, Bioengineering, and Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

The mechanical environment of cells changes during cancer development, especially in the liver, where stiffening from fibrosis is often a precursor to cancer initiation. In many cancer cell types, there is correlation between deregulated nuclear morphology or protein expression and cancer grade, which is poorly understood. In this work we report the effect of substrate stiffness on nuclear shape and defects in the human hepatocellular carcinoma cell line Huh7, which exhibits distorted nuclear morphology compared to normal human hepatocytes. The percentage of blebbing nuclei and the number of micronuclei depend on the stiffness of the substrate. Both blebbing and micronuclei are rare on substrates mimicking the stiffness of healthy liver (<1 kPa) and increase as substrate stiffness increases to levels found in cirrhotic livers and liver tumors (10 kPa). Nuclear membrane tension is assessed by dynamic nuclear envelope (NE) fluctuation through live cell imaging, showing larger fluctuations on softer substrates. To investigate the underlying mechanism of nucleo-mechanosensing, we perturbed actin and microtubule systems. Inhibiting ROCK to decrease actomyosin contractility slows down nuclear fluctuation. These in vitro results provide a background with which to compare the impact of stiffness differences on micronuclei formation in normal and HCC tissues from patient samples.
Extracellular matrix (ECM) stiffness has emerged as an important regulator of cellular processes and a significant parameter of the tumor microenvironment. In general, solid tumors are known to be much stiffer than normal tissue, with increased fibrosis being indicative of a worse prognosis for many cancers. The present study focuses on pancreatic ductal adenocarcinoma (PDAC), in which ECM desmoplasia is exceptionally pronounced. Such stromal amassment has been proposed to be a driver of malignancy and a key barrier to efficient drug delivery. With a five year survival rate of 5%, PDAC is in urgent need of research into more effective and personalized therapies. Here we investigate the interplay of varying stiffness with pancreatic stellate cells (PSCs), and their influence on tumor cell behavior. As an integral element of the stromal compartment, PSCs have simultaneously been suggested to be a driver of malignancy and a restraint on cancer progression. Our studies aim to bridge missing links in our understanding of PSC regulation and activity, particularly in regards to ECM stiffness and heterogeneity and their influence on cancer progression. We assess stiffness effects (0.2, 4, and 12 kPa; 3 GPa) on PSC secretomes across patients, and examine tumor-stroma crosstalk with and without treatment. Interestingly, cytokine secretion levels vary in response to stiffness, and differ between tumor-derived PSCs and normal immortalized pancreatic fibroblasts. Intermediate stiffness levels upregulate growth factors that promote fibrosis (TSP-1), increase migratory potential (PTX3) and are predictive of worse prognosis (IGFBP-3), among others. Importantly, we observed expression differences between 3 GPa (plastic) and 4 and 12 kPa (biologically relevant range), indicating that the mechanical environment of typical cell culture methods introduce considerable secretome deviations. We also observe inter-patient variation in PSC morphologies in response to stiffness, as well as differing molecular signatures. These studies highlight the significance of the stromal compartment in PDAC, both with respect to patient heterogeneity and ECM stiffness.

Hypoxia is an important phenomenon in many physiological processes and involved in many human diseases including cancer, cardiovascular and neurodegenerative diseases. The study of hypoxia has been complicated with the lack of sensitive dyes to measure hypoxia at greater than 1% O2. Here, we describe a live cell-based method to conveniently measure hypoxia using a new Image-iT™ Hypoxia Green Probe. The Image-iT™ Hypoxia Green Probe is a hypoxia sensing fluorescent probe, and has excitation and emission peaks of 488 and 520 nm respectively. The probe is sensitive to varying concentrations of oxygen and can detect as low as 5% O2 concentrations in cells. Using this probe, we measured hypoxia in several cell lines including A549, HeLa and U-2 OS using fluorescence microscopy, high content imaging and fluorescence plate reader. The Image-iT™ Hypoxia Green Probe is multiplex
able with other important physiological parameters like mitochondrial membrane potential, apoptosis and oxidative stress. Image-iT™ Hypoxia Green Probe works well in detecting hypoxia in 3D tumor spheroids. The Image-iT™ Hypoxia Green Probe is formaldehyde-fixable that allows end-point measurement of hypoxia in cells. The Image-iT™ Hypoxia Green Probe facilitates sensitive, robust and reproducible measurements of hypoxia in cells.

¹Pathology and Anatomical Sciences, State University of New York at Buffalo, Buffalo, NY

Fibroblast growth factor receptor 1 in its nuclear form (nFGFR1) binds to genomic sites on every chromosome in both the mouse and human cell models. Upon mouse embryonic stem cell (mESC) neuronal differentiation with Retinoic Acid (RA), there is an increased influx of nFGFR1 into the nucleus, increased nFGFR1 proximal promoter binding, and a shift in GO associated nFGFR1 binding locations from stem cell maintenance associated loci bound in ESCs, to binding at mRNA processing, protein folding, and differentiation associated loci post RA treatment. nFGFR1 has widespread binding across the genome and ChIP-seq data from our lab has shown that several binding sites can be present across entire developmentally important gene clusters, one of which being the Hoxa gene cluster. We hypothesize that the widespread binding of nFGFR1 may reflect its potential involvement in chromatin structure organization. Using the Chromatin Conformation Capture (3C) assay and ChIP-qPCR we are investigating the involvement of nFGFR1 chromatin binding dynamics with how it relates to structural changes in topological domains in the Hoxa gene cluster. The current results indicate that nFGFR1 binding is increased at Hoxa topological structures which are maintained between ESCs and RA induced neuronal cells and reduced at sites where topological domains are lost as a result of RA treatment. Human Neuronal Progenitor Cells (NPCs), like mESCs, result in FGFR1 nuclear influx and neuronal differentiation as result of RA treatment. PD173074 (PD) is a specific FGFR1 kinase inhibitor which is able to inhibit nFGFR1 from binding to and affecting gene transcription. RNA-seq was performed on NPCs treated under control, RA, PD, and RA + PD conditions. Comparative analyses showed treatment versus control NPCs having altered expression in 896 genes. Three of the top dysregulated genes (WNT4, GHR, TUBBIII) were chosen to quantify nFGFR1 promoter binding using ChIP-qPCR. The current data shows increased promoter binding resulting from RA treatment and unexpectedly also an increase to promoter binding following PD treatment. Further work is being completed to continue 3C analyses with nFGFR1 binding in human NPCs and following PD treatment. The data together indicates that FGFR1 binding activity may be involved in regulating chromatin architecture through modulating nFGFR1 levels, and that PD inhibition of FGFR1 results in increased FGFR1 binding, possibly due to upregulation of nFGFR1 activity to offset its activity reduction by PD. Supported by NYSTEM (C026415, C026714), NSF (CBET-1555720, CBET-1706050) and Patrick P. Lee Foundation.
Midbrain Dopamine neurons (mDA) can arise from the floor plate of the midbrain and are responsible for the symptoms of Parkinson’s disease when they cease to function. mDA neurogenesis and maturation are regulated by multiple genes such as Shh, Foxa2, Lmx1a/b, Wnt1, among others. Genes that promote formation of mDA have potential to be used for clinical therapy development in Parkinson’s disease. One gene involved in dopamine neurogenesis is the basic helix-loop-helix transcription factor Nato3. However, its mechanism of action is not well known. We hypothesized that Nato3 had the ability to upregulate the LMX1 markers in vivo and in vitro. Previous unpublished data produced by our lab using qPCR and immunostaining showed that overexpression of Nato3 upregulates LMX1b gene in vivo. These current data show upregulation of the LMX1a gene expression by Nato3 in the immortalized mouse midbrain SN4741 cell line, shown through qPCR data. Nato3 upregulation of Lmx1 genes indicate that Nato3 can influence the expression of genes known to drive dopamine neurogenesis, raising it as a potential target for therapeutic development.

Construction of a complex functional system, such as a living organism, requires not only raw building materials (genes encoding structural and other functional proteins), but also an assembly program, organized into flexible feedback and feed-forward subroutines that can function within, and readily adapt to a nonstable environment. Our studies utilizing pluripotent stem cells and organoids revealed a new pan-ontogenic mechanism, Integrative Nuclear FGFR1 signaling (INFS), which underwrites gene programming during development. Genetic experiments have indicated that the fgfr1 gene sits on top of the gene hierarchy that governs gastrulation, as well as the subsequent development of the major body axes, nervous system, muscles, and bones, by affecting downstream genes that control the cell cycle, pluripotency and differentiation, as well as microRNAs. The regulatory control exerted by INFS is due to a single protein, the nuclear isoform of FGFR1 (nFGFR1), which integrates signals from development-initiating factors and operates at the interface of genomic and epigenomic information. nFGFR1 cooperates with a panoply of transcription factors, and targets thousands of genes encoding mRNAs, as well as miRNAs in critical ontogenic networks. nFGFR1 binds to promoters of ancient proto-oncogenes and tumor suppressor genes which serve as switches in cell proliferation, binds and regulates the pluripotency core genes as well as metazoan morphogens that delineate body axes, construct the nervous system and the mesodermal and endodermal tissues. The panontogenic gene programming by INFS feed-forward and feedback loops expands our understanding of ontogeny, the roots of cancer, schizophrenia and other developmental diseases, and holds new promise for reconstructive medicine and cancer therapy. Dissecting the cell-type specific regulatory landscape of a Nuclear Hormone Receptor in C. elegans.
D.M. Thurtle-Schmidt1,2, M. Asahina1, J.D. Ward3, K. Yamamoto1;
1Cellular and Molecular Pharmacology, University of California, San Francisco, San Francisco, CA,
2Biology, Davidson College, Davidson, NC, 3Molecular, Cell Developmental Biology, University of California, Santa Cruz, Santa Cruz, CA

Metazoan Transcriptional Regulatory Factors (TFs) bind to genomic response elements, controlling gene expression precisely to establish and maintain tissue-specific cellular identity. Importantly, TFs also display remarkable plasticity, governing distinct gene networks in different tissues and developmental stages. For example, the conserved C. elegans TF, NHR-25, regulates two different developmental programs in larvae: vulva patterning and molting. To characterize NHR-25 activity and its role in defining these distinct cell types, we used CRISPR/Cas9 to introduce GFP, 3xFLAG, and an auxin inducible tag (AID) into the endogenous NHR-25 gene. The multiple tags simultaneously enabled live imaging of NHR-25 in L1 larvae, ensuring NHR-25 expression in both the developing vulva and seam cells, and ChIP-seq. We found that 75% of our NHR-25 enrichment sites overlapped with those in the modENCODE ChIP-seq NHR-25 dataset at a similar developmental time. However, we identified about one-third fewer enrichment peaks for NHR-25 than modENCODE, suggesting that even modest overexpression of TFs results in substantial promiscuous binding. Sequence analysis of the enriched regions revealed an NHR-25 consensus motif highly similar to its mammalian orthologs as well as an additional consensus motif for another C. elegans’ TF, EOR-1. Interestingly, RNA-seq analysis of worms where NHR-25 was transiently depleted for four hours through addition of auxin, revealed that genes directly adjacent to an NHR-25 enriched site were not necessarily responsive to loss of NHR-25. Thus, NHR-25 may act at a distance. To definitively correlate NHR-25 binding to its target gene, we have deleted NHR-25 occupied regions utilizing CRISPR/Cas9. Phenotypic and transcriptional characterization of these mutants leads us poised to define functional NHR-25 response elements responsible for establishing cell-type specific gene regulatory networks.

Repression of CDON expression by Nuclear Factor One.
B. Kutay1, C. Lektemur1, A. Kumbasar1;
1Department of Molecular Biology and Genetics, Istanbul Technical University, Istanbul, Turkey

Nuclear Factor One (NFI) family of transcription factors regulate gene expression by associating with and maintaining open chromatin sites during embryonic development as well as in certain types of cancer. NFI family comprises four members: NFIA, NFIB, NFIC, and NFIX. NFIB, can both act as and oncogene and tumor suppressor, depending on the context. For example, in glioblastoma, low NFIB expression is associated with classical and mesenchymal subtypes, where if expressed NFIB induces genes associated with differentiation; while in neural and proneural subtypes, it is upregulated and promotes proliferation and invasiveness. In the developing mouse brain, cell adhesion associated, oncogene regulated (CDON) is upregulated when NFIIs are silenced. Interestingly, analysis of data from The Cancer Genome Atlas (TCGA) found that expression of CDON is negatively correlated with NFIB expression in these glioblastoma subtypes. CDON, an Ig superfamily glycoprotein, takes part in a signaling complex to
promote differentiation of neural and muscle stem cells. Bioinformatic analysis of the 5 kb of sequence upstream of the human CDON gene transcription start site identified five NFI binding sites which cluster in the first 1 kb region, or in the 3.5 kb upstream region. Electrophoretic mobility shift and supershift assays showed that NFIIB binds to all five sites. Furthermore, using chromatin immunoprecipitation, we found that NFIIB occupies two sites in the first 1 kb region in vivo. In luciferase reporter assays carried out in HEK293T cells, overexpression of all NFI members represses the CDON promoter by up to 85% and this repression can be reversed by mutation of one NFI motif. As CDON’s regulatory role in development is also emulated in cancer where it has a pro-apoptotic effect in neuroblastoma cells, we are now investigating if NFIIB indeed regulates CDON expression in brain cancer cell lines. We gratefully acknowledge funding from TUBITAK (KBAG 212T017 and 115Z524) and Istanbul Technical University Research Fund.

B.A. Christian¹, A.J. Kim¹, J. Medh¹;
¹Chemistry and Biochemistry, California State University Northridge, Northridge, CA

Introduction: Atherosclerosis is characterized by an accumulation of cholesterol-loaded macrophages in the vascular wall. Several factors regulate macrophage cholesterol content. Lipoprotein lipase (LPL) hydrolyzes triglycerides from circulating lipoproteins thereby promoting cellular lipid uptake. ATP-Binding Cassette A1 (ABCA1) facilitates cholesterol efflux from cells toward high-density lipoprotein (HDL) formation. Peroxisome Proliferator-Activated Receptors (PPAR) are nuclear receptor transcription factors which bind to PPAR response elements (PPRE) on target genes to drive their expression. LPL contains a PPRE in its promoter region, indicating that transcription of LPL is PPAR-γ-dependent. ABCA1 is also regulated by PPAR-γ, by way of another nuclear receptor transcription factor, Liver X Receptor alpha (LXR-α). In previous studies, we demonstrated an upregulation of ABCA1 in LPL-knock-down (KD) THP-1-derived macrophages. Hypothesis and Objective: We hypothesized that fatty acid products of LPL’s activity may act as agonists/antagonists for PPARs, thus the objective of this study was to determine if the upregulation of ABCA1 by LPL-silencing may be via a PPAR-dependent pathway. Methods: Our objective was to examine the relationship between LPL and PPAR-γ in differentiated THP-1 macrophages. Short hairpin RNA was used to specifically silence LPL or PPAR-γ gene, and lentivirus was used to over-express PPAR-γ in THP-1 macrophages. We performed end-point reverse transcriptase polymerase chain reaction (RT-PCR) to compare gene-specific transcript levels in wild-type (WT) cells and either LPL-KD or PPAR-γ-KD macrophages. RT-PCR was performed on PPAR-γ-expressing cells to observe differences in LPL expression. A PPAR-luciferase reporter gene assay was performed to investigate the PPAR-activating potential of lipid extracts or lysates prepared from WT or LPL-KD macrophages. Results: RT-PCR showed that the level of PPAR-γ transcripts in LPL-KD cells was 93% of that in WT cells. Specific repression of PPAR-γ resulted in down-regulation of LPL to 27% of WT levels, while over-expression of PPAR-γ upregulated transcription of LPL two-fold. Luciferase assay data showed that lipid extracts from LPL-KD macrophages exhibited more PPAR activation than WT lipid extracts, while lysates from WT macrophages induced greater PPAR activation than LPL-KD lysates. Conclusion: Our data show that PPAR-γ expression levels directly affect LPL transcription. It appears that while LPL expression levels may not influence PPAR-γ transcription, lipolysis products of LPL may repress the transcription of PPAR-γ-responsive genes. Thus, LPL silencing may upregulate ABCA1 transcription because of the absence of lipolysis products capable of inhibiting PPAR-γ activation.

The lower expression of ABCA1 in LPL-expressing THP-1 macrophages may be mediated by fatty acid products of lipolysis.
A.J. Kim1, B.A. Christian1, J. Medh1;
1Chemistry and Biochemistry, California State University Northridge, Northridge, CA

Introduction: Atherosclerosis is characterized by the thickening and hardening of vascular walls, a process initiated by infiltration of cholesterol-loaded macrophages. Cellular cholesterol accumulation is the net result of receptor-mediated uptake and transporter-mediated efflux. Scavenger receptors (CD36, SR-AI, SR-BI) mediate cellular cholesterol uptake whereas the ATP-binding cassette transporter A1 (ABCA1) mediates the unidirectional efflux of excess cholesterol. Lipoprotein lipase (LPL) is secreted by macrophages and catalyzes the hydrolysis of circulating triglycerides, facilitating cellular lipid uptake. We recently demonstrated that the expression of ABCA1 as well as ABCA1-mediated cholesterol efflux is upregulated in LPL-knock-down (LPL_KD) THP-1 cells

Hypothesis and Objectives: We hypothesized that in addition to regulating cholesterol efflux, LPL may also regulate the expression of macrophage scavenger receptors responsible for cellular cholesterol uptake. Further, we hypothesized that regulatory effects of LPL may be mediated by fatty acid products of LPL’s lipolytic activity. Thus, the objective of this study was (i) to determine if LPL expression levels correlate with the transcription of scavenger receptors and (ii) to directly examine the effect of fatty acids on the expression of ABCA1.

Methods: The LPL gene was silenced in THP-1 macrophages (LPL-KD) by siRNA interference and its expression was compared against wild type (WT) macrophages. Transcript levels of scavenger receptors were compared in WT and LPL-KD macrophages by RT-PCR. The mass of total cholesterol in cell lysates was compared using a cholesterol oxidase-based colorimetric quantification assay. To mimic the presence of lipolysis products, WT cells were incubated in the presence of various saturated and unsaturated fatty acids, followed by measurement of ABCA1-mediated cholesterol efflux.

Results: LPL-KD cells showed an increase in ABCA1 expression (161% of WT). Cholesterol content in LPL-KD cells was 75% compared to WT macrophages. The expression of scavenger receptors SR-BI and CD36 was lower in LPL-KD THP-1 cells compared to WT macrophages (55% and 60%, respectively). Treatment of cells with Oleic acid reduced ABCA1 expression and efflux to 55% of control. Stearic acid and Linoleic acid also significantly reduced ABCA1 transcription compared to a cholesterol loaded control group (67 and 65% respectively).

Conclusion: LPL may function as a signaling molecule that modulates cellular cholesterol content by regulating the expression of scavenger receptors as well as the cholesterol transporter. The presence of fatty acid products of lipolysis may contribute to repress the expression of ABCA1 in WT cells resulting in lower transcript levels compared to LPL-KD cells.

Regulation of anterior lineage genes in C. elegans embryogenesis.
J.D. Rumley1, A. Zacharias1, J.I. Murray1;
1Genetics, University of Pennsylvania, Philadephia, PA

Embryonic patterning requires many signaling pathways to control cell fates. Anterior-posterior axis patterning depends on the Wnt pathway, which acts through the transcription factor TCF and its
coactivator β-catenin. Classic Wnt targets are activated when Wnt signaling is on by the TCF:β-catenin complex binding to cis regulatory regions and are repressed when Wnt signaling is off by TCF binding without β-catenin. In contrast, emerging evidence suggests the existence of direct “opposite” targets, activated by TCF without β-catenin and repressed by TCF:β-catenin. In the C. elegans embryo, almost all cell divisions, including anterior-posterior divisions, are patterned by the Wnt/β-catenin asymmetry pathway, in which nuclear POP-1/TCF is high and SYS-1/β-catenin is low in the unsignaled anterior sister cell and the reverse is true in the signaled posterior sister cell. Although many genes expressed in posterior sister lineages are classic Wnt targets, the regulation of anterior lineage genes is not well understood. These genes may be direct opposite Wnt targets. I am working to determine which anterior genes are opposite targets and how they are regulated. I am testing if POP-1 and SYS-1 are necessary for regulation of anterior genes and identifying sites bound by POP-1 in their cis regulatory regions. I am identifying anterior gene enhancers, and determining if their POP-1 bound sites are necessary for anterior expression. I will also determine if POP-1 binds to opposite Wnt target sites directly, as in mice and Drosophila, or indirectly by interacting with a binding partner, as for a target in C. elegans. If the Wnt pathway does not directly regulate anterior genes, I will determine what other mechanisms regulate their expression. Regardless of the mode of regulation, this work will clarify mechanisms regulating expression of anterior genes in the C. elegans embryo, and may have implications for Wnt regulation of genes expressed in unsignaled cells in other species. So far, I have identified four anterior lineage genes that depend on POP-1 and/or SYS-1 for their wild type expression patterns.

Age-dependent regulation of the FOXO transcription factor DAF-16 by SMK-1 in the roundworm Caenorhabditis elegans.
M.J. Youngman1, K. Carrasco1, J. Morris1;
1Biology, Villanova University, Villanova, PA

In the roundworm Caenorhabditis elegans the insulin/IGF-1(IIS) DAF-2 signaling pathway confers stress-resistance and determines lifespan by modulating the activity of DAF-16, an evolutionarily conserved Forkhead box (FOXO) transcription factor. Transcriptional targets of DAF-16 encode proteins that primarily function in immunity, detoxification, and DNA repair. In the presence of ligands of the DAF-2 insulin receptor, an inhibitory phosphate group added by the AKT-1 kinase prevents DAF-16 from translocating to the nucleus. However, in younger animals DAF-16 is activated in response to acute environmental stresses such as heat shock and ultraviolet irradiation. Several studies suggest that through an association with one or more cofactors in the nucleus, the transcriptional output of DAF-16 is tailored to a particular stressful stimulus. Through functional analysis of DAF-16 in reproductively mature and post-reproductive animals, we found that aging alone triggers DAF-16 transcriptional activity. In non-stressed, well-fed, wild type adults, the expression of many DAF-16 targets increases in an age-dependent manner. Accordingly, DAF-16 plays a role in the innate immunity of adult but not larval stage worms. To understand the mechanistic basis of the dynamic activity of DAF-16 during aging, we took a candidate gene approach to ask about the role of specific nuclear proteins and found that SMK-1 is necessary for the age-dependent increase in DAF-16 function. SMK-1 is the C. elegans orthologue of mammalian SMEK1 (Suppressor of MEK1) and is a regulatory subunit of the Protein Phosphatase 4 (PP4) complex. Functional analysis of genes encoding other putative subunits of this complex in C. elegans, including PPFR-1, suggest a role for PP4 in modulating the function of DAF-16 during adulthood. Phylogenetic analysis suggests that PP4 is closely related to the PP2 and PP6 phosphatases, and some subunits appear to associate with more than one of these phosphatase
complexes. Using an RNAi-based reverse genetic approach to probe the role of individual complex members, we are investigating the possibility that all three phosphatases may coregulate DAF-16 later in life, and our preliminary data suggest that this is the case. We anticipate that our studies will have implications regarding regulatory modules that govern gene expression during aging in evolutionarily diverse species, including humans.

cAMP Reduces Non-Specific DNA-Protein Interactions During Transcription Regulation in Mycobacterium Tuberculosis.
F. Garate¹, C. Canavan¹, M. Lanfrancó¹, I. Wang¹, R.A. Maillard¹;
¹Chemistry, Georgetown University, Washington, DC

The cAMP Receptor Protein in Mycobacterium tuberculosis (CRPMTB) is a transcription factor responsible for regulating genes involved in virulence, carbon metabolism and energy conservation. CRPMTB is a homodimer capable of binding to DNA promoter sequences and up to two cAMP molecules. Here, we investigate the linkage mechanisms between cAMP binding cooperativity and DNA interactions. By using isothermal titration calorimetry and fluorescence spectroscopy, we find that negative cooperativity exists between the binding of the first and the second cAMP molecule to CRPMTB. Interestingly, protein-DNA interactions monitored by fluorescence anisotropy show that the affinity between CRPMTB and its promoter sequence is similar in the presence and in the absence of cAMP, indicating that the cyclic nucleotide does not regulate transcription at the level of binding affinities to specific DNA promoter sequences. Instead, we find that cAMP stabilizes a one-to-one stoichiometric CRPMTB-DNA complex, prevents the formation of high-order CRPMTB-DNA oligomers, and reduces the affinity of CRPMTB for non-specific DNA sequences. Moreover, DNA binding assays taken as function of cAMP concentration show that only one cAMP molecule bound per homodimer is required to fully reverse and dissociate high-order CRPMTB-DNA oligomers into stable one-to-one CRPMTB-DNA complexes. In combination, these results provide an archetype of cAMP-mediated regulation that is significantly different from those described previously for other structurally similar CRPs, like the Escherichia coli homolog.

Glandular cell-specific DNA demethylation in a carnivorous plant Drosera adelae.
N. Arai¹, Y. Hamaji¹, T. Ohyama¹;
¹Biology, Waseda University, Tokyo, Japan

Using carnivorous plants, we are studying the relationship between the environmental responses of plants and gene evolution (Nishimura et al., Planta 2013, 2014; Arai et al., Biochem. Biophys. Res. Commun. 2015). Carnivorous plants have adapted themselves to the nutrient-deficient habitats. They can obtain nitrogen and phosphate, which are necessary for amino acid and nucleotide syntheses, from insects. We showed that the carnivorous plant Drosera adelae (sundew) contains an abundance of an S-like ribonuclease (RNase) in the digestive liquid (Okabe et al., FEBS Lett. 2005). Besides the S-like RNase, recently, we also identified 8-1, 3-glucanase, a class I chitinase, a thaumatin-like protein, a cysteine protease, a lipid-transfer protein and several proteins belonging to the PR4 and PR17 families in the digestive liquid of D. adelae. Interestingly, they all are self-defense-related proteins. More recently, we clarified that most of the genes encoding these proteins are expressed in a glandular cell-specific expression manner. Here, we report on the mechanism underlying the glandular cell-specific expression of these genes.
genes. The analyses of DNA methylation showed that the promoters of the genes encoding the S-like RNase (da-1), the β-1, 3-glucanase (DaGlu) and the protein belonging to the PR4 (DaPR4-L) are unmethylated only in the glandular cells, while the promoters of the other genes are unmethylated in all organs examined (Nishimura et al., *Planta* 2013, 2014; in preparation). All of these genes are the self-defense-related genes. Furthermore, we revealed that the gene encoding the DNA demethylase DEMETER is also expressed highly in the glandular cells. Many studies have shown that plants, in response to biotic stress, regulate the expression of the self-defense-related genes by DNA methylation. Accordingly, it seems that *D. adelae* makes use of the self-defense-related genes for carnivory by making these genes be constitutively unmethylated in the glandular cells.

**Yeast Hsf1 drives a dynamic gene restructuring program in response to heat shock.**  
L.S. Rubio¹, S. Chowdhary¹, A.S. Kainth¹, D.S. Gross¹;  
¹Biochemistry and Molecular Biology, Louisiana State University Health Sciences Center, Shreveport, LA

The evolutionarily conserved heat shock response is an essential mechanism that allows eukaryotic organisms to survive thermally stressful conditions. The master regulator of this response is Heat Shock Factor 1 (Hsf1). In the yeast *Saccharomyces cerevisiae*, several domains of Hsf1 are well-characterized. These allow Hsf1 to respond to proteotoxic conditions triggered by thermal stress: two transactivation domains (N-terminal, C-terminal), a DNA binding domain, a trimerization domain, and a regulatory domain (CE2). Recent work from our lab has revealed that robust activation of Hsf1-regulated *Heat Shock Protein* (*HSP*) genes is accompanied by a dynamic restructuring of the chromatin landscape. Using a sensitive version of chromosome conformation capture (3C), we have discovered that intra- as well as inter-chromosome interactions (5′-3′ end gene looping, intragenic ‘crumpling’, and intergenic coalescence) take place amongst *HSP* genes during heat shock. Strikingly, the coalescence that we observe with Hsf1-regulated genes is not seen with other transcriptionally active genes, even those activated by heat shock. Indeed, DNA-bound Hsf1 is absolutely required for *HSP* gene coalescence. We hypothesize that a domain within Hsf1 is responsible for driving *HSP* genes into coalesced foci within the yeast nucleus during heat shock.

In order to test this hypothesis, we are using *S. cerevisiae* strains bearing different Hsf1 domain deletions. Using ChIP, we have obtained preliminary evidence that Hsf1 bearing a deletion of its N-terminal activation (NTA) domain leads to its increased occupancy of *HSP* genes under basal conditions. This enriched binding is further increased during acute heat shock (39°C). An explanation for this is the unmasking of the potent C-terminal activation domain (CTA) in the Hsf1ΔNTA mutant. It will be interesting to determine whether enhanced binding of Hsf1ΔNTA is accompanied by an increase in looping, crumpling and coalescence of Hsf1-target genes. This will be addressed in our future studies. Identification of the domain within Hsf1 responsible for coalescence would give us a tool to understand the mechanism and biological significance of this fascinating phenomenon. Moreover, it will allow the engineering of heterologous transcription factors capable of driving the coalescence of their own regulons.

Chromosome analysis of Glyptotendipes glaucus and Glyptotendipes paripes (Chironomidae, Diptera) from reservoirs of the Kaliningrad city, Russia.
A.Y. Sharton¹, T.A. Chervotkina¹, N.G. Litvina¹, N.G. Kolesnik¹, V.A. Kasymov¹;
¹School of Life Science, Immanuel Kant Baltic Federal University, Kaliningrad, Russia

G.glaucus and G.paripes are species of Chironomidae family, the larvae of which are sensitive indicators of water contamination by toxic substances. The polytene chromosomes in salivary glands of larvae allow to observe the level of chromosomal alterations in their populations and make conclusions about the ecological conditions of water reservoir. Widespread species G.glaucus and G.paripes have high level of chromosomal polymorphism that allows use them as biological indicators of a reservoirs condition. Here we investigate karyotypes of G.glaucus and G.paripes populations living in the same reservoirs of Kaliningrad and analyze key indicators of their chromosomal polymorphism. The materials for these studies were samples of 4-th instar larvae collected in 2008-2010 during the winter and summer periods from three reservoirs in Kaliningrad: Shkolnoe lake, Isakovskiy (Chistiy) pond and Karasevka ponds system. Collected larvae were fixed in 96% ethanol and concentrated acetic acid (3:1). The polytene chromosome preparations have been made by a standard aceto-orcein technique. From 156 totally studied samples of G.glaucus only 16 (10,25%) samples had a standard karyotype owing to prevalence of the inverted sequence of gla B2 in population. In G.paripes populations the standard karyotype had only 25% of individuals: chromosomal arms A and B were the most polymorphic, frequency of inversions in these arms relating to standard arms averaged 56.5% and 66.7%, respectively. These data correspond to the findings of other authors about G.paripes populations of the Saratov region where heterozygous inversions in A and B shoulders also most often met. The number of heterozygous inversions on individuals in population of G.glaucus varies in low limits from 0.91 to 1.0, average 0.95. This value doesn't exceed the level of natural polymorphism in the previously studied populations of G.glaucus in Saratov region where the number of heterozygous inversions on an individual had average 0.97. In G.paripes population this indicator varies from 0.77 to 1.0 and average 0.85, that exceed the data of populations of this species in Saratov region (0.667). This indicator also higher, than in European G.paripes populations (Bulgarian and Hungarian). In the G. paripes population studied, genomic polymorphism (the presence of B-chromosome in a karyotype), which is characteristic of a number of other populations of species, was also found. In Kaliningrad region G.glaucus and G.paripes are mass and can be recommended as convenient indicators of reservoirs condition from the point of view of the karyotype indicators.

Analysis of irradiation resistance mechanism in S. cerevisiae.

K. Kamata¹, H. Maeda², M. Tanaka³, M. Hatahita³, H. Uchida³, M. Oki¹;
¹University of Fukui, Fukui, Japan, ²Fukui senior high school, Fukui, Japan, ³Wakasa Wan Energy Research Center, Fukui, Japan

Epigenetic control is critical for regulation of gene expression. Our purpose is that reveal how the epigenetic alteration effect on organisms. There is silencing mechanism as one of epigenetic control. In Saccharomyces cerevisiae, Sir complex consisting of Sir2, Sir3 and Sir4 is a key regulator of silencing mechanism. Sir2 is a histone deacetyltransferase that deacetylates histone H4 lysine 16. Deacetylation of histones promotes chromatin compaction, leading to gene repression. Sir2 is need for telomere, HM and rDNA silencing. Especially, rDNA silencing requires Sir2 but not Sir3 or Sir4. Irradiation causes dramatic changes of epigenetic profile in organisms. We determined whether Sir complex genes play critical role in epigenetic changes by measuring survival rate after irradiation. We found that sir3 or sir4 deletion strains increased radiation resistance. Interestingly, sir4 deletion strain exhibited various survival rates. In order to reveal the resistance mechanism, we performed microarray analysis of sir4 deletion strain and wild type. Compared with wild type and sir4 deleted low survival strain, iron and copper related genes were decreased in sir4 deleted high survival strain. Iron can mediate generation of reactive oxygen species (ROS) in response to irradiation. Therefore, we hypothesized that low iron concentration in cell was a key factor for resistance to irradiation. In addition to iron genes, anaerobic genes were also decreased in sir4 deleted high survival strain. These genes are thought to be inversely correlated with mitochondrial activity. Furthermore, it was reported that telomere dysfunction activate mitochondrial activity and that Sir complex maintain telomere length. Thus we presumed below model. First, sir4 deletion activates mitochondrial activity. Then, cellular iron concentration is decreased. Finally, decreased ROS generation contributes to high survival after irradiation. We would like to report and discuss our data at this meeting.

Determining the role of chromatin context on repair of DNA double-breaks formed by a Cas9-linked camptothecin mimic.

T. Rodriguez Cintora¹, R. James¹, R.C. Burgess¹;
¹Biology, Stevenson University, Owings Mills, MD

DNA double-strand breaks (DSBs) can cause genome instability or genetic diversity in cells, depending on their context and the repair outcome. The response to DSBs is called the DNA damage response (DDR), which includes repair by either non-homologous end joining (NHEJ) or homologous recombination (HR). Previous research indicates that chromatin is a major contributor in the DDR signaling pathways which can include cell death, cell cycle arrest, or activation of one of the two DSB repair processes. The long-term goal of this project is to understand the role of chromatin landscape in DSB vulnerability and repair outcome in Saccharomyces cerevisiae. To begin to examine this, the formation and repair frequency of a DSB in a genome region with an active chromatin signature and one with a repressed signature will be compared. In order to induce DNA DSBs at specific regions, we use inducible CRISPR-Cas9 systems under a galactose promoter to target DSBs to active and inactive chromatin regions. We have found in pilot studies that the break frequency can be accurately quantified using the reduction in the real-time PCR signal across the targeted region upon breakage. Using this method, we will test the hypothesis that
active chromatin regions are more vulnerable to DSBs, however they are repaired more rapidly by the NHEJ pathway.

The CRISPR-Cas9 systems that will be used include wild-type Cas9 nuclease but also a novel system composed of a topoisomerase I mutant (Top1-T722A) fused to nuclease-dead Cas9 enzyme. This system will induce DSBs that have a protein-bound DNA end, which requires further processing, and mimics the mechanism of topoisomerase poisons that are used for cancer therapy like camptothecin. These results help us understand the mechanism by which DSBs are processed and repaired, which has implications for understanding both how cells maintain their genome and how it can be manipulated for driving genetic change. Also, these differences can provide insight on how the chromatin environment may restrict or enhance the cytotoxic effects of chemotherapy drugs.

The Optimization of CRISPR Systems for Double Strand Break Induction in *S. cerevisiae*.

R.C. James¹, E.C. Wills¹, R. Reimer¹, P.J. Horn¹, T. Rodriguez Cintora¹, R.C. Burgess¹;

¹Department of Biological Sciences, Stevenson University, Owings Mills, MD

Double strand breaks (DSBs) are a form of DNA damage that can result from an array of chemicals as well as ionizing radiation. Unresolved DSBs are detrimental to cell health, necessitating efficient repair; however, DSBs can result in mutations that knock out gene function. While DSB repair mechanisms are heavily studied, the relationship of repair kinetics to chromatin environment is weakly understood. To study repair kinetics in the context of chromatin modifications, DSBs can be induced in a controlled manner and their repair can subsequently be studied; however, we must first optimize the induction of DSBs before beginning to study repair.

CRISPR-Cas9 is a robust new system for DSB induction (and genome editing) that can be directed to almost any site in a genome simply by changing its guide RNA sequence. While Cas9 is a useful tool for DSB induction, modifications of this system have also been engineered to increase specificity. fCas9 is comprised of catalytically inactive Cas9 fused to the FokI endonuclease, which must dimerize to induce a DSB. This increases specificity by doubling the required guide RNA hybridization. Cas9 nickases also double the required gRNA binding by only inducing single stranded “nicks.” The goal of our study is to compare the cutting efficiency and specificity of fCas9, dual Cas9 nickase complexes, wild-type Cas9, I-SceI, and the HO endonuclease in the yeast genome. The hypothesis is that the Cas9 enzyme will have the highest frequency of cutting at the target site, but with the lowest specificity, while Cas9 nickase and FokI-dCas9 will have lower cutting efficiencies, but higher specificity. In order to test this hypothesis, qPCR will be performed with amplification across break sites, causing breaks to knock down initial template quantities. Preliminary testing of the HO and I-SceI assays have yielded calculated cutting frequencies of 25 and 90 percent, respectively. While further optimization is required, these results demonstrate that qPCR assays are an effective approach to a measurement of DSB induction.

Characterizing the interaction between Rad54 and PCNA.
A. Gannon\textsuperscript{1}, R.C. Burgess\textsuperscript{1}, L. Krejci\textsuperscript{1,3}, B. Stefanovic\textsuperscript{1,3};
\textsuperscript{1}Department of Biological Sciences, Stevenson University, Owings Mills, MD, \textsuperscript{2}National Centre for Biomolecular Research, Masaryk University, Brno, Czech Republic, \textsuperscript{3}International Clinical Research Center, St. Anne’s University Hospital, Brno, Czech Republic

Rad54 is a eukaryotic protein known to be involved in homologous recombination (HR), a process used by cells to repair DNA double-strand breaks (DSB). Malfunctions in HR drive human diseases such as breast and ovarian cancer, and Fanconi anemia. The goal of this study is to investigate the function of the interaction between two proteins that are critical in HR, Rad54 and the replication clamp PCNA (proliferating cell nuclear antigen). Using a candidate approach we identified two N-terminal point mutations, K102A and R103A, in Saccharomyces cerevisiae that we believed would exclusively disable the Rad54-PCNA interaction. It was important that this mutation, rad54-KR/AA, only affected the interaction with PCNA so we could study it in isolation. Microscale thermophoresis assays revealed that rad54-KR/AA creates a fivefold decrease in interaction between Rad54 and PCNA. To verify that rad54-KR/AA is a separation-of-function mutation, we tested its ability to form displacement loops (D-loops). Rad54 normally aids in the formation of D-loops to facilitate strand invasion during HR; if D-loops cannot form, HR cannot happen. Results showed that rad54-KR/AA can in fact form D-loops in levels comparable to wild type. We then examined the rad54-KR/AA phenotype for defects seen in rad54\textsuperscript{Δ} cells, particularly, sensitivity to DNA damage and genetic interactions. First, we tested if KR/AA interacted with Rad27, a flap endonuclease whose deletion causes synthetic lethality with rad54\textsuperscript{Δ} due to an accumulation of replication intermediates that depend on HR for resolution. Double mutants had a synthetic sick phenotype and is extremely sensitive to DNA damage, indicating a defect in repair. In a follow-up spot assay, we investigated if non-homologous end joining (NHEJ) played a role in the synthetic interaction between rad54-KR/AA and rad27\textsuperscript{Δ}, by testing the effect of mutating a gene required for the initiation of the NHEJ, Ku70. Interestingly, the triple mutant with ku70\textsuperscript{Δ} did not exhibit a synthetic sick phenotype but instead grew nearly as well as wild type. The growth rescue in its absence could indicate that either NHEJ processes are creating toxic intermediates, or the Ku70 protein itself is inhibiting repair of replication damage in the KR/AA mutant. Future experiments will examine other NHEJ proteins, such as Lif1 to determine which is the correct hypothesis. We will also use a primer extension assay to gauge the cells ability to perform repair synthesis during recombination events, and a two hybrid assay to see if rad54-KR/AA can interact with other HR proteins like Rad51. Understanding the mechanisms of HR is essential for advancing research in other fields that pertain directly to human health, including genomic stability, hereditary diseases, and cancer.

Signaling via DNA breaks and RUVB proteins activates the germline genome.
M. Wong\textsuperscript{1}, W.M. Michael\textsuperscript{1};
\textsuperscript{1}Biological Sciences, University of Southern California, Los Angeles, CA

In \textit{C. elegans}, the primordial germ cells Z2 and Z3 are born during early embryogenesis and then held in a transcriptionally quiescent state until hatched larvae begin to feed. During this period of transcriptional quiescence Z2/Z3 are blocked at G2 of the cell cycle. Upon feeding, RNAPII is abruptly and globally activated and the ensuing gene expression breaks the cell cycle arrest and drives Z2/Z3
division. A previously documented (1) yet unexplained feature of germline genome activation in the worm is the appearance of numerous DNA breaks coincident with RNAPII activation. Here, we describe a novel pathway whereby nutrients trigger topoisomerase II-dependent DNA breaks that, in turn, recruit RUVB proteins to decompact the chromatin. Chromatin decompaction then allows for global activation of RNAPII and ensuing gene expression. Our results suggest that DNA break-induced chromatin decompaction may be a general mechanism for the rapid induction of signal-mediated gene expression. Our results also provide just the third-ever example of programmed DNA breaks in eukaryotic biology, after meiotic and V(DJ) recombination.

The co-repressor complex mSin3A/HDAC1 is involved in the down-regulation of CRTC2 target genes during B cell differentiation.
Y.V. Arancibia¹, A.H. Zambrano¹, C. Cárcamo¹;
¹Instituto de Bioquímica y Microbiología, Universidad Austral de Chile, Valdivia, NJ

Introduction: Germinal center is the principal source of memory B cells and plasmatic cells. During class switch recombination (CSR), the cytidine deaminase induced by activation (AID) produces double-strand breaks in the DNA that requires to be repaired by the DNA damage response (DDR). This response is attenuated in B cells allowing to the cells of the germinal center replicate without entering to apoptosis or senescence. Recently, it was shown that B cell differentiation is associated with genotoxic stress produced by DNA damage. During this process, the co-transcriptional activator CRTC2 is phosphorylated, inactivated and translocated to the cytoplasm, which results in the down-regulation of several genes. It was shown that CRTC2 is part of an alternative DDR that couples genotoxic stress and cellular differentiation, however, it’s not the well understood the molecular mechanism of this process. Results obtained by our laboratory points to the co-repressor complex mSin3A/HDAC1 as a potential complex involved in the down-regulation of CRTC2 target genes. Therefore, our main goal was to discover if this complex is involved in the transcriptional regulation of CRTC2 target genes. Material and Methods: We used Ramos cell line to study B cell differentiation and etoposide as a double-strand breaks inductor. Through immunoprecipitation, western blot and chromatin immunoprecipitation assays we evaluated the participation of this complex during this process. Results: Our results showed that mSin3A and HDAC1 interacted with CRTC2 in the nucleus and this interaction is decreased under genotoxic stress. Also, we showed an enrichment of mSin3A and HDAC1 in the promotor region of the target genes of CRTC2 during genotoxic stress. The presence of this repressor complex is accompanied by an increase of the epigenetic mark of repression H3K9me3 and a decreased of the epigenetics marks of activation, H3K9Ac, H3K27Ac and H3K4me3 in the promoter regions of the CRTC2 target genes. Discussion: Our results showed that co-repressor mSin3A/HDAC1 complex could be involved in the transcriptional regulation of CRTC2 target genes during B cell differentiation. Regardless this process is necessary to the formation of plasma cells that produce high-affinity antibodies, it is associated with cancer, since most B-cell lymphomas originate from B cell differentiation process, which why is important to study the molecular biology associated with this event.

Histone dynamics during oocyte meiosis in \textit{C. elegans}.
S. Rosu\(^1\), P. Thepmankorn\(^1\), O. Cohen-Fix\(^1\);
\(^1\)LCMB, NIH-NIDDK, Bethesda, MD

During meiosis, the process through which gametes are formed, homologous chromosomes must pair, undergo recombination, and segregate from each other. Chromatin dynamics, which have been studied extensively in somatic cells, have been less explored in the context of meiosis. To gain new insights into this process, we are using live imaging in \textit{C. elegans} to examine chromatin dynamics during various stages of meiotic prophase. Unexpectedly, we have found widespread histone H2B exchange in the late stages (diplotene and diakinesis) of oocyte meiotic prophase. We have confirmed this observation in three different ways: 1) by the complete recovery of mCherry::H2B fluorescence after photobleaching in a strain carrying a mCherry::H2B transgene (indicating new unbleached histones are loaded onto chromatin), 2) by the disappearance of photoconverted Dendra2::H2B in a strain overexpressing the Dendra2::H2B transgene in the germline (indicating that converted histones are unloaded, and new unconverted histones are loaded onto chromatin), and finally, 3) by the redistribution of photoconverted H2B::Dendra2 from a sub-region of chromatin to the entire chromatin in a strain where the Dendra2 tag was inserted at an endogenous H2B locus by CRISPR. This suggests that H2B histones are widely unloaded from chromatin at the diplotene and diakinesis stages in meiosis. Furthermore, our data suggests that when the nucleoplasmic pool of the tagged H2B is limited (as in the endogenously tagged strain), the converted histones are reloaded, and when the nucleoplasmic pool is large (as in the over-expressing transgenic strain), they are degraded. This widespread exchange is specific to meiosis, as we have not observed this phenomenon in terminally differentiated somatic cells in the timeframe assayed. The histone exchange at this stage of meiosis is surprising, as no replication is occurring and transcription is thought to be shut down by diakinesis. The mechanism and role of histone exchange at this stage are unknown, but possible roles include enabling changes in chromosome configuration important for the meiotic divisions, and/or resetting of chromatin marks. In future work, we will screen candidate histone chaperones and chromatin remodelers to find factors involved in this meiotic histone exchange. We will also examine the consequence of blocking histone exchange, which may lead to defects in meiosis or embryo development.

Oligo-conjugated antibodies and massively parallel single-cell sequencing reveal the high-parameter correlation of protein and mRNA expression in individual immune cells.
D. Jensen\(^1\), C. Chang\(^1\), E.Y. Shum\(^1\), J.C. Martin\(^2\), J. Ghadiali\(^2\), J. Hu\(^1\), D. Rosenfeld\(^1\), H.C. Fan\(^1\);
\(^1\)BD Genomics, Menlo Park, CA, \(^2\)BD Biosciences, San Diego, CA

Recent developments in high-throughput single-cell mRNA sequencing have enhanced our knowledge of the cell populations found in individual tissues or disease states. However, prior studies have shown a low correlation between mRNA expression levels and protein expression levels, suggesting that the addition of high-parameter single-cell protein expression data would significantly improve our understanding of cellular functions and states. Traditional single-cell protein assays (flow cytometry and microscopy) are limited in the number of parameters that can be achieved within one experiment, and can be difficult to combine with mRNA expression analysis in a single workflow.
Here we use oligo-conjugated antibodies (BD Ab-seq) in combination with massively parallel single cell mRNA sequencing on the BD Rhapsody™ platform to simultaneously measure the protein and mRNA content of individual human peripheral blood mononuclear cells (PBMCs). To accomplish this, a 30+ parameter oligo-conjugated antibody panel against immune relevant cell-surface markers was created and paired with the BD Rhapsody Immune Response Panel (a targeted gene expression panel consisting of 399 targets). The combined sequencing data and subsequent analysis generated from this single workflow experiment provides a measurement of both gene expression and protein expression. These digital measurements have significantly reduced PCR bias through the use of the unique molecular indices (UMIs). Our results showed that protein molecule expression detected with BD Ab-seq was highly sensitive and specific. Protein expression patterns correlate well with results from flow cytometry data on the same samples. BD Ab-seq allowed the robust detection of protein markers like CD4 and CD8, even when their cognate mRNA transcripts were found in low abundance. Certain markers cannot be easily distinguished at the mRNA level, like T-cell memory marker isoforms CD45RA and CD45RO, but are easily distinguished at the protein level. Finally, we are able to correlate the mRNA and protein expression on 30+ genes in thousands of individual cells. Our study shows the successful combination of high-parameter protein and mRNA expression data within a single workflow, and should enable the further elucidation single cells within different tissues, developmental time points, and disease states.

The Role of Mps3 and Htz1 in Telomere Cohesion and Telomere Position Effect.
L.M. Antoniacci, C.M. Breymeier; 1Science, Marywood University, Scranton, PA

The yeast nuclear envelope protein Mps3 functions in several components of chromosome metabolism such as sister chromatid cohesion, telomere clustering, and DNA damage repair. Mps3 also physically and functionally interacts with the histone variant Htz1 in DNA damage repair. Htz1 is found near the telomeres and is involved in preventing DNA from forming silent heterochromatin as a way to regulate transcription and provide chromosome stability. Because Mps3 functions in cohesion and has been also shown to have a defect in cohesion at the telomeres, our lab is interested in determining if Htz1 also functions in cohesion near the telomeres. In addition because both Mps3 and Htz1 function near/at telomeres, our lab is interested in determining if either function in telomere position effect (TPE). TPE is a phenomenon where genes located next to telomeres are transcriptionally repressed. It has been extensively studied in Saccharomyces cerevisiae and recent studies in mammalian cells show TPE is implicated in several human syndromes where genes are relocated near the telomeres and then lose their expression. To better understand TPE our lab used a yeast strain that contains URA3 adjacent to the VII-L telomere. Mutations of Mps3 or a deletion of Htz1 in this strain was then observed for defects in TPE.

Muscleblind-like RNA binding proteins form RNA transport granules associated with Kif1b.
1Cell Biology, Emory University, Atlanta, GA, 2Center for Neurogenetics, University of Florida, Gainesville, FL

Myotonic Dystrophy, Type 1 (DM1) is an autosomal dominant disease that affects multiple tissues of the body, including muscle and neurons. DM1 is caused by expanded CTG repeats in the 3' UTR of DMPK, which form toxic intranuclear RNA foci that sequester Muscleblind-like RNA binding proteins (MBNL). While regulation of alternative splicing by MBNL proteins in the context of muscle development and DM1 have been extensively studied, MBNL proteins also regulate mRNA localization in myoblasts and young neurons by binding to cis-elements in 3' UTRs. However, mechanisms of MBNL-mediated RNA trafficking is not well understood. We have investigated the role of cytoplasmic isoforms of MBNL in mRNA localization in differentiated cortical neurons in culture. MBNL proteins were localized in a punctate distribution in axons and dendrites. Live cell imaging of GFP tagged cytoplasmic MBNL isoforms revealed particles that exhibited bidirectional transport. A split kinesin assay revealed selective interactions of MBNL proteins with the tail domain of Kif1bα that was required for transport. MBNL did not interact with the splice variant, Kif1bβ, or other kinesins. Interaction of Kif1bα with RNA transport granules has not been previously reported. Using a biochemical approach, overexpression of Kif1bα but not Kif1bβ increased the association of cytoplasmic MBNL with microtubules. Experiments in progress are to identify MBNL target mRNAs that are transported by Kif1bα. These results suggest a new function for Kif1bα-MBNL interactions in mRNA localization that may be impaired in DM. Cytoplasmic MBNL isoforms may play a key role in coupling cytoskeleton-dependent mRNA transport that is altered in DM.

Localizing mRNAs in skeletal muscle cells.
1Instituto de Medicina Molecular, Faculdade de Medicina da Universidade de Lisboa, Lisboa, Portugal

Skeletal muscle is formed by multinucleated myofibers, the biggest cells in the human body. The multiple nuclei in these cells are regularly positioned so that the distance between them is maximized. We previously found nuclear positioning to be important for skeletal muscle function. We hypothesize that each nucleus influences the nearby cytoplasm by differential mRNA transport along myofibers. Using highly matured mouse myofibers differentiated in vitro, we found that overall mRNA distribution depends on nuclear position. smFISH demonstrated mRNA clustering around the nucleus along with myofiber maturation in a dynein dependent manner. We have also confirmed that the levels of protein translation can depend on nuclear location. Interestingly, a peculiar subset of mRNAs localizes regardless of where the nucleus is placed. We are now dissecting the intrinsic properties of these mRNAs that determine their distribution in order to question the reason for this distinct localization pattern. Understanding the mechanisms of mRNA transport and anchoring that govern its subcellular destinations in myofibers may be the key to understand how nuclear positioning impacts muscle activity.

Certain types of inverted repeat sequences can organize local chromatin infrastructure in *Saccharomyces cerevisiae*.  
O. Miura\(^1\), T. Ohyama\(^1\);  
\(^1\)Biology, Waseda University, Tokyo, Japan  
DNA segments that read the same from 5' to 3' in either strand are called inverted repeat sequences or simply IRs. Although IRs are widely found in both prokaryotic and eukaryotic genomes, their *in vivo* functions, if any, are still enigma. We developed a computer program that can identify the IRs with cruciform-forming potential in a given genome. Using the *S. cerevisiae* genome and this computer program, we performed genome-wide analyses for the distribution, occurrence frequency, position, sequence characteristics and relevance to chromatin structure for the IRs. We clarified the following points. Firstly, nucleosome-excluding IRs are rare in open reading frames. Secondly, the ApT- or TpA-rich IRs function in the 3'-UTRs, and the A-tract (or T-tract)-rich IRs function in the core promoter regions as the nucleosome depletion centers. The mechanism underlying the nucleosome depletion, however, seems to be different between the two types of IRs. Thirdly, there is a strong structural correlation between the IRs and the poly(A) signals in the mRNA precursor. We will discuss possible roles of the IRs in transcription and the formation of mRNA 3'-end in the yeast.

\(^3\)Department of Biology, University of North Carolina, Chapel Hill, NC  
*Neurospora crassa* has long been an important model for circadian biology. However, the spatio-temporal dynamics of the *N. crassa* clock components at the single cell level have remained elusive. The core oscillator in the Neurospora clock is a negative feedback loop in which WC-1 and WC-2 acting together as a transcription factor drive expression of frequency (frq) whose product, the Intrinsically Disordered Protein FRQ, dimerizes, complexes with the DEAD-Box Helicase FRH and with CK1, and depresses the activity of WC-1/WC-2. We set out to investigate whether frq mRNA is non-randomly positioned in the cytoplasm. We hypothesized that frq mRNA translation may be spatially controlled through the association with an RNA-binding protein. To examine if frq transcript is spatially patterned, we employed single molecule RNA FISH coupled with quantitative image processing. We also used immunofluorescence to understand the relationship between FRQ protein and mRNA localization. The image analysis suggested that there is non-random clustering of frq, indicating that there is spatial regulation of mRNA position. We are currently investigating the role of known frq binding proteins in this phenomenon to better understand the spatio-temporal dynamics of FRQ throughout the circadian day.

Transcription factor-mediated targeting of genes to the nuclear pore complex is the major pathway controlling peripheral localization of genes in budding yeast.
D.G. Brickner¹, M. LeBrun¹, C.R. Hinchliff¹, J.H. Brickner¹;
¹Molecular Biosciences, Northwestern University, Evanston, IL

Hundreds of genes physically interact with the nuclear pore complex (NPC) and many inducible genes reposition to the nuclear periphery when they are activated. In budding yeast, interaction with the NPC is controlled by cis-acting targeting elements (or “DNA zip codes”) and requires both NPC proteins and transcription factors (TFs). Here, we describe the mechanistic dissection of the function of TFs and transcriptional regulators/mRNA export factors in mediating targeting to the nuclear periphery. Further, we have performed a global screen of all ~200 yeast transcription factors to test the generality of this phenomenon. Each TF was tagged with the DNA binding domain from LexA and crossed against a strain having the LexA binding site integrated at a locus that normally localizes to the nucleoplasm. The position of this locus with respect to the nuclear envelope was scored using confocal microscopy. Approximately 50% of the tested transcription factors were sufficient to cause localization to the nuclear periphery. The major pathway by which this targeting was mediated required the NPC; CRISPR-meditated mutations in the NPC protein Nup2 blocked peripheral targeting by >95% of these TFs. This suggests that controlling gene positioning within the nucleus is an important and unappreciated function of TFs and that interaction with the NPC is the major pathway by which genes localize at the nuclear periphery. The TFs identified in the screen regulate over 1000 genes, including housekeeping genes as well environmentally or developmentally regulated genes. The TFs are found in all transcription factor families in budding yeast and a large subset (50%) of the transcription factors identified have human homologs. A human TF was able to mediate targeting to the nuclear periphery in yeast, suggesting that the molecular mechanism of gene recruitment to the NPC has been deeply conserved and likely plays a fundamental role in genome organization.

Asymmetric Distribution of Hexose Transporter mRNA Provides a Growth Advantage.
T. Stahl¹, S. Hümmer¹, A. Spang¹;
¹Biozentrum, University of Basel, Basel, Switzerland

Asymmetric localization of mRNA is important for cell fate decisions in eukaryotes and provides the means of localized protein synthesis in a variety of cell types. Here we show that hexose transporter mRNAs are retained in the mother cell until metaphase-anaphase transition (MAT) and then released in the bud in S. cerevisiae. The retained mRNA was translationally inactive but was already ribosome-bound before MAT. Treatment with a translation initiation inhibitor caused degradation of HXT mRNA, while blocking elongation, prevented release of the mRNA into the bud, indicating translational control of mRNA localization. Consistently, unlike in large added cell, in small and medium budded cells, HXT proteins were not found at the plasma membrane in the bud. Importantly, when cells were released from starvation into rich, glucose containing medium, HXT2 mRNA, but none of the other HXT mRNAs tested, was enriched in the bud after MAT. This enrichment was dependent on the cAMP/Ras2/PKA pathway, microtubules and correct nuclear segregation into the bud. Using strains that only expressed one hexose transporter allowed us to demonstrate that Hxt2 only strains grow faster than their counterparts. Therefore, asymmetric distribution of HXT2 mRNA provides a growth advantage for young
daughters who are better prepared for nutritional changes in the environment. Our data provides strong evidence that asymmetric mRNA localization is an important factor in determining cellular fitness and may influence lifespan as well as aging.

Functional map of the DEAD-box ATPase Dbp5 at single amino acid resolution.
A. Lari\(^1\), B.P. Young\(^2\), C.J. Loewen\(^2\), B. Montpetit\(^1,3\),
\(^1\)Cell Biology, University of Alberta, Edmonton, AB, \(^2\)Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, \(^3\)Viticulture and Enology, University of California, Davis, Davis, CA

Dbp5p (DDX19) is an essential DEAD-box protein that interacts with multiple nuclear pore complex (NPC) proteins to drive the directional export of mRNAs through RNA-protein complex remodeling. However, Dbp5p also shuttles between the nuclear and cytoplasmic compartments and has been functionally linked to transcription, export of pre-ribosomal subunits, DNA damage responses, and translation. The mechanism(s) by which Dbp5p contributes to these other cellular processes, or is shuttled through the nucleus, remains largely unknown. Towards understanding the specific molecular interactions mediating these functions of Dbp5p, we have generated a yeast mutant collection containing strains with single amino acid substitutions at residues 2-482 of Dbp5p. Phenotypic screening of this collection to identify separation-of-function mutants has included assays to define sensitivity to transcriptional and translational inhibitors, sensitivity to DNA damage, and defects in mRNA or rRNA export. Through this approach, we have identified key residues mediating functions of Dbp5p outside of mRNA export, thus providing a means to detail the molecular mechanisms by which Dbp5p may be contributing to these processes. The mutant collection was further screened for changes in Dbp5p subcellular localization, which led to the identification of a nuclear export signal (NES) within Dbp5p. Mutation of the NES results in the localization of Dbp5p mainly to the nucleus and is not lethal, suggesting that the normally observed enrichment at NPCs and large cytoplasmic pool of Dbp5p are not required for the essential functions of this protein. Synthetic genetic array (SGA) analysis with a strain carrying the mutated Dbp5p NES identified genes encoding the nuclear exosome components Rrp6p and Lrp1p, providing a link between Dbp5p shuttling and exosome mediated RNA processing and surveillance. We expect that continued characterization of these separation-of-function mutants will provide detailed mechanistic insight into the multiple functions of Dbp5p in gene expression and beyond.

Ribosome biogenesis is closely linked to the cell growth and proliferation. Dysregulation of this process causes several diseases collectively known as ribosomopathies. For the final step of the maturation of the ribosome, the nascent 40S and 60S subunits are exported from the nucleus to the cell cytoplasm. To
prevent premature association of these ribosomal subunits, eukaryotic initiation factor 6 (elf6) binds the 60S subunit within the nucleus. Its release in the cytoplasm requires the interaction of EFL1 and SBDS proteins. In Shwachman-Diamond syndrome (SDS), a defective SBDS protein prevents elf6 eviction, inhibiting its recycle to the nucleus and subsequent formation of the active 80S ribosome. We have shown that the interaction of EFL1 with SBDS resulted in a decrease of the Michaelis-Menten constant (KM) for GTP and thus SBDS acts as a GEF for EFL1 [1]. Subsequent studies demonstrated that SBDS debilitates the interaction of EFL1 with GDP without altering that for GTP [2]. The interaction of EFL1 alone or in complex with SBDS to guanine nucleotides is followed by a conformational rearrangement. Understanding the molecular strategy used by SBDS to disrupt the binding of EFL1 for GDP and the associated conformational changes will be key to understand their mode of action and alterations occurring in the disease. In this study, we aim to show, using BIO-SAXS and ab-initio modelling techniques, the conformational changes in EFL1 during its mutation [3] and the results from the interactions between EFL1 and its binding partners, the SBDS protein and the guanine nucleotides.

The SUMO-Specific Isopeptidase SENP2 is Targeted to Intracellular Membranes via a Predicted N-Terminal Amphipathic α-Helix.

H.M. Odeh¹, É. Coyaud², B. Raught², M.J. Matunis¹;
¹Biochemistry and Molecular Biology, Johns Hopkins School of Public Health, Baltimore, MD,
²Department of Medical Biophysics, University of Toronto, Toronto, ON

Sumoylation regulates a wide range of essential cellular functions, many of which are associated with activities in the nucleus. Although there is also emerging evidence for the involvement of SUMO at intracellular membranes, the mechanisms by which sumoylation is regulated at membranes is largely unexplored. In this study, we report that the SUMO-specific isopeptidase, SENP2, uniquely associates with intracellular membranes. Using in vivo analyses and in vitro binding assays, we show that SENP2 is targeted to intracellular membranes via a predicted N-terminal amphipathic α-helix that promotes direct membrane binding. Furthermore, we demonstrate that SENP2 binding to intracellular membranes is regulated by interactions with the nuclear import receptor karyopherin-α (Kap-α). Consistent with membrane association, BioID-mass spectrometry (BioID-MS) revealed interactions between SENP2 and ER, Golgi and inner nuclear membrane-associated proteins. Collectively, our findings indicate that SENP2 binds to intracellular membranes where it interacts with membrane-associated proteins and has the potential to regulate their sumoylation and membrane-associated functions.

The VAP family member Scs2 functions to organize chromatin at the yeast inner nuclear membrane through recruitment of the SUMO E3 ligase Siz2 and telomeres.
N.O. Saik1, C. Ptak1, B. Montpetit1,2, J.D. Aitchison1,3, R. Wozniak1;
1Cell Biology, University of Alberta, Edmonton, AB, 2Viticulture and Enology, University of California, Davis, CA, 3CIDR, Seattle, WA

The nuclear envelope (NE) provides an environment for the proper regulation and organization of interacting chromatin. In budding yeast, NE-associated chromatin includes telomeres and silenced subtelomeric regions. Multiple mechanisms are employed to tether these chromatin regions to the NE and silence resident genes. Among the factors required for telomere association with the NE is Siz2, a SUMO E3 ligase (Ferreira, et al., 2011. Nature Cell Biology, 13(7), 867–74). We further investigated the role of Siz2 and sumoylation in telomere association with the NE. We found that Siz2 is predominantly distributed throughout the nucleoplasm during interphase, but is recruited to the NE during the early stages of mitosis, when newly replicated telomeres re-associate with the NE. We show that enrichment of Siz2 at the NE is dependent on its mitotic phosphorylation, a SUMO interacting motif within Siz2, and a nuclear pore complex protein, Nup170, which is known to interact with subtelomeric chromatin (Van De Vosse et al., 2013. Cell, 152(5), 969–983). In all cases, mutant cells which fail to recruit Siz2 to the NE results in telomere tethering defects. We hypothesize that NE recruitment of Siz2, during mitosis, functions to target specific proteins for sumoylation that are required for proper chromatin organization at the NE. Consistent with this model, we show that NE recruitment of Siz2 correlates with the mitotic specific sumoylation of several proteins. This includes Scs2, an integral membrane protein and member of the VAP protein family. Scs2 resides in the endoplasmic reticulum (ER) and the NE where it appears to function in phospholipid metabolism, endoplasmic reticulum/plasma membrane interactions, and telomeric silencing. We show that Scs2 is required for telomere association with the NE and our data suggests that Scs2 functions as a receptor for Siz2 on the inner nuclear membrane. Data on the role of Scs2 in subtelomeric gene silencing and its functional links to nuclear pore complex proteins to will also be discussed. Together these data suggests that Scs2 plays an essential role in the spatial and temporal control of sumoylation at the inner nuclear membrane, an important post-translational modification involved in chromatin organization.

Metazoan Nuclear Pores provide a scaffold for poised genes and stabilized induced Enhancer-Promoter contacts.
P. Pascual-Garcia1, S.C. Little1, Y. Lan1, M. Capelson1;
1Department of Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Understanding how patterns of gene expression are established, maintained, and transmitted during cell division is crucial to decipher how cells initiate and preserve their developmental identity. A growing number of components of gene expression machinery are known to be non-randomly arranged in the nucleoplasm but located in distinct structural and functional nuclear compartments and scaffolds. Concomitant with this non-random organization, individual chromosome regions can be repositioned in nuclear space, establishing contacts between distant genomic loci as well as protein components of nuclear scaffolds. One of the most prominent nuclear scaffolds is the Nuclear Pore Complex (NPC) which is embedded in the Nuclear Envelope, and consists of approximately 30 different subunits, called
Nucleoporins (Nups). This large protein complex mediates nucleo-cytoplasmic transport of macromolecules, but it has also been implicated in additional cellular processes such as regulation of gene expression via direct binding to the genome. In yeast, gene recruitment to the NPC has been linked to transcriptional activation and to epigenetic memory of the activated state. Yet in animal cells, it is still unclear what function NPC-genome association brings to gene regulation. In Drosophila melanogaster culture cells and isolated tissues, we have identified genome-wide presence of multiple Nups at regulatory DNA elements, including promoters, enhancers, and insulators. Strikingly, we discovered that the NPC component Nup98 facilitates the looping contacts between promoters and enhancers, revealing Nups as a new class of architectural proteins that organize the 3D architecture of the genome and therefore, influence gene regulation. Consistent with this idea, we characterized the role of different Nups in a new mechanism of developmental transcriptional memory, in which Ecdysone hormone-induced genes are more rapidly or more strongly expressed in cells that have previously experienced the presence of the hormone. Interestingly, loss of Nup98 did not affect transcription during initial induction, but resulted in slow activation during re-induction, demonstrating a complete loss of transcriptional memory. To further characterize this phenomenon, we used single-molecule mRNA quantification to measure the magnitude of fluctuations in the expression of the Ecdysone-induced gene, E74. Together, our findings introduce a previously unrecognized role of metazoan nuclear pores in functioning as scaffolds for topological genome organization and suggest that in animal cells, nuclear pores stabilize enhancer-promoter loops and facilitate transcriptional memory.

Chromatin-bound nuclear pore proteins recruit chromatin remodeling complexes to induce DNA decondensation in Metazoan cells.
T. Kuhn1, S.C. Little1, M. Capelson1;
1Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

Nuclear pore complexes (NPCs) span the eukaryotic nuclear envelope and regulate nucleo-cytoplasmic traffic of large molecules, RNA and protein. NPCs are comprised of about 30 distinct nuclear pore proteins (nucleoporins, Nups), each present in many copies to form an 8-fold rotationally symmetric pore structure. In recent years, it has become clear that NPCs interact with the genome, and this interaction has a functional impact on gene expression. In yeast, recently activated metabolic genes re-localize to NPCs, and this interaction is required for the phenomenon of transcriptional memory, whereby subsequent gene induction results in dramatically faster and higher levels of gene transcription. Transcriptional memory of inducible genes has also been found in Drosophila and human cells, and in both organisms, NPCs, or separate “off-pore” nucleoporins, respectively, have been found to be critical for the increased second round of transcriptional up-regulation. Genome-wide binding data in Drosophila and human cells show specific nuclear pore proteins at genetic targets throughout the genome, both as components of the peripheral pore complex and as intranuclear off-pore entities. These genomic targets tend to be open chromatin associated with active, developmental or cell cycle genes, suggesting a possible role for nucleoporins in regulating expression of developmental programs. One specific nucleoporin, Nup98, commonly binds enhancers and promoters of target genes, and is required for E-P looping, as well as transcriptional memory, upon target gene transcriptional induction. The mechanism by which Nups are involved in these processes however, and at what stage of gene activation, is not known. To probe this, we have developed a tethering system in Drosophila melanogaster by which to study the function of Nup-genome interactions. Using transgenic Drosophila containing integrated genomic lacO arrays and LacI-Nup fusion proteins, we have determined that
tethering nucleoporins Nup98, Nup62, and Sec13 to ectopic lacO loci is sufficient to induce chromatin decondensation of larval salivary gland polytene chromosomes in a chromatin context dependent manner. Furthermore, by probing the functions of Sec13 specifically, we are able to show that at an endogenously condensed lacO locus, tethering Sec13 is sufficient to recruit a Brahma chromatin remodeling complex, as well as GAGA Factor, another Drosophila protein associated with chromatin decondensation, and subsequently decondense the target chromatin. These experiments show a role for components of NPCs in recruiting chromatin remodelers to target loci to facilitate chromatin decondensation, regulating a crucial step at an early stage in gene activation.

Uncovering a role for nucleoporin Megator in a novel nuclear scaffold structure.
J. Aleman¹, M. Capelson¹;
¹Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

The Nuclear Pore Complex consists of ~30 Nucleoporin proteins or Nups. Beyond their structural transport role, Nups have recently been shown to play a role in genome organization and transcriptional regulation. These gene regulatory events occur during Drosophila melanogaster development. The details and the mechanisms by which Nups regulate gene expression is not well understood. Our lab has identified a novel nuclear structure formed by specific Nups. We refer to this structure as the nuclear scaffold or nuclear cables since this accurately describes the localization of the Nups – binding in large interspersed domains along chromatin, as observed by immunofluorescence staining of polytene chromosomes of Drosophila larval salivary glands. One of the functional players is a nuclear basket Nup, Megator (Mtor), which has been implicated in both transcriptional regulation and transport functions of the nuclear pore. The goal of my research is to define the biological role of the Mtor formed nuclear scaffold as well as its effect on gene regulation. To determine if Mtor plays a role in defining the rate of transcription, we have performed single molecule RNA FISH experiments in whole mounted larval salivary glands targeting a developmentally important transcription factor that responds to ecdysone hormone, Eip74. Results from confocal imaging indicate that upon Mtor knock down: 1) Eip74 transcription seems to be upregulated, as indicated by a bigger, brighter site of nascent transcription and 2) there is an accumulation of single mRNAs in the nucleus. We are also interested in a possible implication of Mtor in the targeting of non-coding RNAs (ncRNA) Rox1 to chromatin since Mtor has been shown to play a role in dosage compensation. Preliminary results from single molecule RNA FISH experiments against Rox1 ncRNA in larval salivary glands indicate that upon Mtor knock down, targeting of ncRNA to the X chromosome may not be as efficient as in wild type conditions. This work will help to establish a potential role for the Mtor nuclear scaffold in transcriptional regulation as well as potentially in ncRNA transport and targeting for the epigenetic process of dosage compensation.

Mapping Nucleoporins in the D. Melanogaster Genome.
A. Gozalo¹,², Y. Lan¹, M. Capelson¹;
¹Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA, ²Biochemistry and Molecular Biophysics, University of Pennsylvania, Philadelphia, PA

Regarded as the gateway to the genome, nuclear pore complexes (NPCs) consist of approximately 30 proteins termed Nucleoporins (Nups). While the canonical function of the 30-120 MDa NPC is to act as a
selective barrier and regulate intranuclear traffic, recent studies have shown that Nups are also involved in chromatin-related processes such as the regulation of genes and chromatin architecture. However, the organization of individual Nups on chromatin and how Nups are recruited to chromatin and remains poorly understood. To decipher how Nups are organized on chromatin we conducted ChIP-seq of three Nups in two different D. melanogaster cell lines. One of the Nups, Elys, is the only Nup that exhibits DNA-binding ability. The other two Nups, Nup93 and Nup107, are members of the inner and outer ring structural subunits of the NPC, respectively. Due to the roles of Nup93 and Nup107 as structural Nups we hypothesized that these two Nups would share the majority of their binding sites and demarcate NPC binding sites. Preliminary analysis shows that contrary to expectation, these two Nups share only a small number of their binding sites. Moreover, Nup107 and Elys share a large fraction of their sites independent of Nup93 suggesting that either we have captured immature pores or that Elys is recruiting Nup107 for another function. While a majority of Nup binding sites are conserved between cell types, all three Nups exhibit cell type-specific binding patterns. Through this study we have begun to map Nups on chromatin and by expanding upon this study we will be able to further understand what roles Nups have in regulating chromatin architecture and gene regulation. Additionally, by cross referencing these data sets with all available data sets of chromatin/DNA binding proteins we will be able to predict candidates which recruit Nups to chromatin.

Epigenetic modifications and DNA replication in striated muscles rely on LINC-mediated mechanotransduction coupling.
T. Volk¹, S. Wang¹, U. C. P.¹, E. Stoops¹, B. Markus², A. Reuveny¹;
¹Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, ²G-INCPM/Mantoux Institute for bioinformatics, Weizmann Institute of Science, Rehovot, Israel

Nuclear mechano-transduction has been implicated in epigenetic control of gene expression, however its in vivo contribution to mature contractile striated myofibers, has yet to be elucidated. We find that perturbation of nuclear constraints mediated by the Linker of Nucleoskeleton and Cytoskeleton (LINC) complex induced differential nuclear size caused by a varying degree of DNA endocycle progression within myonuclei of single myofibers of Drosophila larvae. Unlike control myonuclei, temporal regulation of DNA replication and its arrest were abolished in LINC mutant myonuclei resulting with variable DNA content in the myonuclei of single myofibers. Furthermore, altered levels of epigenetic chromatin modifications were observed in the LINC mutant myonuclei, which varied between myonuclei of individual myofibers, implicating variability in the transcription activity of the mutant myonuclei. Genomic analysis, using muscle-specific expression of Dam-RNA Pol II indicated that the altered epigenetic modifications correlated with modified RNA-Pol II occupancy of essential genes. Specifically, expression of the chromatin regulator Barrier-to-autointegration Factor (BAF), and the Ca++-dependent myosin regulator Troponin-C were downregulated. We propose that in mature myofibers nuclear constraints determine cell cycle progression, and epigenetic chromatin modifications required for muscle function.

Macronuclear positioning in the giant ciliate, *Stentor coeruleus*.
R.M. McGillivary¹, P. Sood², W.F. Marshall³;
¹Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

The giant ciliate *Stentor coeruleus* takes nuclear positioning to the extreme: this unicellular organism can reach 1 mm in length, and it possesses one of the largest known nuclei. This nodulated macronucleus occupies a specific location and orientation within *Stentor*, and extends down its anterior-posterior axis. *Stentor* has a complex cortical structure that is highly asymmetric. The anterior end features an oral apparatus, while the posterior end tapers into a holdfast. *Stentor* also has the ability to regenerate its oral apparatus after sucrose shocking. During the process of regeneration, the macronucleus dramatically changes shape, condensing into a rod and then renodulating at defined stages of regeneration. How does *Stentor* achieve precise nuclear positioning over large length scales? How is the shape of the macronucleus regulated? Our first molecular foothold into these questions comes from an RNAi screen of genes differentially expressed during oral regeneration in *Stentor*. Knockdown of the exportin gene CSE1 results in *Stentor* with rounded posterior ends and macronuclei that are mispositioned to the anterior end of the cell. Another differently expressed gene contains a SUN domain. SUN proteins are components of the LINC complex, which connect the nuclear envelope to the cytoskeleton and play a role in nuclear positioning. RNAi knockdown of one of *Stentor*’s SUN-domain genes results in cells with irregularly sized macronuclear nodes. Further work will identify more key proteins used to position the macronucleus and begin to parse the mechanisms *Stentor* uses to achieve this positioning.

Characterizing LINC complex assembly in budding yeast meiosis.
J. Fan¹, H. Jin¹, H. Yu¹;
¹Cellular and Molecular Biology, Florida State University, Tallahassee, FL

The conserved linker of nucleoskeleton and cytoskeleton (LINC) complex is composed of a SUN-domain integral membrane protein of the inner nuclear membrane and a KASH-domain integral membrane protein of the outer nuclear membrane. In most organisms investigated to date, a direct interaction between the SUN and KASH domains, which takes place in the lumen of the nuclear envelope, mediates LINC complex assembly.

In budding yeast, Mps3 is the SUN-domain protein, whereas two KASH-like proteins, Csm4 and Mps2, have been proposed. Unlike Mps2, which is present in both mitosis and meiosis, Csm4 is meiosis-specific and is required for organizing actin microfilaments that engage telomere motility during meiotic prophase I. The predicted transmembrane domain of Csm4 is located very close to its C-terminus, leaving about three amino acids available for its interaction with the SUN-domain of Mps3 in the nuclear lumen.

In this study, we seek to understand how Csm4 interacts with Mps3 and mediates LINC complex assembly in budding yeast. We have confirmed the genetic interaction between Csm4 and Mps3 by ectopically expressing Csm4 in vegetative yeast cells. We propose two models for how Csm4 interacts with Mps3. First, the very C-terminal end of Csm4 is sufficient for direct binding to the SUN-domain of Mps3. Alternatively, another factor is present to mediate the interaction between Csm4 and Mps3. To distinguish between these two models, we use a combined genetic and biochemical approach. Our
preliminary findings support the idea that a third component is required for bridging Csm4 and the SUN domain of Mps3, thus indicating the formation of a trimeric LINC protein complex in budding yeast meiosis.

**Molecular insights into the mechanisms of SUN1 oligomerization in the nuclear envelope.**

Z. Jahed\(^1\), D. Fadavi\(^1\), U.T. Vu\(^1\), E. Asgari\(^1\), J. Hennen\(^1\), J.D. Mueller\(^2\), G. Luxton\(^3\), M. Mofrad\(^4\);  
\(^1\)University of California Berkeley, Berkeley, CA, \(^2\)University of Minnesota, Minneapolis, MN

SUN proteins are inner nuclear membrane proteins, which interact with the outer nuclear membrane KASH proteins to form conserved nuclear envelope-spanning molecular bridges that mechanically integrate the nucleus with the cytoskeleton. These bridges, or linker of nucleoskeleton and cytoskeleton (LINC) complexes, are important for several cellular functions including DNA damage repair, mechanotransduction, meiotic chromosome pairing, and nuclear positioning. Underscoring their significance is a growing list of human diseases associated with genetic mutations in LINC complex proteins including ataxia, cancer, and muscular dystrophy.

In this study, we combined sophisticated multifunctional computational modeling approaches with in vivo biochemical experiments to understand the functional specification of the two major mammalian SUN proteins: SUN1 and SUN2. While SUN1 and SUN2 play functionally redundant roles in several cellular functions, more recent studies have revealed diverse and distinct functions for SUN1. There is also evidence in the literature to suggest that SUN1 may assemble a wider range of homo-oligomers than SUN2. To understanding the molecular mechanisms underlying SUN1 oligomerization in the nuclear envelope we first made structural models of SUN1 based on the structure of SUN2. Our models predict that both SUN1 and SUN2 favor trimeric SUN domains, however, our results imply that in monomeric (inactive) SUN1, the alpha helical regions preceding the SUN domain adopt a conformation that is distinct from that of SUN2 which may result in differential activation mechanisms for SUN1. Having established the likelihood that SUN1 can homo-trimerize, we next sought to investigate how SUN1 homo-trimers might be assembled into higher-order oligomers as observed experimentally. We show that SUN1 but not SUN2 trimer can associate through their SUN domains to form lateral complexes. In agreement with our models, our in vivo Z-scan Fluorescence Fluctuation Spectroscopy (FFS) results show that exchanging the SUN domains of SUN1 and SUN2 can alter their oligomer states. Finally, by predicting the large-scale functional motions of SUN proteins, we propose a model in which bending of the luminal coiled coil regions may mediate clustering and higher order assembly formation of SUN domain proteins.

The LINC complex, consisting of KASH proteins in the outer nuclear membrane and SUN proteins in the inner nuclear membrane mediates nuclear positioning to specific locations in a cell. Defects in LINC
components result in failure to position nuclei during fertilization, cell migration, cell polarization, neuronal development, and muscle development. The cores of LINC complexes are the interfaces between KASH and SUN domains in the perinuclear space. However, the regulation of the SUN/KASH interaction is poorly understood. Crystal structures predicted that KASH peptides form three interfaces with SUN proteins. Our goal here is to test the functional consequences of disrupting these three interfaces. Significantly, we show that a conserved disulfide bond between SUN and KASH proteins plays an important role in the developmental switch between nuclear migration and anchorage. We use a three-pronged approach combining in vivo C. elegans developmental genetics, a functional assay for nuclear migration in polarizing tissue culture cells, and molecular dynamic simulations to better understand the molecular mechanisms for how SUN and KASH domains interact. The C-termini of KASH proteins are pointed into a SUN protomer forming the first SUN/KASH interface. We showed that extension of the KASH domain by a single alanine residue completely blocked the nuclear migration function of C. elegans UNC-83. At the second interface, KASH peptides then interact in a cleft between two SUN protomers. We showed that mutation of tyrosine at -7 to an alanine blocks UNC-83 function. Molecular modeling showed that the alanine is too short to reach a conserved region in of the SUN domain necessary for hydrogen-bond formation. Finally, before leaving for the outer nuclear membrane, KASH peptides stretch along the surface of a second SUN protomer and form a di-sulfide bond. Interestingly, the C. elegans nuclear migration KASH protein UNC-83 does not contain this third interaction domain, while the anchorage KASH ANC-1 and its mammalian ortholog Nesprin-2G does. Mutations of the conserved cysteines in SUN or KASH disrupted ANC-1 dependent nuclear anchorage in C. elegans and Nesprin-2G/SUN2 dependent nuclear movements in polarizing NIH3T3 fibroblasts. However, the SUN cysteine mutation did not disrupt UNC-83 function during nuclear migration. Finally, molecular dynamic simulations showed that the disulfide bond is necessary to transfer maximal forces from the cytoskeleton to the nucleoskeleton. Thus, the intermolecular disulfide bond is critically important for LINC complex-mediated mechanotransmission and the developmental switch from nuclear migration to nuclear anchorage.

The LINC complex contributes to epithelial cell homeostasis.
V. Narayanan1, P.T. Arsenovic1, C. Mayer1, G. Luxton2, D.E. Conway1;  
1Biomedical Engineering, Virginia Commonwealth University, Richmond, VA, 2Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN

Mechanical forces, both at cell-cell junctions and cell-matrix adhesions, have been shown to be important for regulating homeostatic processes of the epithelium, such as proliferation, collective cell migration, and 3D organization. More recently the nuclear LINC (linker of the nucleoskeleton and cytoskeleton) complex has emerged as another critical structural and mechanosensitive region of the cell. However, the majority of studies of the LINC complex have occurred in fibroblasts. We hypothesized that the LINC complex, both structurally and mechanically, was necessary for epithelial function. Using a previously developed nesprin-2G force biosensor, we confirmed that the LINC complex is subject to mechanical tension in 2D MDCK cell monolayers. We also observed that biaxial stretch increased the mechanical force applied across the LINC complex, indicating that externally applied forces affect LINC complex force. Additionally, we measured higher nesprin-2G force in 3D epithelial acini (grown in Matrigel) as compared to 2D monolayers. To disrupt the LINC complex, we developed an MDCK II cell line expressing inducible dominant negative (DN) KASH, a peptide which disrupts the endogenous nesprin-SUN interactions and blocks nuclear-cytoskeleton interactions. Cells expressing DN KASH exhibited slower migration speeds in response in a scratch wound cell migration assay, consistent
with prior reports in fibroblasts. Expression of DN KASH in MDCK 3D acini cultures resulted in a rapid filling of the central lumen with cells, suggesting that the LINC complex is necessary for acini equilibrium. This filling of the lumen occurs without measurable increases in cellular proliferation, suggesting either a defect in apoptosis, migration, or cellular polarity. Taken together our results indicate that the LINC complex is a critical structure in the epithelium.

Identification and characterization of *Medicago truncatula* LINC complex components with potential functions in root symbioses.
A.H. Newman-Griffis¹², I. Meier¹²;
¹Molecular Genetics, The Ohio State University, Columbus, OH, ²Center for RNA Biology, The Ohio State University, Columbus, OH

Nuclear movement is vital for cellular and developmental processes across eukaryotic life. Nuclear movement often requires LINC complexes, which link the nucleoskeleton and cytoskeleton and bridge the nuclear envelope (NE) through the interaction of outer nuclear membrane (ONM) KASH proteins and inner nuclear membrane SUN proteins. These proteins interact in the NE lumen through the C-terminal SUN-interacting tail (SIT) of KASH proteins and the KASH-binding lid of SUN proteins. LINC complexes are conserved throughout eukaryotes, and recently our lab has shown that they are involved in nuclear movement and positioning in the model plant *Arabidopsis thaliana*. Our interest in plant LINC complexes stems from the many elements of the plant life cycle that involve nuclear movement and positioning, from cell division to fertilization. Among these, one of the most important is symbiosis between plants and soil-dwelling microbes. It has long been known that nuclei move during symbiosis initiation, but it has never been established whether these movements are functional or incidental. *Arabidopsis* does not form symbiotic interactions, thus we have adopted the model legume *Medicago truncatula* - an alfalfa relative widely used as a model for root symbiosis - to determine if plant LINC complexes are involved in symbiosis initiation. Using bioinformatic tools, we identified *Medicago* genes that encode 12 putative proteins: nine KASH proteins, two ONM KASH interacting partners (WIT), and one SUN protein. Several of them are limited to non-Brassica Rosids, and thus may have functionally diversified. Ten of the 12 candidate proteins are properly targeted to the plant NE. NE-associated KASH candidates bind plant SUN, and the interaction depends both on the SIT of the KASH protein and the KASH-binding lid of the SUN protein. Furthermore, NE targeting of all SUN-binding KASH proteins depends on their ability to interact with SUN. Together, these data indicate that *Medicago* expresses *bona fide* LINC complexes that function *in planta*. To broadly inhibit LINC complex function, a dominant-negative version of *Arabidopsis* SUN2 was created that resides in the ER lumen, disrupts LINC-complex function at the NE in *Arabidopsis*, and can bind to *Medicago* KASH proteins. Data showing its effect on both nuclear movement in root hairs and symbiosis initiation and establishment will be presented.

Nesprin-2G, a key player in regulating nuclear mechanics.
H. Shams1, G. Luxton2, M. Mofrad3;
1Bioengineering, University of California Berkeley, Berkeley, CA, 2Genetics, Cell Biology, and Development, University of Minnesota, Minneapolis, MN

Nucleo-cytoskeletal coupling directly affects nuclear mechanics, which is critical in various cell functions such as migration and differentiation. Linkers of the nucleoskeleton and cytoskeleton, known as LINC complexes, physically anchor the nucleus to the cytoskeleton. Nesprin-2G is a giant component of the LINC complex directly connecting the actin cytoskeleton to SUN proteins, another core component of the LINC complex in the perinuclear space. Nesprin-2G was shown to undergo tension in various nuclear planes and transmit forces to the inner nuclear space. The present study employs integrated experimental and computational techniques across different scales with the aim to investigate the relation between tension along nesprins and nuclear mechanics. Specifically, we explored molecular response of nesprin-2G to cytoskeletal forces using a structural model of nesprin-2G in molecular dynamics simulations. Then, we performed in vitro pulling experiments on nesprin-2G with magnetic tweezers in order to study the effect of mutations identified in silico on force-extension curves. At the cellular level, we observed the effect of these mutations in rescuing the rearward motion of NIH 3T3 fibroblasts. Past efforts have been focused on fully disrupting the connection between the nucleus and the cytoskeleton, which results in completely impaired nuclear anchorage. Here, we designed a protocol for fine-tuning mechanoresponse at the molecular level by introducing site-specific mutations, which can result in major advances in controlling the emergence of nuclear phenotypes to physiological cues.

Nesprin-1alpha 2 mediates MTOC and motor protein recruitment to the nuclear envelope during myogenesis to control myonuclear positioning.
C. Shak1, V. Koullourou1, A. Haworth1, D. Shah1, S. Shackleton1;
1Department of Molecular and Cell Biology, University of Leicester, Leicester, United Kingdom

At the onset of myogenesis, the microtubule (MT) network is reorganised to facilitate the changes in cell morphology and myonuclear positioning that occur upon myotube formation. MT nucleating capacity transfers from the centrosome to the NE through recruitment of pericentriolar material (PCM) components to the NE, including PCM1, pericentrin and γ-tubulin. Following myoblast fusion, MTs then reorganise to form a longitudinal array and their associated motor proteins, dynein and kinesin-1, are recruited to the NE to drive regular myonuclear spreading along the length of the myotube. The LINC complex, comprised of SUN and nesprin proteins, resides in the NE and connects the nucleus to the cytoskeleton. Here, we provide evidence supporting a role for the LINC complex in nuclear-MT connection to control myonuclear positioning. We found that nesprin-1 expression at the NE is induced early in myogenesis, whereas nesprin-2 is largely cytoplasmic. Furthermore, nesprin-1 is required for recruitment of PCM1, pericentrin and kinesin light chains 1/2 to the NE, whilst SUN1/SUN2 act redundantly. Expression of the muscle-specific nesprin-1α2 isoform is induced at the onset of myogenesis, concomitant with pericentrin recruitment to the NE. In nesprin-1 null myotubes, exogenous expression of nesprin-1α2 was sufficient to rescue defects in PCM protein recruitment to the NE. Our data support a model in which nesprin-1α2, anchored at the NE through redundant SUN1/SUN2 interactions, acts as a muscle-specific receptor for recruitment of the MTOC and motor proteins to the
NE. In line with this, muscular dystrophy-associated mutations in LINC complex proteins impaired pericentrin recruitment and MT nuclear nucleation at the NE and led to defects in myonuclear spreading. These defects are likely to contribute to muscle disease pathophysiology.

Multiple isoforms of Nesprin1 associate homogenously with the nuclear envelope (NE) where they interact with Sun proteins to form Linkers of the Nucleoskeleton and the Cytoskeleton (LINC complexes) that span the whole NE. In a stark departure from this biological paradigm for Nesprin1 at the NE, we show that Nesprin1α colocalizes with the ciliary rootlets of mouse photoreceptors and also forms asymmetric NE aggregates that dock rootletin filaments at the nuclear surface of photoreceptors. Strikingly, recombinant filaments of rootletin expressed in NIH3t3 cells induce the aggregation of specific Sun2/Nesprin1 LINC complexes that are required for the docking of rootletin filaments at the nuclear surface. In agreement with these data, we show that the N-terminal region of rootletin interacts with the cytoplasmic domain of Nesprin1α and that larger isoforms of Nesprin1 are integral components of ciliary rootlets of multiciliated ependymal and tracheal cells. From a biological standpoint, these data provide a novel paradigm for multiple isoforms of Nesprin1 at ciliary rootlets and suggest a unique role for Nesprin1 in anchoring rootletin filaments at the nuclear surface in vivo. From a clinical standpoint, our data suggest that the wide spectrum of human pathologies linked to nonsense mutations of SYNE1, which encodes isoforms of Nesprin1, may in part originate from ciliary defects due to a loss of function of ciliary Nesprin1.

**Dissecting the role of LINC complex in meiotic chromosome pairing and synapsis.**  
C. Liu¹, A.F. Dernburg¹;  
¹Molecular and Cell Biology, HHMI/UC Berkeley, Berkeley, CA

Meiosis is the specialized cell division that enables sexual reproduction by producing haploid gametes from diploid cells. Following one round of DNA replication, the two parental copies of each chromosome, known as ‘homologs’, are segregated such that the resulting gametes only inherit one copy of each. To achieve this accurate segregation, each chromosome must first pair with its homologous partner and establish a physical connection between them called the synaptonemal complex (SC). Despite the identification of many of the molecular components essential for this process, how homology is recognized and how synapsis is prevented between nonhomologous chromosomes remain important unsolved questions. In *C. elegans*, homologous recognition requires the pairing centers, specialized cis-regulatory regions on each chromosome, connected to the microtubule motor dynein through the LINC complex. Without dynein, synapsis fails to initiate even when homologous pairing centers eventually pair; without SUN-1 function, promiscuous synapsis occurs between nonhomologous chromosomes. Loss of SUN-1 function allows extensive synapsis formation even in the absence of dynein, although SC forms between nonhomologous chromosomes (Sato et al., 2009). This
epistasis suggests that SUN-1 is part of a barrier that inhibits promiscuous synapsis while dynein acts to promote synapsis between homologs by overcoming this barrier. To test and extend this model, we are investigating the roles of additional LINC complex components. The LINC complex spans inner and outer nuclear envelopes, and the component of LINC complex connecting dynein and SUN-1 is the KASH-protein ZYG-12. ZYG-12 is essential for development and germline proliferation, but can be depleted specifically during meiosis using the auxin-inducible degradation (AID) system. Acute depletion of ZYG-12 results in distinct defects in paring and synapsis, suggesting a boundary of the putative inhibitory barrier necessary to prevent synapsis between nonhomologous chromosomes. Our data also suggest that different components in the LINC complex connected to the dynein motor could have different functions in controlling pairing and synapsis, during the mechano-regulation of meiotic homology recognition.

Novel human mutation in KASH5 transmembrane domain causes protein mislocalization and male infertility.
S.A. Bentebbal1, A. Salter2,3, K. Fakhr4,5, V. Allan2, B. Burke3, H. Horn1;
1Life Sciences Division, Hamad Bin Khalifa University, Doha, Qatar, 2Faculty of Life Sciences, University of Manchester, Manchester, United Kingdom, 3Laboratory of Nuclear Dynamics and Architecture, Institute of Medical Biology, Singapore, Singapore, 4Human Genetics Division, Sidra Medical and Research Center, Doha, Qatar, 5Department of Genetic Medicine, Weill Cornell Medical College in Qatar, Doha, Qatar

Azoospernia is a type of male infertility characterized by a complete absence of sperm production. The recent identification of a human mutation in the KASH5 transmembrane domain (TMD) has been correlated with an azoospernia phenotype. KASH5 is the most recently identified member of the KASH domain protein family. The KASH domain proteins localize to the outer nuclear membrane through an interaction with inner nuclear membrane SUN domain proteins. KASH and SUN protein interactions form a physical bridge spanning the nuclear envelope, which is known as the LINC complex (linker of Nuclear Envelope and Cytoskeleton). LINC complexes play a key role in the mechanical force transmission required for various cellular processes such as migration and differentiation. During prophase of meiosis I, the SUN1/KASH5 LINC complex connects telomere ends of meiotic chromosomes to the molecular motor protein dynein, which is necessary for chromosome movement and homologue pairing.

The recently identified KASH5 TMD mutation has been found in a family where two affected brothers are carrying homozygous mutations. The mutation consists of a single base pair substitution resulting in an amino acid change from leucine to glutamine at the position 535 (L535Q). In this study, we aim to characterize the KASH5 L535Q mutation and its involvement in the cellular and molecular mechanism leading to azoospernia.

To assess potential changes in secondary structure caused by this mutation, we utilized an in-silico structure prediction program (I-TASSER, University of Michigan) and compared wild-type KASH5 to L535Q mutant. The simulation showed no alteration of the secondary structure and a preserved alpha-helical TMD in the L535Q mutant, similar to what is predicted for wild-type KASH5. However, when we analyzed the TMD using the GES hydrophobicity scale, we found that KASH5 L535Q is less hydrophobic than the wild-type KASH5, with a TMD hydrophobicity of 31.7 and 38.6 kcal/mol, respectively. Changes in the hydrophobicity of TMDs have been shown to affect the targeting of proteins to various organelles. Indeed, when we expressed a GFP-tagged versions of the wild-type and L535Q KASH5 proteins in HeLa
cells, we found a mislocalization of the mutant KASH5 to the mitochondria. We predict that this mislocalization is a key factor underlying the azoospermia phenotype in patients.

*SUN2 regulates mitotic duration in response to extracellular matrix rigidity.*
N. Bélaadi1, L. Pernet2, J. Aureille2, L. Nguyen3, M. Rio1, G. Louarn1, G. Loirand1, C. Guilluy2; 1Inserm, Nantes, France, 2Institute for Advanced Biosciences, Inserm, Grenoble, France, 3IMN, CNRS, Nantes, France

How cells adjust their growth to the mechanical properties of their surrounding environment is central to many aspects of biology. During interphase, changes in extracellular matrix (ECM) rigidity affect gene expression and cell cycle progression, which can compromise tissue homeostasis. Here we examined the effect of extracellular matrix rigidity on cell division. We found that cells divide more rapidly when cultured on rigid substrate. Surprisingly, we observed no effect of extracellular matrix rigidity on rounding or post-mitotic spreading duration, but instead we found that changes in matrix stiffness impact metaphase to anaphase transition. We nest compared the proteomic content of cells dividing on soft and stiff substrates and we found that ECM rigidity regulates the stability of the LINC complex component SUN2, whose level of expression affects mitotic progression. On rigid substrates high level of SUN2 promotes cortical tension and mitotic progression, while low level of SUN2 delays the onset of anaphase when cells are grown on soft extracellular matrix.

*DNA Damage Causes Rapid Accumulation of Nuclear Phosphoinositides for ATR Signaling.*
Y. Wang1, A. Hariharan1, G. Bastianello2,3, G. Shivashankar1,2,4, M. Foiani1,2,3, M.P. Sheetz1,5; 1Mechanobiology Institute, National University of Singapore, Singapore, Singapore, 2IFOM, The FIRC Institute of Molecular Oncology, Milan, Italy, 3Dipartimento di Bioscienze, Università degli Studi di Milano, Milan, Italy, 4Department of Biological Sciences, National University of Singapore, Singapore, 5Department of Biological Sciences, Columbia University, New York, NY

Phosphoinositide lipids (PPIs) are enriched in the nucleus and the role of nuclear PPI signaling has remained enigmatic. A hint from earlier studies suggests involvement of nuclear PPIs in DNA damage response and is evident from the transient increase of nuclear PIP2 level upon DNA damage. To investigate the role and visualize the distribution of the PPIs in response to DNA damage, we followed NLS-tagged GFP-PH fusions that localized to specific PPIs. Expression of nuclear-targeted PH domains that sequester specific PPIs dramatically inhibit recruitment of Ataxia telangiectasia and Rad3-related protein (ATR) plus ATR interacting protein (ATRIP) to the damage site and consequently reduces activation of Chk1, as confirmed by both laser microirradiation and western blots. PPI-binding domains rapidly (<1s) accumulate at damage sites with local enrichment of PPIs, as observed from immunostaining against anti-PIP2 antibody. The magnitude of accumulation is altered by wortmannin and decreased with ATP depletion or lower temperatures. Accumulation of PIP2 in complex with the nuclear receptor protein, SF1, at damage sites requires phosphorylation by inositol polyphosphate multikinase (IPMK) and promotes actin assembly at damage sites that is required for the recruitment of endogenous ATR. Suppressed ATR recruitment/activation is confirmed with Latrunculin A and
wortmannin treatment as well as IPMK or SF1 depletion. Other DNA repair pathways involving ATM and DNA-PKcs are unaffected by PPI sequestration. Together, these findings revealed that nuclear PPI metabolism mediates an early DNA damage response through the IPMK-dependent pathway to specifically recruit ATR/ATRIP complex for Chk1 activation.

Direct visualization and quantitative classification of interphase hetero- and euchromatin using two-color, 3D super-resolution microscopy.
J.J. Otterstrom¹, A. Castells Garcia², J. Borbely¹³, M. Ricci¹², M. Cosma², M. Lakadamyali¹⁴; ¹AFIB, The Institute of Photonic Sciences (ICFO), Castelldefels (Barcelona), Spain, ²Reprogramming and Regeneration, Center for Genomic Regulation (CRG), Barcelona, Spain, ³Measurement and Standards Laboratory of New Zealand, Lower Hutt, New Zealand, ⁴Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Limitations impeding the direct visualization of both histones and DNA of interphase chromatin is a substantial barrier to understanding the dynamic organization of the genome within the eukaryotic nucleus. The building block of chromatin is the nucleosome, which is ~11nm in diameter and comprised of DNA wrapped around a cylindrical octamer of the core histone proteins. Higher levels of chromatin organization are broadly categorized into either transcriptionally active euchromatin or repressed heterochromatin. Though these two general organizations can be visualized via conventional light or electron microscopy, the nucleosome organization that underlie them have not been resolved due to a lack of either spatial resolution or molecular specificity, respectively. Single-Molecule Localization Microscopy methods, such as STORM and PAINT, overcome these shortcomings and have spatial resolutions approaching the length scales necessary for determining nucleosome organization (20nm laterally, 50nm axially). Previous studies have utilized STORM to visualize interphase DNA structure [Zessin 2012] and histone H2B structure [Ricci 2015], but no super-resolved overlay of the two structures exists due to the difficulty in capturing both structures in the same nuclear plane at the nanoscale level. Indeed, we have found that many STORM-compatible dyes failed to reconstruct nucleosome organization at high density. Here, we combine STORM with DNA-PAINT [Jungmann 2014] to resolve this deficiency and simultaneously visualize DNA and histone H2B in 3D. Our approach enables the first direct visualization of both DNA and histones of interphase chromatin in intact nuclei. By chemically inducing the euchromatin conformation via hyperacetylation, we demonstrate the capacity to quantify chromatin compaction between hetero- and euchromatin, and correlate it with nucleosome organization.

Canonical, Alternative and Multistranded DNA, and Cell Death.
C.E. Gagna¹²³, W. Lambert²³, P. Lambert¹, M. Rabbani¹, A. Pillay¹, U. Mughal¹; ¹Life Sciences, New York Institute of Technology, Old Westbury, NY, ²Medicine (Dermatology), Rutgers - New Jersey Medical School, Newark, NJ, ³Pathology Laboratory Medicine, Rutgers - New Jersey Medical School, Newark, NJ

Cell death [e.g., apoptosis, necrosis and terminal differentiation (i.e., denucleation)] plays an important role in normal and pathological conditions. Nucleic acids have many different structures that regulate gene expression in normal and diseased tissues. Our goal was to see the effect of two different types of
cell death on nucleic acid structure and function. Therefore, we immunohistochemically [i.e., on frozen and fresh tissue samples (FFPE)] examined the effect of cell death on the integrity of canonical [e.g., right-handed double-stranded (ds) B-DNA], alternative (e.g., left-handed ds-Z-DNA), and multistranded (e.g., quadruplex DNA) nucleic acids, using a variety of different normal and diseased adult and embryological tissues (e.g., adult epidermis, adult crystalline lens and embryologically developing crystalline lenses). Different fixatives (e.g., formalin and non-formalin-based fixatives) were used in order to obtain information on how different nucleic acid structures are affected by diverse types of cell death; apoptosis versus terminal differentiation (i.e., denucleation). Some of the fixatives used were: 10% NBF, Formalin-Alcohol-Acetic Acid, Clarke’s, Carnoy’s, Methacarn, HOPE, Bouin’s, Zenker’s and acetone-methylbenzoate-xylene. Both fluorescent and colorimetric techniques were employed with positive and negative controls, along with Hematoxylin & Eosin staining and the Feulgen Reaction (i.e., DNA content). We used anti-B-DNA, anti-Z-DNA, anti-single-stranded DNA, and G4 anti-quadruplex DNA monoclonal and polyclonal antibodies to investigate the effects of different types of cell death on the presence and amounts of canonical, alternative and multistranded nucleic acids. Data was quantified using a computerized image analysis system, i.e., mean optical density (MOD) units. Our data reveals that each type of nucleic acid structure manifests a different pattern of destruction during cell death, and that apoptosis and terminal differentiation (i.e., denucleation) have certain factors in common, and many differences. Understanding the relationship between cell death and the degradation of nucleic acids will shed light on the pathways that can be targeted by nucleic acid therapeutics. The goal of this project is to provide new knowledge on the processes of cell death including morphology, cell biology, biochemistry and molecular biology. This research is supported by a NYIT-ISRC grant and a TriBeta Biological Honor Society Research Foundation Grant.

Dengue virus NS5 protein targets PML nuclear bodies involved in intrinsic immunity.
F. Giovannnoni¹, P. Hemmerich², C.C. Garcia¹;
¹Biochemistry, School of Sciences, University of Buenos Aires, Buenos Aires, Argentina, ²Leibniz Institute for Age Research, Fritz Lipmann Institute, Jena, Germany

Promyelocytic leukemia (PML) protein is the key organizer of sub nuclear structures called nuclear bodies (PML-NBs). PML-NBs are known to be involved in many basic cellular processes including apoptosis, proliferation, DNA repair and antiviral response. Accumulating reports have revealed that PML-NBs can restrict the replication of many DNA viruses (that must replicate in the nucleus), but also RNA viruses (that replicate in the cytoplasm), such as dengue virus (DENV). A total of 390 million DENV infections occur each year around the world, turning DENV into a major public health problem. DENV can cause dengue fever, which is often a self-limited febrile illness. However, more severe forms of the disease lead to 500,000 hospitalizations and 25,000 deaths worldwide annually. Here, we shed light on the antiviral role of PML in the in-vitro replication of DENV as well as the mechanism underlying this effect.

In order to determine if PML has an inhibitory effect on DENV replication, the expression of PML in A549 cells was silenced by using siRNAs. Then, cells were infected with four DENV serotypes (DENV 1-4) and the amount of virus particles produced was quantified. A549 cells silenced for PML produced 3-4 times more DENV particles than control cells. Next, to determine if DENV infection has an impact on PML-NBs distribution, confocal microscopy of DENV-infected cells was performed. Image analysis revealed that the number of PML-NBs was significantly lower in infected cells.

Even though flaviviruses, such as DENV, replicate in the cytoplasm of infected cells, DENV proteins C, NS3 and NS5 can localize to the nucleus. This nuclear localization is still considered enigmatic in DENV
biology. To determine if the disruption of PML-NBs could be a consequence of the interaction between PML and viral proteins, cells were transfected with vectors encoding for C or NS5. Confocal images showed that quantitative expression of NS5, but not C, was sufficient to reduce the number of PML-NBs. Furthermore, immunoprecipitation studies confirmed the interaction between NS5 and PML. Finally, we observed that overexpression of PML isoforms III and IV, but not the other nuclear PML isoforms induced an accumulation of NS5 at PML-NBs. Overall, we show for the first time a phenotypic as well as functional interplay between PML and DENV. DENV-2 NS5 is found in a complex with PML and its expression alone is sufficient to disrupt PML-NBs. We conclude that NS5 nuclear localization may be important for inhibiting PML-mediated antiviral response.

Optogenetic control of nuclear body assembly.
H. Zhang1, C. Aonbangkhen2, M. Liu1, R. Dilley3, R.A. Greenberg3, D.M. Chenoweth2, M.A. Lampson1;
1Biology, University of Pennsylvania, Philadelphia, PA, 2Chemistry, University of Pennsylvania, Philadelphia, PA, 3Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

Nuclear bodies are membrane-free sub-organelles found in the nucleus of mammalian cells. Recent studies show that nuclear bodies such as nucleoli assemble by phase transition through liquid-liquid demixing, based on evidence from in vitro reconstitution and in vivo observation. However, our understanding of this process in vivo and its functional consequences is limited due to the lack of tools to experimentally manipulate phase transition in live cells. We developed an optogenetic approach to induce phase transition in live cells by controlling protein-protein interactions using photocaged chemical inducers of protein dimerization. We applied these tools to probe nuclear body assembly and its biological functions in vivo, focusing on a subset of promyelocytic leukemia (PML) nuclear bodies that associates with telomeres in telomerase-negative cancer cells. Those cells employ an alternative lengthening of telomere (ALT) pathway using homologous recombination to maintain telomere length. ALT-associated PML nuclear bodies (APBs) are a hallmark of ALT cancers and are used for diagnosis, but the assembly mechanism and functional role of APBs are not clear. We induced de novo APB assembly with light and provide evidence that APBs assemble by liquid-liquid demixing, which promotes telomere clustering in ALT cells. Our results demonstrate the use of our optogenetic tools for manipulating phase transition to probe biological function in vivo.

RICC-seq: Variable chromatin structure revealed by in situ spatially correlated DNA cleavage mapping.
V.I. Risca1, S.K. Denny2, A.F. Straight3,4, W.J. Greenleaf1;
1Genetics, Stanford University School of Medicine, Stanford, CA, 2Biophysics, Stanford University, Stanford, CA, 3Biochemistry, Stanford University School of Medicine, Stanford, CA, 4Chemical and Systems Biology, Stanford University School of Medicine, Stanford, CA

Chromatin structure at the length scale encompassing local nucleosome–nucleosome interactions is thought to play a crucial role in regulating transcription and access to DNA. However, the local three-dimensional structure of chromatin remains poorly understood compared with the structure of single nucleosomes or long-range looping interactions. We report a genome-wide map of chromatin conformation in human cells at the 1–3 nucleosome (50–500 bp) scale, obtained using ionizing
radiation-induced spatially correlated cleavage of DNA with sequencing (RICC-seq). RICC-seq can serve as a nuclease-independent orthogonal method for mapping nucleosome positions, complementing methods that sometimes yield contradictory results about nuclease-labile fragile nucleosomes. Importantly, RICC-seq data from low radiation doses that cause sparse DNA damage also reveal DNA–DNA contacts that are spatially proximal via spatially correlated DNA strand breaks. Analysis of RICC-seq signal spanning tri-nucleosome units reveals regional enrichment of DNA fragments characteristic of DNA-DNA contacts between alternating nucleosomes. These contacts are particularly enriched in H3K9me3-marked heterochromatin and depleted in open or transcriptionally active chromatin. Our data support a model of chromatin architecture consisting of fibers with local zig-zag order and variable longitudinal compaction that correlates with changes in histone modifications.

Phase transitions in the nucleolus: modulating material properties and protein dynamics using optogenetics.
L. Zhu1, T. Richardson2, C.P. Brangwynne1;
1Chemical and Biological Engineering, Princeton University, Princeton, NJ, 2Molecular Biology, Princeton University, Princeton, NJ

The nucleolus is a liquid-like membrane-less nuclear body which plays an important role in cell growth and size control. By modulating nucleolar component concentration through RNAi conditions that change C. elegans cell size, it was previously found that nucleoli only assemble above a threshold concentration; moreover, the ripening dynamics of nucleated droplets are consistent with the hypothesis that the assembly of the nucleolus represents an intracellular liquid-liquid phase transition. A key question following this work is how the material properties of the nucleolus are tuned and linked to the primary function of the nucleolus, in transcribing and processing ribosomal RNA. To address this, we perturb protein-protein interactions in the nucleolus using CRY2olig, an optogenetic clustering protein. Our results suggest that using 488nm light, we can tune the concentration and mobility of nucleolar proteins as well as nucleate and recruit nucleolar proteins from the nucleoplasm. Finally, we present results showing changes in timescale of nucleolar fusion in the X. laevis nucleus. These results lay the foundation for a quantitative understanding of the regulation of nucleolar material properties and their effect on biomedically-critical RNA-processing steps.

Nuclear speckle biology as revealed by HIV-1 infection.
H. Yu1, K. Lee1, X. Wu2, S.H. Hughes3, V.N. KewalRamani1;
1Basic Research Laboratory, National Cancer Institute, Frederick, MD, 2Laboratory of Molecular Technology, Leidos Biomedical Research Inc., Frederick, MD, 3HIV Dynamics and Replication Program, National Cancer Institute, Frederick, MD

HIV-1 integration into the host cell chromatin is an essential part of virus replication. HIV-1 selectively integrates into gene dense regions of chromosomes as a result of CPSF6 interaction with capsid (CA). CPSF6 is present broadly in the nucleoplasm of cells, but accumulates in nuclear speckles soon after HIV-1 infection. CPSF6 enrichment in speckles depends on interaction with CA and occurs within hours of infection. Speckles are nuclear bodies present at 15-30 copies per cell that are enriched in transcription and splicing factors. We considered the possibility that HIV-1 trafficked to speckles to facilitate
integration in gene dense regions of chromatin. We obtained fluorescent in situ hybridization (FISH) probes to known hotspots for CPSF6-dependent HIV-1 integration and FISH probes to CPSF6-independent HIV-1 integration hotspots. Indeed, genetic hotspots for HIV-1 integration on 8 different chromosomes co-localized with nuclear speckles, whereas hotspots for HIV-1 integration in the absence of CPSF6-interaction were rarely associated with nuclear speckles. FISH probes were also designed to detect HIV-1 DNA. In the absence of CPSF6 interaction, HIV-1 failed to access speckles and integrated outside of gene-rich regions. Finally, we examined the physical location of speckle-associated regions of chromatin. Speckle-associated regions were in fixed, regular proximity to the nuclear membrane in comparison to other regions that were otherwise accessible to HIV-1 integration. Collectively, our data indicate that the speckles serve as functional organizing centers for HIV-1 after nuclear entry, providing a critical waypoint that HIV-1 uses to access factors that shuttle to gene-rich regions of chromatin. We hypothesize that speckles are anchored to the nuclear lamin in mitotic cells and may hold decondensed, gene-rich regions of chromatin in a fixed position in proximity to the nuclear membrane.

Loss of capsid protein at the nuclear membrane is a pre-requisite for translocation of HIV-1 pre-integration complexes into the nucleus.
G.B. Melikian1,2, A.C. Francis1;
1Pediatrics, Emory University, Atlanta, GA, 2Children’s Healthcare of Atlanta, Atlanta, GA

HIV-1 cores released into the cytoplasm as a result of virus-cell fusion undergo reverse transcription and shed a major portion of the capsid protein (CA) as they traffic to the nucleus. The extent, the sites and the dynamics of CA loss (referred to as uncoating) are poorly understood. We visualized single HIV-1 uncoating in living cells, using a novel fluorescent CA marker, cyclophilin-A DsRed (CypA-DsRed), which binds tightly to the viral core without considerably affecting infectivity. Imaging single cores co-labeled with integrase-GFP (IN-GFP) and CypA-DsRed revealed distinct uncoating phenotypes in the cytoplasm: an abrupt loss of CypA-DsRed from cores at early times post-infection vs. gradual release of this marker over several hours. To assess the relevance of these uncoating phenotypes to productive infection, we tracked single IN-GFP labeled complexes that entered the nucleus and thus had reasonable probability of integrating in the host genome. We examined temporal and spatial characteristics of CA release from IN-GFP complexes entering the nucleus by 3-color live cell imaging of HeLa-derived cells expressing a nuclear membrane marker, EBFP2-lamin. Nearly all IN-GFP complexes entering the nucleus (n=105) contained detectable amounts of CypA-DsRed upon arrival at the nuclear envelope (NE). On average, these complexes docked at the NE for 36 min prior to nuclear import. Importantly, all docked HIV-1 cores lost CypA-DsRed before entering the nucleus. By contrast, double-labeled docked particles that did not lose a major portion of the CypA-DsRed at the NE never entered the nucleus, suggesting that loss of CA at the nuclear pore is a necessary step for nuclear import. Of note, a fraction of nuclear complexes contained small amounts of CypA-DsRed and stained for p24/CA, indicating that CA shedding at the nuclear pore does not always reach completion. The requirement for uncoating at the NE is further supported by the lack of nuclear entry of the hyper-stable E45A CA mutant that retains CypA-DsRed and accumulates in the perinuclear area. We also found evidence that uncoating in the cytoplasm destabilized IN complexes, as evidenced by the loss of the IN-GFP signal. Collectively, our results suggest that loosing CA in the cytoplasm disfavors the nuclear entry of IN complexes, whereas partial or full loss of CA at the NE is a prerequisite for productive infection. This work was supported by the NIH R01 GM054787 and AI129862 grants to GBM.

Defining the Genetic Context of the D. Melanogaster Histone Locus Body.
J.L. Gross¹, L.E. Rieder¹, E.N. Larschan²;
¹Molecular and Cell Biology and Biochemistry (MCB), Brown University, Providence, RI

Many proteins bind locations all over the genome, yet promote different functions at different loci. One example is the Chromatin Linked Adaptor for MSL Proteins (CLAMP), a D. melanogaster transcription factor that recognizes GA-repeats throughout the genome. CLAMP binding to GA-repeats on the male X-chromosome recruits Male Specific Lethal (MSL) complex, which increases transcription of male X-linked genes during dosage compensation. However, CLAMP also binds at the locus of the arrayed, repetitive histone genes, where GA-repeats are contained within the histone3/histone4 promoter (H3-H4p). In contrast to the male X-chromosome, at the histone locus CLAMP recruits Histone Locus Body (HLB) factors that promote histone biosynthesis. It is not understood why CLAMP does not recruit HLB factors to the male X-chromosome or MSL complex to the histone locus. Interestingly, another GA-repeat binding factor, GAGA-Factor (GAF) is specifically excluded from both the male X-chromosome and the HLB, suggesting that one function of CLAMP at both loci is to exclude GAF. However, GAF recruits to the HLB when CLAMP is depleted, suggesting it may partially compensate for CLAMP function.

Our experiments aim to systematically separate the effects of CLAMP binding to specific sequences from the genomic context in which they reside. To do this we created a series of transgenes that introduce non-endogenous DNA sequences into the H3-H4p region of a single copy of the histone gene array. A transgene containing a single copy of the intact array attracts HLB factors when inserted ectopically into the genome. We engineered transgenes in which the GA-repeats in the H3-H4p are replaced with X-chromosome CLAMP binding sites (which normally attract MSL complex), GA-rich GAF binding sites (which do not normally attract CLAMP, MSL complex, or HLB factors), and the H3-H4p region of the Drosophila virilis histone gene array (which contains shortened GA-repeats but still attracts CLAMP and HLB factors). We created stable, homozygous transgenic lines carrying each transgene and immunostained third instar larval salivary gland polytene chromosomes to determine which proteins (CLAMP, MSL complex members, HLB factors, GAF) are recruited to each transgene. CLAMP and HLB factors are not recruited to the transgene if the GA-repeats are deleted from the H3-H4p region. By determining which factors bind to each modified transgenic array, we will learn about how CLAMP promotes distinct functions in different genomic locations and thus better understand how one protein can have multiple context-specific functions.

Molecular Dissection of Zc3h8 Localization to Nuclear Bodies.
J.A. Schmidt¹, T. Doan¹, E. Harris¹, E.R. Duffner¹, K.G. Danielson¹, J.E. Knepper¹;
¹Biology, Villanova University, Villanova, PA

We have identified the zinc-finger protein Zc3h8 as a promoter of cancer and aggressive cellular phenotypes including cell proliferation, migration, invasion, and 3D growth. Overexpression of Zc3h8 also promotes tumor growth in mice while knockdown of Zc3h8 reduces tumor incidence and growth. Very little is known about Zc3h8, but sequence analysis indicates a putative casein kinase 2 (CK2) phosphorylation site at the n-terminus and three C3H zinc fingers at the c-terminus that are suspected to bind RNA. Furthermore, we have localized Zc3h8 to nuclear bodies that contain PML (promyelocytic...
leukemia protein). This localization can be disrupted and changed by altering the CK2 phosphorylation site on Zc3h8 (T32), or the use of specific kinase inhibitors that block CK2 activity. A Zc3h8 T32A mutation results in larger nuclear bodies, while a T32E mutation results in a large increase in the number of, but a decrease in the size of, nuclear bodies. Similarly, the CK2 inhibitor TBB causes nuclear bodies to become larger and fewer in number. Disruption of Zc3h8 also seems to affect correct localization of other nuclear body proteins including PML. At these nuclear bodies, Zc3h8 may interact with nascent RNA (or DNA) and have a critical role in the modification of RNA including alternative poly-adenylation. The zinc finger motifs are important for nucleic acid binding and, therefore, Zc3h8’s function in cells. We have generated stable cell lines expressing Zc3h8 with mutations in one or more zinc finger and have found some domains are more important for generating aggressive cellular characteristics. Here we present a molecular dissection of Zc3h8 to describe amino acid motifs that are important for localization to nuclear bodies, maintenance of nuclear bodies, and function. Ascertaining the implications of the amino acid motifs of Zc3h8 is critical for understanding the molecular mechanisms that result in altered cellular behavior and oncogenic phenotypes.

Nuclei spin prior to mitosis in epithelial tissues.
M.J. Siedlik¹, M. Pang¹, C.M. Nelson¹²;
¹Chemical and Biological Engineering, Princeton University, Princeton, NJ, ²Molecular Biology, Princeton University, Princeton, NJ

The force-generating machinery within cells is critical for sculpting tissue, powering cellular locomotion, and maintaining a properly functioning organism. On a smaller length scale, cells also generate forces to move organelles, change their shape, and partition cellular material during cell division. Here, we found that nuclei in mammary epithelial cells often spin during the time immediately preceding cell division. We combined live-cell imaging and quantitative image analysis to provide insight into the biophysics underlying nuclear spin. In particular, we developed and implemented a four-dimensional (4D) imaging strategy to quantify nuclear rotation from nucleolar movements. Using this strategy, we found that nuclear spin requires a dynamic microtubule cytoskeleton and myosin-mediated cytoskeletal contraction. Furthermore, analyzing E-cadherin-knockout cells and isolated epithelial cells revealed a non-intuitive instructional role for the local microenvironment. Taken together, our results characterize a hitherto unexplored epithelial cell behavior and highlight how dynamic subcellular motion arises within a multicellular cohort.

Genetically Encoded Multimeric nanoparticles (GEMs) to visualize the biophysical properties of the nucleus.
S. Pinlay¹, G. Brittingham¹, M. Delarue¹, K.J. Kennedy², G. Poterewicz¹, L.J. Holt¹;
¹Institute for Systems Genetics, NYU School of Medicine, New York City, NY, ²Plant and Microbial Biology , University of California, Berkeley , Berkeley, CA

The mechanisms that determine the physical properties of the nucleus remain largely unknown. We recently developed Genetically Encoded Multimeric (GEM) nanoparticles to study the physical properties of the cell. GEMs are homomultimeric proteins that self-assemble into bright, stable fluorescent particles of defined size and shape. By adding a nuclear localization signal (NLS), we were
able to direct GEMs to assemble within the nucleus. Once assembled, the NLS was buried within the interior of the icosahedral GEM compartment, thus the NLS did not cause significant interactions with the nuclear transport machinery. Tracking the diffusion of nuclear GEMs allowed us to infer the biophysical nature of the nucleoplasm. Using this approach we discovered that mTORC1 inhibition doubles the effective diffusion coefficient of 40 nm particles in the nucleus. This effect on nuclear rheology is similar to the effect of mTORC1 on cytoplasmic crowding through ribosome biogenesis. rRNA can account for 80% of nucleic acid in the nucleus, therefore we hypothesise that ribosomal assembly intermediates have a significant impact on the physical properties of the nucleus. We will now screen mutants to identify the dominant mechanisms that set the rheology of the nucleoplasm.

Nuclear envelope rupture under confinement triggers TREX1-dependent DNA damage and cell senescence.
G. Nader, M. Gentili, M. Maurin, Y. Liu, O. Shi, N. Manel, M. Piel;
1Subcellular Structures and Cellular Dynamics, Institut Curie, Paris, France, 2Immunity and Cancer, Institut Curie, Paris, France

During in vivo invasion, intracellular forces are transmitted across the cytoskeleton to the nucleus. Nuclear deformability limits the cell ability to pass through tight spaces. It was recently shown that cells migrating in confined spaces display nuclear envelope (NE) rupture events (assessed by a cytosolic DNA sensor) and DNA damage. Of note, only cells displaying entry of the DNA sensor into the nucleus showed an increase in DNA damage (assessed by 53BP1 foci). This finding suggested that 1) DNA damage associated to confinement might stem from NE rupture, 2) that diffusing cytoplasmic molecules/organelles are entering the nucleus after NE rupture and attacking the DNA. In this study, we used confining slides containing a layer of micro-pillars of different heights to apply a controlled deformation to cells and their nuclei. In order to test if DNA damage is associated to NE rupture, we first determined the confinement heights that induce either NE deformation without NE rupture or NE deformation with NE rupture. We found that at 2μm confinement, 70% of the cells displayed NE rupture as opposed to only 25% and 10% of the cells, at 3 and 4μm respectively. Moreover, cells confined at 2μm displayed higher number of 53BP1 foci compared to cells confined at 3 and 4μm. Careful analysis showed that DNA damage was pronounced only in cells displaying NE rupture, thus demonstrating that DNA damage is linked to NE rupture. Critically, compromised DNA integrity may trigger non-lethal changes, such as premature aging. Therefore we explored whether DNA damage associated to NE rupture caused cell senescence. Cells confined at 2 but not 4μm displayed senescence phenotypes such as increased percentage of β-Gal positive cells and number of HP1y heterochromatin foci. Next, we aimed at identifying the factor responsible for DNA damage following NE rupture. TREX1 is the most abundant cytosolic exonuclease and it was shown to attack chromatin bridges that persisted in cytokinesis, following rupture of the NE that reformed around them. Strikingly, DNA damage was greatly reduced in TREX1-depleted cells (rescued to the same levels of cells not displaying NE rupture). Importantly, TREX1 knockdown rescued cell senescence in cells confined at 2μm, suggesting that TREX1-associated DNA damage following NE rupture is promoting cell senescence. Here we described for the first time a causal relationship between NE rupture, DNA damage and cell senescence in cells under confinement and identified TREX1 as a key player in this pathway. Importantly, cancer cells often migrate through narrow environments and if cell senescence is not activated upon DNA damage they might survive confined migration to colonize distant tissues with an increased genomic instability.

A potential link between DNA damage-induced nuclear actin filaments and the cell cycle.
T. Lee1, J. Salat1, R.D. Mullins1;
1Biochemistry, UC San Francisco, San Francisco, CA

Nuclear actin filaments form upon DNA double strand breaks, which are in the most detrimental class of DNA damage. Previous work from the lab has shown an increase in 53BP1 foci, a canonical DNA damage marker, when the cell’s ability to form nuclear actin filaments is inhibited. This result indicates that nuclear actin filaments play a role in the repair process, and that DNA damage persists in the absence of nuclear actin filaments. The role of nuclear actin filaments in DNA repair has been the subject of ongoing work in the lab, and in this ongoing study, we seek to determine which DNA repair pathway(s) are affected by the loss of nuclear actin filaments and whether the presence of nuclear actin filaments during DNA repair corresponds to certain phases of the cell cycle. In this study, cells have been depleted of nuclear actin filaments by knock down of either the nuclear actin importer, Importin9, or an actin nucleator, Formin2, that we previously found to be required for DNA damage-induced nuclear actin filament formation. In these knock-down cells, DNA damage was induced and the extent of the damage was quantified by Comet Assay after one hour and then 24hr later in recovery. Cells unable to make nuclear actin filaments were found to exhibit significantly more DNA damage 24hr later than WT cells. An additional observation showed that nuclear actin filaments formed in ~20% of cells after DNA damage, which hints at a dependency on the cell cycle. We have imaged cell cycle synchronized cells in the presence and absence of nuclear actin filaments, due to the two major pathways of DNA repair being cell cycle dependent. DNA damage-induced nuclear actin filaments likely correspond to certain phases of the cell cycle, which appears to affect the DNA repair pathway that they are involved in.

Golgi Fragmentation in Alzheimer's Disease.
M.E. Bekier1, X. Wang1, D. Rector1, J. Yang3, Y. Wang1;
1MCDB, University of Michigan, Ann ARbor, MI

Amyloid beta (Aβ) peptide accumulation and amyloid formation are central events that mediate neurodegeneration in Alzheimer’s disease (AD). Aβ is produced by proteolysis of the amyloid precursor protein (APP). Trafficking and maturation of APP and its processing enzymes requires proper functioning of the Golgi apparatus, which depends on the highly ordered stacked structure. The Golgi apparatus is fragmented in the neurons of AD patient’s brain; however, the relationship between Golgi fragmentation and neurodegeneration in AD is largely unknown. Previous studies in AD transgenic mouse and tissue culture models suggests that Aβ accumulation induces Golgi fragmentation by activating cdk5, which phosphorylates the Golgi stacking factor GRASP65. Inhibiting cdk5 or expression of non-phosphorylatable mutants of GRASP65 restores Golgi morphology and reduces amyloidogenic trafficking and processing of APP in cell culture models of AD. These results suggest that Golgi fragmentation is an important mechanism through which Aβ may exert its toxic effects. A potential unrecognized source of Aβ toxicity may be that it compromises Golgi integrity and perturbs trafficking and processing of cell-surface proteins that are essential for neuronal function and viability. Therefore,
we hypothesize that Aβ-induced Golgi fragmentation disrupts trafficking and processing of APP and essential cell-surface proteins, which increases Aβ production and compromises the function and viability of neurons in AD. Preliminary analysis of AD transgenic mice of 1, 3, 6, 9, and 12 months indicates that Golgi defects are present as early as 3 months compared to age-matched controls. Interestingly, Golgi fragmentation does not correlate with proximity to plaques in AD mice with significant plaque deposition and oligomeric preparations of Aβ induces a more severe Golgi fragmentation phenotype compared to fibrilar preparations. Importantly, knockdown of Golgi structural proteins GRASP55 and GRASP65 increases Aβ secretion and impacts APP-CTF stability. Finally, proteomic analysis of cell-surface protein expression in response to Aβ-mediated Golgi defects indicates that Golgi structural abnormalities impacts the expression of numerous cell-surface proteins that are relevant to AD. Future studies will be aimed determining the mechanism of increased Aβ secretion in response to Golgi defects and exploring how Golgi defects influence cell-surface expression of AD-related proteins that were identified in our proteomic studies.

Sonic Hedgehog (Shh) is a secreted hydrophobic morphogen with essential roles in tissue patterning and differentiation during vertebrate development. To date, the molecular machinery and underlying mechanisms regulating Shh release in the extracellular environment remain poorly characterized. Here, we provide in vivo and in vitro evidence for a critical role of the ESCRT-III family member Chmp1a in Shh secretion on small extracellular vesicles (sEVs) during brain development. Chmp1a loss-of-function mutations cause microcephaly in newborn patients. To better characterize the role of Chmp1a in vivo, we generated Chmp1a null mice that recapitulate the phenotype observed in patients, i.e. microcephaly and severe cerebellar hypoplasia. These features correlate with reduced levels of secreted Shh in the cerebrospinal fluid. We further show that Chmp1a depletion affects the release of Shh-loaded sEVs in cell culture supernatant, and that Shh co-purifies with the exosome fraction, together with CD63, CD81, CD9, TSG101 and Syntenin, but not actin nor GP96. Accordingly, transmission electron microscopy analyses in Chmp1a null embryos revealed that multivesicular bodies (MVBs) contain a reduced number of intraluminal vesicles compared to control littermates. However, immunoisolation of exosomes co-purified residual amounts of Shh. Mass-spectrometry analysis and immunoblotting of Shh-positive sEVs
identified specific protein markers, enriched in Shh-positive vesicles but absent in CD63-positive exosomes. Our data highlight a critical function of Chmp1a in brain development by mediating the secretion of Shh on a novel type of sEVs with a unique protein signature.

Signaling by the T cell receptor (TCR) is key in establishing an adaptive immune response. It takes place in a specific zone of the contact between T lymphocyte and antigen presenting cell: the immune synapse. We have previously shown that TCR signaling is regulated by the polarized transport of vesicles containing the adaptor molecule LAT1. Moreover, we and others have also shown that intraflagellar protein 20 (IFT20 a protein controlling cillum formation) and the SNARE VAMP7 protein regulate T-cell activation and LAT transport to the immune synapse\(^1,2,3\). Since that the golgin protein GMAP-210 anchors IFT20 to the golgi\(^4\), we are now investigating the role of the GMAP-210 in T cell activation. We found that the golgin protein GMAP-210 was present in LAT containing vesicles and that silencing of GMAP-210 inhibited the polarized delivery of LAT at the immune synapse. Moreover, silencing of GMAP-210 impairs the localization of VAMP7 and IFT20 in the golgi apparatus. The impaired recruitment of LAT and the lack-off in the localization of IFT-20 and VAMP7 in the golgi resulted in impaired TCR-induced signaling and T cell activation. To our knowledge this study shows for the first time the role of the GMAP-210 golgin in T lymphocyte activation and reinforces previous studies pointing to the similarities between the primary cilium and the immune synapse.

**The Arl3 and Arl1 GTPases cooperate with Cog8 to regulate selective autophagy via Atg9 trafficking.**
F.S. Lee\(^4\), I. Wang\(^1\), J. Hsu\(^1\), Y. Chen\(^1\);
\(^1\)Molecular Medicine, National Taiwan University, Taipei, Taiwan

The Arl3-Arl1 GTPase cascade plays important roles in vesicle trafficking at the late Golgi and endosomes. Subunits of the conserved oligomeric Golgi (COG) complex, a tethering factor, are important for endosome-to-Golgi transport and contribute to the efficient functioning of the cytoplasm-to-vacuole (Cvt) pathway, a well-known selective autophagy pathway. According to our findings, the Arl3-Arl1 GTPase cascade cooperates with Cog8 to regulate the Cvt pathway via Atg9 trafficking.
arl3cog8Δ and arl1cog8Δ exhibit profound defects in aminopeptidase I maturation in rich medium. Additionally, the Arl3-Arl1 cascade acts on the Cvt pathway via dynamic nucleotide binding. Furthermore, Atg9 accumulates at the late Golgi in arl3cog8Δ and arl1cog8Δ cells under normal growth conditions but not under starvation conditions. Thus, our results offer insight into the requirement for multiple components in the Golgi-endosome system to determine Atg9 trafficking at the Golgi, thereby regulating selective autophagy.

Mechanism of action of GTPase-activating protein Gcs1 in modulating GTP hydrolysis of Arl1. W. Chiu1, J. Hsu1, Z. Chen1, Y. Liu1, F.S. Lee1,2; 1Institute of Molecular Medicine, National Taiwan University, Taipei, Taiwan, 2Department of Medical Research, National Taiwan University Hospital, Taipei, Taiwan

Small GTPase ADP-ribosylation factors (Arf) are key regulators of membrane trafficking and their activities are determined by guanine nucleotide-binding status. Arl1 localizes to the trans-Golgi network (TGN) and participates in multiple membrane trafficking pathways in both mammalian cells and yeast. In yeast, Arl1p is activated by the guanine nucleotide exchange factor (GEF) Syt1 and inactivated by its GTPase activating protein (GAP), Gcs1. Activated Arl1p localizes to the TGN and then recruits the golgin protein Imh1 to the Golgi and activates phosphatidylserine (PS) flippase Drs2, thereby promoting vesicle transport from the Golgi. Previously, we found that Imh1 prolongs Arl1 activity through positive feedback regulation via a steric effect that modifies Gcs1 binding to Arl1. By altering the lipid environment, Drs2 facilitates Gcs1 targeting to the TGN and hence its interaction with Arl1, leading to Arl1 inactivation. These studies showed that Imh1p and Drs2 modulate the activity of Gcs1 by timing its interaction with the Golgi membrane and Arl1, hence providing feedback regulation of Arl1 activity. However, the regulation involved in the timing of Gcs1 to access the Golgi membrane for promoting Arl1 inactivation is unclear. Gcs1 is a highly phosphorylated protein. In addition to the residues identified from the prior large-scale screening, we found several new phosphorylation sites on Gcs1 by mass spectroscopy. Several phosphorylation sites of Gcs1 are highly regulated in response to glucose starvation. Interestingly, three of these phosphorylation sites are located at the lipid packing sensor (+ALPS) motif of Gcs1. We generated phospho-mimetic and phospho-deficient Gcs1 mutants to examine whether Gcs1 phosphorylation may regulate its function. We showed that phosphorylation at ALPS of Gcs1 is involved in Gcs1 function, which may for Gcs1-stimulated inactivation of Arl1. We infer that spatial and temporal regulation of Gcs1p phosphorylation might contribute to the Arl1p inactivation.

AKAP12-mediated PKA phosphorylation of NKD2 S223 facilitated TGF-α cell surface delivery and EGFR transactivation. Z.J. Cao1, B. Singh1, C. Li1, R.J. Coffey1; 1Epithelial Biology Center, Vanderbilt University, Nashville, TN

EGF receptor (EGFR) transactivation induced by GPCR agonists is mediated by metalloprotease-dependent cell surface cleavage of the EGFR ligand TGF-α where upon this soluble ligand binds to and activates the receptor. We previously showed that NKD2 is a short-lived, myristoylated basolateral sorting adaptor for the EGFR ligand TGFα. Herein, we show that this transactivation procedure is likely regulated by NKD2 phosphorylation at S223 through PKA signaling pathway, which is greatly boosted by
forskolin and the GPCR agonist vasoactive intestinal peptide (VIP). The S223 phosphorylation of NKD2 enhances TGFα precursor delivery to the cell surface for its subsequent cleavage by metalloproteases and EGFR activation. PKA-mediated NKD2 phosphorylation is facilitated by the scaffold protein, AKAP12. Mapping of interaction domain was between NKD2 (283-357aa) and AKAP12 (834-947aa). Thus, TGFα delivery regulated by PKA/AKAP12 complex to the cell surface represents a new mechanism of EGFR transactivation that occurs proximal to ligand cleavage by metalloproteases.

Iterative Sorting of Apical and Basolateral Cargo in Mardin-Darby Canine Kidney Cells.
A. Treyer1, M. Pujato2,3, X. Pechuan1, A. Muesch1;
1Developmental and Molecular Biology, Albert Einstein College of Medicine, Bronx, NY, 2Center for Autoimmune Genomics and Etiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, 3Department of Systems and Computational Biology, Albert Einstein College of Medicine, Bronx, NY

Epithelial tissues rely on their cells’ ability to generate and maintain surface polarity for transport and barrier functions. Keeping the cells polarized requires initial segregation of apical and basolateral domains on the cell surface, followed by continuous and regulated secretion of appropriate membrane proteins to the apical and basolateral domains. For several decades, the trans-Golgi network (TGN) was considered the most distal stop and hence – the ultimate protein sorting station for the distinct apical and basolateral transport carriers that reach their respective surface domains via the direct biosynthetic pathway. However, recent reports of apical and basolateral cargoes traversing post-Golgi compartments accessible to endocytic ligands, prior to their arrival at the cell surface, as well as of the post-TGN breakup of large pleomorphic membrane fragments that exit the Golgi region toward the surface, raised the possibility that compartments distal to the TGN either mediate or contribute to biosynthetic sorting. Here, we describe the development of a novel assay that quantitatively distinguishes different cargo pairs according to the degree of their correlation at the TGN and to the evolution of this correlation during their TGN-to-surface transport. Key to the high resolution capacity of our approach are: 1) the conversion of dense perinuclear clustering of organelles in 3D into a two-dimensional sample of spread-out microsomal fluorescence, and 2) the identification of TGN and post-TGN membrane protein cargo without the need for a TGN marker that would universally co-segregate with all types of cargo. Utilizing our assay, we provide the first evidence that in MDCK cells, apical NTRp75 and basolateral VSVG cargo proteins continue to undergo progressive sorting after they exit the TGN toward the cell surface. Our study contributes to the emerging view that intracellular sorting in the biosynthetic pathway is an iterative process rather than a series of crossroad decisions at discrete compartments.

A kinesin-3 motor transports newly synthesized basement membrane proteins specifically to a basal subregion of the lateral plasma membrane in epithelial cells.
A.L. Zajac1, A.J. Isabella1,2, K.E. Sy1, S. Horne-Badovina2;
1Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, 2Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA

Basement membranes (BMs) are sheet-like extracellular matrices (ECMs) that play many important roles in tissue organization. In addition to providing attachment sites to cells, these structures act as a reservoir for growth factors, provide polarity information to cells, and provide instructive cues for tissue
morphogenesis. Polarized secretion of BM proteins ensures that the BM matrix assembles exclusively along the basal surface of epithelial cells. However, BM proteins rely on a poorly understood polarized secretion pathway that is distinct from that used by general basolateral cargo. The follicular epithelium of the Drosophila egg chamber secretes all major BM proteins and assembles a BM along its basal surface on the outside of the tissue. This geometry places the trafficking events involved in BM secretion near the tissue’s exterior and allows high-resolution imaging of the secretion process in a living, intact organ. We previously identified the GTPase Rab10 as a central regulator of BM polarized secretion. Here we show that a surprisingly small region of the basolateral membrane is targeted for BM secretion and that a kinesin-3 family motor is required for transport to this location. To identify the site of BM protein secretion, we blocked the final tethering stage of exocytosis using mutations in the exocyst complex, a known Rab10 interaction partner. In exocyst mutant cells, BM proteins accumulate just inside the basalmost ~0.5 um of the lateral plasma membrane (PM). To understand how this small region is targeted for secretion, we investigated the dynamics of Rab10+ vesicles leaving the Golgi. Rab10+ vesicles move rapidly and processively on microtubules (MTs) and accumulate near the basal-most region of the lateral PM. Since MT plus-ends are enriched basally, we performed an RNAi screen against plus-end-directed kinesin motors and identified the kinesin-3 family member Khc-73 as a novel regulator of BM trafficking. Khc-73 colocalizes with Rab10, and loss of Khc-73 reduces the basal accumulation of Rab10. We therefore propose that Khc-73 transports Rab10+ vesicles from the Golgi to the basalmost region of the lateral PM for secretion. To test the importance of this targeted secretion, we examined the structure of the BM after loss of Khc-73. In this mutant condition, BM proteins accumulate in between cells along the entire lateral domain and form an intercellular network of BM proteins that disrupts tissue organization. Altogether, this work highlights the importance of precisely targeting BM protein secretion, as this precise targeting ensures that the BM is assembled in the correct location to properly organize a developing tissue.

Microtubule-interaction with apical transport vesicles is mediated by the large GTPase Mx1.
K. Ringer¹, J. Riehl¹, M. Müller¹, F. Hoff¹, R. Jacob¹;
¹Cell Biology, Philipps Universität Marburg, Marburg, Germany

In epithelial cells apical proteins are delivered by specific transport carriers to the correct membrane domain. These vesicular carriers are composed of a heterogeneous population of proteins like motor proteins, annexins, lectins, Rab-GTPases and cargo molecules. Recently, association of the dynamin-related polypeptide Mx1 with apical post Golgi vesicles was described. Downregulation of Mx1 using Mx1-specific small interfering RNA significantly decreased the delivery of apical cargo in Madin Darby Canine Kidney (MDCK) cells, suggesting that this large GTPase plays crucial roles in the transport of distinct post-Golgi vesicles to the apical membrane of polarized cells.

We now demonstrate by co-immunoprecipitation that Mx1 associates with the tubulin cytoskeleton and Kif5B, a motor protein of the kinesin-1 family. As assessed by immunofluorescence microscopy, Mx1-positive vesicles are in close proximity to microtubules and co-localize with kinesin motors.

Furthermore, depolymerisation of microtubule in the presence of nocodazole significantly reduces the long distance transport of Mx1-positive vesicles. This supports the idea that Mx1 is involved in directed vesicle-movement along microtubules to the apical membrane.

The biogenesis and structure of a unique class of large pleomorphic transport intermediates arising from the Golgi apparatus is intricately tied to its cisternal architecture.
R. Sengupta1, E.M. Mihelc1, R.J. Kuhn1, J.K. Lanman1;
1Biology, Purdue University, West Lafayette, IN

The components of the secretory pathway in the eukaryotic cell are known to exhibit distinct morphological and biochemical fingerprints. The complex cisternal and tubular morphology of the ER gives way to the unique stacked cisternal morphology of the Golgi apparatus (GA) via the vesiculo-tubular structure of the ERGIC. Operating in-between these organelles and from these organelles to the plasma membrane, are transport intermediates (TI) that are either vesicular (50-100nm in diameter) or large (up to 2 μm) non-vesicular and pleomorphic in nature. While much is known about biogenesis, structure and mode of operation of the former class of TI’s, information on the latter is scarce. Trafficking of large cargoes that neither enter vesicular carriers nor leaves the Golgi cisternae have been shown to take place via these non-vesicular TI’s operating between the GA and plasma membrane. This implicates the conversion of large subdomains of the progenitor organelle into these transport intermediates directly by its cargo. Although, light and traditional electron microscopy has provided us some idea about the pleomorphic nature of these TI’s, their biogenesis, details of their elaborate 3D structure and their physical relationship to their progenitor organelle remains unknown. In this work, we use electron tomography in conjunction with a peroxidase tagging technique to dissect the mechanism of biogenesis, architecture and maturation of a system of unique alphavirus-induced TI’s from the GA that plays a role in alphavirus egress. We show that the biogenesis of the unique structure of these TI’s is tied mechanistically both to the structure of the GA as well and the nature of interaction of the viral proteins with the Golgi membrane. Our statistical analysis exhibits a good correlation between the size of the cargo with the size of the TI’s indicating that the size of the cargo, in this case, determines the size and shape of its carrier. Temporal snapshots from infected cells using peroxidase-tagged sub-compartment markers show that the TI-system exhibits a morphological flux that correlates with the structural and biochemical identity of the subdomain of the GA that it originates from, as the virus gradually transforms the GA into pleomorphic TI clusters. In summary, our work, for the first time, dissects the intricate and elaborate three-dimensional structure of a system of unconventional TI from the GA and pieces together its mechanism of biogenesis, mode of transport and its function. We further show that the morphological variations within this system of TI is intricately tied to the unique architecture of the Golgi apparatus.

Multiple PLA2 Enzymes Contribute to Membrane-Tubule Mediated Export from the TGN.
J. Roscoe1, J.M. Beckinghausen1, W.J. Brown1;
1Molecular Biology and Genetics, Cornell University, Ithaca, NY

Export of cargo from the trans Golgi network (TGN) occurs via the formation of multiple carriers including coated vesicles, non-coated vesicles, and membrane tubules. The molecular mechanisms involved in the formation of membrane tubules remain poorly understood, but may be linked to specific types of cargo molecules. Previous studies have established that membrane tubules emanating from the TGN require the activity of cytoplasmic phospholipase A2 (PLA2) enzymes; however, the specific enzyme(s) have not been identified. Here we report that membrane tubule-mediated export of certain
cargoes from the TGN is facilitated by a specific cytoplasmic PLA₂, platelet activating factor acetylhydrolase lb (PAFAHlb). PAFAHlb consists of a homo- or heterodimer of two catalytic subunits (alpha 1 and alpha 2) together with Lis1, and CRISPR-mediated knockout of alpha 1 and alpha 2 in HeLa cells significantly reduced the formation of TGN membrane tubules that transport newly synthesized gp130, a protein destined for the plasma membrane. Moreover, siRNA-mediated knockdown of another Golgi-associated phospholipase, cPLA₂alpha, further reduced the formation of TGN membrane tubules in PAFAHlb knockout cells. Inhibition of PLA₂-dependent TGN membrane tubules may have downstream effects on other organelles because PAFAHlb knockout cells were found to have enlarged lysosomes that were redistributed to the juxtanuclear region. This redistribution was exacerbated in cells knocked down for cPLA₂alpha. These results show that multiple Golgi-associated PLA₂ enzymes contribute to the formation of TGN membrane tubules, which in turn may contribute to downstream trafficking pathways. This work supported by NIH grant GM101027 to WJB.

Manganese-induced trafficking and turnover of GPP130 is mediated by sortilin.
S. Venkat¹, A.D. Linstedt¹;
¹Biological Sciences, Carnegie Mellon University, Pittsburgh, PA

Elevated, non-toxic doses of manganese (Mn) protect against Shiga toxin-1 induced cell death via down regulation of GPP130, a cycling Golgi membrane protein that serves as an endosome-to-Golgi trafficking receptor for the toxin. Mn binds to GPP130 in the Golgi, causes GPP130 to oligomerize/aggregate and the complexes are diverted to lysosomes. In fact, based on experiments using the self-interacting FM domain, it appears generally true that aggregation of a Golgi protein leads to its lysosomal degradation. How such oligomers are selectively sorted out of the Golgi is unknown. Here we provide evidence that Mn-induced exit of GPP130 from the trans Golgi network (TGN) towards lysosomes is mediated by the sorting receptor sortilin interacting with the lumenal stem domain of GPP130. In contrast, FM-induced lysosomal trafficking of the Golgi protein galactosyltransferase was sortilin independent and occurred even in the absence of its native luminal domain. Thus, sortilin-dependent as well as sortilin-independent sorting mechanisms target aggregated Golgi membrane proteins for lysosomal degradation.

¹Biology, Birmingham-Southern College, Birmingham, AL

Membrane trafficking is critical for transport of lipids and membrane proteins throughout the endomembrane system. In particular, defects in trafficking pathways that transport proteins and lipids to the lysosome have been linked to a number of human diseases, including Hermansky-Pudlak syndrome (HPS), a disease characterized by oculocutaneous albinism and pulmonary fibrosis. In eukaryotic cells, lysosomal trafficking is largely regulated by activation of small GTPases called ADP Ribosylation Factors (Arfs). Arf activation by Guanine Nucleotide Exchange Factors (GEFs) controls the formation of transport vesicles by recruiting specific coat proteins to the membrane. These coat proteins in turn recruit the cargo molecules to be trafficked. In Schizosaccharomyces pombe, membrane

Tuesday-260
trafficking pathways that deliver proteins to the vacuole, the yeast equivalent of the lysosome, are likely regulated by the AP-1 and AP-3 coat protein complexes and the single fission yeast class I/II Arf, Arf1p. However, the GEFs that facilitate recruitment of these complexes and their downstream cargoes have not yet been defined in fission yeast. To begin to define these pathways, we explored the phenotypes of cells lacking the GEFs sec71 or sec72 or the coat protein subunits apl4 (AP-1) or apl6 (AP-3). Analysis of vacuolar morphology and pH, salt sensitivity, FM4-64 uptake, and localization of potential vacuolar cargoes revealed both distinct and overlapping phenotypes for these GEF- and coat-deficient strains. Additionally, we also observed different degrees of impaired septation in GEF- and coat-deficient strains, suggesting that these post-Golgi transport pathways may regulate trafficking of enzymes required for septum degradation. Collectively, our results begin to define the membrane trafficking pathways that mediate vacuolar transport in fission yeast and suggest the presence of both distinct and overlapping functions for sec71p and sec72p.

AP-1 mediated trafficking of the lysosomal vitamin B12 transporter ABCD4.
E. Sauvageau1, A. Castonguay1, S. Lefrancois1,2
1Centre INRS-Institut Armand-Frappier, Laval, QC, 2Department of anatomy and cell biology, McGill University, Montreal, QC

A variety of human diseases are caused by improper protein trafficking within the trans-Golgi network (TGN)-endosome-lysosome system. Several bacterial toxins and viruses also employ this transport system in order to infect cells. Fundamental understanding of the mechanisms regulating this trafficking pathway is therefore essential to the development of novel therapeutic approaches. MEDNIK syndrome, a rare genetic disease characterized by mental retardation, enteropathy, deafness, peripheral neuropathy, ichthyosis and keratodermia, is caused by mutations in the AP1S1 gene encoding for the α1A subunit of the clathrin adaptor complex AP-1. This heterotrimeric clathrin adaptor complex is involved in recruiting cargo proteins and initiating the formation of transport vesicles between the TGN and endosomes-lysosomes. Cytosolic AP-1 is recruited by the small GTPase Arf1 to the membranes of the TGN where it interacts with specific motifs within the cytosolic tail of transmembrane proteins while also recruiting clathrin and inducing the formation of clathrin-coated vesicles (CCVs). Although defective trafficking of the ATP7A copper pump and the copper-dependent enzyme PAM have been shown to contribute to the pathogenic mechanism of MEDNIK syndrome, the severity and complexity of the disease, coupled with the broad function of AP-1, suggest that aberrant transport of other proteins also contribute to the syndrome. Mutations in the lysosomal transmembrane protein ABCD4 block vitamin B12 transport to the cytosol and cause a disease sharing clinical manifestations (neuropathy, hypotonia) with MEDNIK syndrome. Using co-immunoprecipitation and bioluminescence resonance energy transfer (BRET), we found that ABCD4 interacts with AP-1 in living cells. Mutations of the classical tyrosine (YXXØ) or dihydrophobically ([DE][XX][L/I]) based motifs in the c-terminal tail of ABCD4 did not lead to a loss of interaction with AP-1, suggesting a novel mode of binding. BRET experiments in an Arf1-KO CRISPR generated HEK293T cell line display reduced levels of interaction between ABCD4 and the µ1 and β1 subunits of AP-1. Moreover, ABCD4 accumulates in the Golgi apparatus in a γ-KO CRISPR generated cell line as determined by fluorescence microscopy. Finally, fluorescence microscopy experiments using bodipy-conjugated vitamin B12 show lysosomal accumulation of vitamin B12 in fibroblasts isolated from a MEDNIK patient. Together, these results suggest that ABCD4 transport to the lysosomes requires AP-1 and that aberrant vitamin B12 metabolism could contribute to MEDNIK syndrome pathogenicity.

Analysis of Myosin 5A recruitment to endothelial Weibel Palade bodies.

V. Llombart¹, S. Le Trionnaire², N. Hellen³, R. Bierings³, M. Hannah⁴, T. Carter⁵;
¹St George’s University of London, London, United Kingdom, ²Imperial College, London, United Kingdom, ³Sanquin Research, Amsterdam, Netherlands, ⁴Public Health England, London, United Kingdom

Endothelial cells store Von Willebrand-factor (vWF) in secretory granules called Weibel-Palade bodies (WPB). vWF trafficking and secretion depends on the interplay between WPBs and the cell cytoskeleton. Interaction with actin filaments is thought to be mediated through a Rab27A-MyRIP complex involving two elements; a direct MyRIP-actin interaction and an indirect actin interaction mediated through recruitment of Myosin 5A (Myo5A). In other cell types Myo5A can bind Rab3 isoforms, Slp4-a, or other effectors (e.g. rabphilin-3A) to mediate organelle-actin interactions. Because WPBs can also recruit Rab3 isoforms and Slp4-a the possibility exists that multiple mechanisms may operate for Myo5A recruitment to WPBs. In this study we aimed to examine the contribution of Rab27-MyRIP, Rab3 isoforms and Slp4-a to Myo5A recruitment to WPBs.

To investigate the role of secretory Rabs and their effectors in WPB-Myo5A recruitment HUVEC were transfected with specific siRNAs to deplete expression of Rab27A, MyRIP, Rab3B and Slp4-a or treated with the potent RabGGTII inhibitor 3-(3-Pyridyl)-2-hydroxy-2-phosphonopropanoic acid (3-PEHPC) to disrupt Rab-protein membrane localization. Depletion was assessed by quantitative PCR, western blot and immunocytochemistry and the subcellular localisation of Rabs, effectors and Myo5A determined by immunocytochemistry.

Myo5A immuno-localised to WPBs in HUVEC. Pre-absorption of the Myo5A antibody with the peptide antigen against which it was raised abolished WPB-Myo5A immunoreactivity. Analysis of endogenous Rab27A, MyRIP and Myo5A localisation on WPBs revealed 1) that WPBs in some cells showed Myo5A but not Rab27A or MyRIP localisation and 2) Myo5A immunoreactivity was associated with newly formed WPBs at the trans-Golgi network which lack Rab27A, MyRIP or Slp4-a. siRNA depletion of Rab27A removed Rab27A and MyRIP from WPBs but failed to deplete Myo5A immunoreactivity. siRNA depletion of MyRIP also failed to deplete WPB-Myo5A. Dual siRNA mediated depletion of Rab27A and Rab3GEP removed all detectable immunoreactivity to Rab27A, Rab3B or D, but failed to deplete Myo5A from WPBs. siRNA mediated depletion of Slp4-a, or Slp4-a and MyRIP failed to deplete Myo5A from WPBs. Selective inhibition of RabGGTase II to block all Rab prenylation and thereby remove all Rab proteins (confirmed by complete removal of all detectable Rab27A, MyRIP and Rab3 isoforms) from WPBs failed to deplete Myo5A from WPBs. PCR and RNA seq analysis showed that rabphilin-3A, is not expressed in the HUVEC cultures used here.

Our results point toward the existence of a Rab- and rabphilin-3A independent mechanism for Myo5A recruitment to WPBs. Future studies aim to determine what the mechanism might be.

Select alpha-arrestins control surface abundance of the mammalian Kir2.1 potassium channel in a yeast model.
N.A. Hager1, C. Krasowski1, P.G. Needham2, T. Mackie2, D. Bain2, M.P. Bruchez3, C. Szent-Gyorgyi4, A.V. Kwiatkowski5, A.F. O'Donnell1, J.L. Brodsky2;
1Dept. of Biological Sciences, Duquesne University, Pittsburgh, PA, 2Dept. of Biological Sciences, University of Pittsburgh, Pittsburgh, PA, 3Dept. of Geology and Environmental Sciences, University of Pittsburgh, Pittsburgh, PA, 4Molecular Biosensor and Imaging Center, Carnegie Mellon University, Pittsburgh, PA, 5Dept. of Cell Biology, University of Pittsburgh, Pittsburgh, PA

Protein composition at the plasma membrane is tightly regulated, with rapid protein internalization and selective targeting to the cell surface in response to environmental changes. For example, ion channels are dynamically relocalized to or from the plasma membrane in response to physiological changes, allowing organisms to maintain osmotic and salt homeostasis. To identify new factors that regulate the selective trafficking of one ion channel, we used a yeast model for a mammalian potassium channel Kir2.1. Kir2.1 maintains potassium homeostasis in heart muscle cells and defects in Kir2.1 lead to human disease. By examining the ability of Kir2.1 to rescue the growth of yeast lacking endogenous potassium channels, we discovered that specific alpha-arrestins regulate Kir2.1 localization. Specifically, we found that the Ldb19/Art1, Aly1/Art6, and Aly2/Art3 alpha-arrestin adaptor proteins promote Kir2.1 trafficking to the cell surface, increase Kir2.1 activity at the plasma membrane, and raise intracellular potassium levels. To better quantify the intracellular and cell surface populations of Kir2.1, we created fluorescence-activating protein (FAP) fusions and for the first time used this technique to quantify the cell surface residency of a membrane protein in yeast. We also identified two other Kir2.1 regulators, which are known effectors of alpha-arrestins: In particular, both the Rsp5 ubiquitin ligase and that the protein phosphatase calcineurin facilitated the alpha-arrestin-mediated trafficking of Kir2.1. We are currently using our yeast model to further define the regulatory elements needed for alpha-arrestin-mediated trafficking of Kir2.1 to the cell surface. We have deleted fourteen genes needed for various protein trafficking pathways in our Kir2.1 reporter system and are currently assessing the impact of each of these mutations on Kir2.1-mediated growth on low potassium and Kir2.1 localization using our FAP technology. Together, our findings implicate alpha-arrestins in regulating an additional class of plasma membrane resident proteins and describe a new tool to dissect the trafficking itinerary of any membrane protein in yeast.

The Role of PKC-ε in Focal Exocytosis.
A.E. D'Amico5, C.M. Hanes5, C. Wong1, M.R. Lennartz2;
1Regenerative and Cancer Cell Biology, Albany Medical College, Albany, NY

Focal exocytosis, the targeted docking and fusion of intracellular vesicles, delivers vesicle contents to specific sites and expands the membrane for processes such as directed cell migration, cell division, neurosecretion, and, in innate immune cells, phagocytosis. Although the mechanisms underlying focal exocytosis in neural cells have been studied, how it occurs in non-polarized cells is not well understood. FcγR-mediated phagocytosis in macrophages (MØ) is a physiologically relevant model of focal exocytosis in non-polarized cells. During phagocytosis, vesicles fuse into the forming phagosome to provide membrane for pseudopod extension in order for MØs to efficiently internalize bound pathogens. We
established that protein kinase C-epsilon (PKC-ε) mediates the addition of membrane during IgG-mediated phagocytosis. These studies probe the mechanism underlying that finding. During phagocytosis, PKC-ε concentrates at the forming phagosome (phagocytic “cup”). PKC-ε binds PI4P. In resting MØ, ~20% of PKC-ε is concentrated at the Golgi, an organelle rich in PI4P. The PI4P reporter, P4M, colocalizes with PKC-ε at the Golgi; P4M competes with PKC-ε for PI4P binding, reducing PKC-ε levels in P4M expressing MØ. Expression of the Golgi-directed PI4 phosphatase, hSac1-K2A, decreases PKC-ε at the Golgi in resting cells, and PKC-ε concentration at the cup during phagocytosis, suggesting that PKC-ε is being trafficked from the Golgi to the cup. TIRF microscopy of MØ attaching to IgG surfaces revealed PKC-ε puncta fusing into the plasma membrane; fusion was confirmed by whole cell patch clamping. PKC-ε+ vesicles co-localize with VAMP3 and TNF-α, a marker of focal exocytosis during phagocytosis, and a cytokine delivered to the cup, respectively. Notably, neither TNF-α nor VAMP3 are delivered to the membrane in PKC-ε knockout MØs; TNF-α is retained in the Golgi. Confocal imaging with 3D rendering shows PKC-ε puncta aligned along microtubules. Together these data support a model in which Golgi-associated PKC-ε orchestrates the delivery of VAMP3/TNF-α+ vesicles to the phagocytic cup. We are currently developing a technique to follow PKC-ε+ vesicle trafficking from the Golgi to the phagocytic cup in real time.

Identification of a barrier to soluble dendritic secretory cargo in the proximal axon of chemosensory neurons in Caenorhabditis elegans.
L. Klabonski¹, T. Gidalevitz¹;
¹Department of Biology, Drexel University, Philadelphia, PA

Neurons are polarized cells with distinct functional compartments called axons and dendrites. Polarity in neurons arises from localization of specific membrane and cytosolic proteins to the axon or dendrite, respectively. The mechanisms by which membrane proteins achieve and maintain a polarized distribution in neurons are relatively well-understood. How soluble secretory proteins, such as growth factors, are sorted and trafficked into specific neuronal compartments, however, remains an open question. We recently found that the soluble TGF-β protein DAF-7 localizes specifically to and is secreted from the dendrite in a chemosensory neuron in C. elegans while being completely excluded from the axon. Using this model, we find at least some machinery that sorts and traffics dendritic membrane proteins is shared by the soluble secretory cargo. Under these conditions, DAF-7 was mislocalized to and accumulated at a specific, predictable region in the proximal axon. Interestingly, DAF-7 never entered the distal, synaptic portion of the axon. These data indicate the presence of a barrier in the proximal axon that can recognize soluble dendritic cargo and prevent its improper entry into axons in C. elegans, much like the barrier within the axonal initial segment (AIS) in mammalian neurons. We are using this model to identify the mechanisms responsible for sorting soluble dendritic proteins and determine the specificity and composition of this axonal barrier.

Imaging the molecular architecture of the protein network that regulates clathrin-mediated endocytosis.
K.A. Sochacki1, A.M. Dickey1, M. Strub1, J.W. Taraska1;
1National Heart Lung and Blood Institute, National Institutes of Health, Bethesda, MD

Clathrin-mediated endocytosis involves a growing list of over 30 helper proteins. It is critical for membrane homeostasis, receptor regulation, and intercellular communication. Clathrin triskelia have three long arms which bind to the arms of other triskelia to form a honeycomb-shaped lattice on the inner side of the eukaryotic cell plasma membrane. A lattice grows and bends with the membrane to create a small vesicle that is taken up into the cell. The edge of the clathrin lattice has previously been studied mostly during vesicle scission, when dynamin is known to cut the neck of membrane to release a vesicle. But in earlier stages of clathrin pit maturation, the edge likely plays an important role in capturing receptors and regulating lattice growth and curvature. What proteins are present at the edge of the lattice during these early stages? Here, we use correlative super-resolution localization microscopy and platinum replica electron microscopy to map 19 different endocytic proteins with respect to clathrin lattices. We find that while some proteins are specifically located at the edge of the lattice and others are present throughout the lattice, some proteins previously assumed to be throughout the lattice, like AP-2, have a distinctly higher density at the edge. The relative nanoscale positions of these proteins and the biochemical composition of the lattice edge and center are a starting point in mapping and understanding the architectural network driving the endocytic machinery.

Unique cargo-specific response landscapes underpin the complex and nuanced role of galectin-glycan interactions on clathrin-independent endocytosis of MHCI and CD59.
M.P. Mathew1, J. Donaldson1;
1Cell Biology and Physiology, National Heart Lung and Blood Institute, Bethesda, MD

Glycosylation of membrane proteins is an often overlooked post-translational modification unique in its complexity and variety. In fact, altered glycosylation is a hallmark of cancer. Although these changes have been viewed as passive by-products of cancer metabolism (often used as biomarkers for detection), more recent studies have shown that these glycans can serve important functional roles. The role that glycan interactions can play in clathrin-independent endocytosis (CIE) is an area of increasing interest especially because CIE is a form of endocytosis which, unlike clathrin mediated endocytosis (CME), does not have well defined cytoplasmic machinery. Therefore, studying the role of glycans working from the outside could help elucidate some of the regulatory mechanisms that govern these trafficking pathways. In this study we show that the perturbation of global cellular glycosylation patterns by metabolic flux modulation affects CIE. Interestingly, these changes in glycosylation have cargo-specific effects. For example, treatment of cells with N-Acetyl Glucosamine (that corresponds to an increase in production of branched glycans) leads to an increase in major histocompatibility complex Class I (MHCI) internalization while at the same time mediating a decrease in endocytosis of CD59, a GPI-anchored protein. In order to better understand the mechanism behind these glycan-mediated effects we focused on the role of Galectin 3. Galectin3 is a secreted galactose binding pentameric lectin that is
essential in forming the galectin lattice which can be a major determinant of membrane characteristics. We found that knocking-down the expression of Galectin 3 led to a small decrease in MHCI uptake and an increase in CD59 uptake. Whereas, the inhibition of all glycan-galectin interactions by lactose treatment inhibits the uptake of both CIE cargo. Our results suggest that glycans play an important role in CIE that is quite nuanced, with each cargo affected in a specific manner and with galectin-driven effects existing on a continuum from stimulatory to inhibitory depending on the extent of galectin-glycan interactions. These treatments did not affect the uptake of transferrin, a CME cargo protein, further implying a CIE-specific role for glycosylation. The galectin lattice was also found to tailor membrane fluidity and cell spreading with disruption leading to more rapid protein diffusion and impaired spreading. The elucidation of the role glycans play in CIE could lead to a better understanding of how these still mysterious pathways are regulated and could offer insight into how altered glycosylation can alter the progress of cancer via the CIE pathway.

Assessing the function of adaptor-clathrin and adaptor-cargo interaction in endocytic progression.
S.M. Di Pietro¹, T.O. Tolsma¹, L.M. Cuevas¹;
¹Biochemistry and Molecular Biology, Colorado State University, Fort Collins, CO

Clathrin mediated endocytosis (CME) is crucial to eukaryote cell biology. CME is initiated by the recruitment of clathrin, specialized adaptors and early endocytic factors to the plasma membrane. Importantly, clathrin is incapable of binding lipids or integral membrane proteins, and its recruitment requires interactions with endocytic adaptor proteins. Following site formation, the plasma membrane invaginates and a coat of endocytic proteins and clathrin forms around the lipid surface until the vesicle is released into the cytoplasm. While basic aspects of this process have been well documented, the regulatory mechanisms that control coat formation, and the role integral membrane protein cargo plays in adaptor recruitment and endocytic progression are incompletely understood. This work focuses on determining a role for the interaction between the adaptor Sla1 and clathrin in endocytosis and the role Sla1-cargo binding plays in adaptor recruitment. By using fluorescent microscopy, electron microscopy, biochemical approaches, and yeast as a model system, we show interaction with Sla1 is necessary for proper clathrin recruitment. We also show Sla1-clathrin binding plays a role in maintaining normal protein dynamics and progression of late stage mechanisms in endocytosis, specially the initiation of actin polymerization. Our results also suggest a role for clathrin in the regulation of the endocytic invagination shape. Interestingly, diminished clathrin recruitment at CME sites due to impaired interaction with Sla1 results in additional actin polymerization perhaps as a compensatory effect. Furthermore, we show endocytic protein cargo plays an active role in Sla1 adaptor recruitment to the plasma membrane via interactions between the Sla1 SHD1 and SH3-3 domains and cargo containing the NPFxD and ubiquitin sorting signal, respectively. Intriguingly, interaction with endocytic cargo regulates Sla1 nuclear localization, a less well-understood localization/function observed for Sla1 and several trafficking and cytoskeletal proteins.

A membrane trafficking screen to identify Clathrin-independent endocytosis machinery: A role for ROCK2 and Cofilin in CIE.
J.L. Wayt1, D. Dutta1, J. Donaldson2;
1NHLBI, National Institutes of Health, Bethesda, MD

Endocytosis is an important event that cells utilize to internalize cell surface proteins and fluid into the cell. There are two main forms of endocytosis: clathrin-mediated endocytosis (CME) and clathrin-independent endocytosis (CIE), amongst which CME is the most studied. While CME is important for the internalization of specific surface proteins, bulk trafficking of fluid and membrane occurs primarily in a clathrin-independent manner. While we have established the trafficking itinerary of many classical CIE cargo proteins, such as CD59 and Major Histocompatibility Complex Class I (MHCI), little is known about the cellular machinery involved in CIE. To identify proteins essential for the internalization of the GPI-anchor protein CD59 and the cell surface protein MHCI in Hela cells, we designed an siRNA screen utilizing the DhharmaconTM Membrane Trafficking library, which contains siRNA targeting 140 established membrane trafficking genes. Expression of target genes were individually knocked down and cells were allowed to internalize primary antibodies against the CIE cargo proteins of interest. Following internalization, the antibody bound proteins were visualized by immunofluorescence, the amount of internalized protein was determined and positive and negative hits were scored. Interestingly, there was little overlap among the list of proteins identified as important for internalization of these two cargo proteins, which suggests that CD59 and MHCI internalization has distinct requirements. Among these candidates was the kinase ROCK2, which upon depletion preferentially inhibited CD59 internalization, a result which was further confirmed using small molecule inhibitors of ROCK2. This phenotype was specific to ROCK2, as knockdown of the homologous protein ROCK1 had no effect on the internalization of either cargo. ROCK2, through the phosphorylation and activation of the LIMK kinase family, regulates the phosphorylation and subsequent deactivation of the actin severing protein Cofilin and thus ROCK2 can be viewed as a negative regulator of Cofilin. Interestingly, knockdown of Cofilin stimulated the internalization of both MHCI and CD59 and resulted in the accumulation of cargo in enlarged vesicles located in a dense actin network at the cell periphery. This phenotype was abolished in ROCK2/Cofilin double knockdown cells, which might suggest a requirement for ROCK2 mediated regulation of Cofilin in CIE. Further elucidating the interplay between ROCK2 and Cofilin and their role in CIE will be the focus of future studies.

Membrane tension regulates the recruitment of membrane bending protein epsin in clathrin-mediated endocytosis.
J.G. Joseph1, A.P. Liu1;
1Mechanical Engineering, University of Michigan, Ann Arbor, MI

The ability for plasma membrane to deform and bend is necessary for the establishment of cellular architecture and mediation of molecular transport across the bilayer. Membrane bending is integral during clathrin-mediated endocytosis (CME) where clathrin-coated pits (CCPs) invaginate. Membrane tension has been shown to have regulatory effect on CME. However, which endocytic component is involved and how it might be differentially regulating CCP dynamics under different tension environments are unknown. We hypothesize that membrane tension has a regulatory effect on

Tuesday-267
recruitment of membrane bending protein epsin. In order to test this, we generated cells stably expressing EGFP-epsin and mCherry-clathrin light chain a (CLCa) and performed live cell imaging by total internal reflection fluorescence microscopy. Under hypo-osmotic shock, which elevate membrane tension, we found an increase in recruitment of epsin into the CCPs. We reason that recruitment of epsin reduces the energy threshold to bend membranes. Initiation density was higher for CCPs with epsin recruitment compared to the ones without epsin recruitment. Irrespective of membrane tension conditions, CCPs containing epsin showed a smaller proportion of short-lived CCPs, which are considered abortive, compared to CCPs that did not contain epsin. However, the decreased proportion of short-lived CCPs is even greater in cells under high tension, which have recruited more epsin. This may allude to the additional stabilization effect of epsin that present more clathrin binding domains which enable the continued formation of mature CCPs. Together, our results highlight a novel mechanosensitive role for epsin that facilitate CCP formation under different tension environments.

The role of membrane curvature in topography-induced cellular signaling.
B. Cui1, W. Zhao1, H. Lou1, F. Santoro1;
1Department of Chemistry, Stanford University, Stanford, CA

Many biomedical applications require direct contact between the cells and non-biological materials. For example, medical implants inserted into the patient’s body have intimate contact with adjacent cells and tissues. Synthetic materials are recognized by cells through their chemical compositions as well as their physical properties. The importance of physical properties in modulating cellular behavior, such as surface topography and material rigidity are increasingly recognized. In particular, studies show that surface topography in the scale of tens of nanometers to a few micrometers significantly affect cell adhesion and tissue integration. As topographic features are stable over long-term and easier to control, they offer unique advantages for modulating cell responses for tissue engineering. Despite a large body of observations, little is known about the origin or underlying mechanisms of the effect of topographical cues on cellular behavior. We explore the underlying mechanisms by employing advanced nanotechnology that generates precisely controlled nanotopography. Our results show that local membrane curvature induced by nanoscale topographical features significantly affect the distribution of curvature-sensitive proteins and stimulate several cellular processes in live cells including clathrin-mediated endocytosis and actin dynamics. We propose that local membrane curvature is the critical player in topography-induced intracellular signaling. Furthermore, our studies show a strong interplay between biological cells and nano-featured surfaces, which is an essential consideration for future development of interfacing devices.

Tuesday-268
Cells regulate their membrane area and tension by finely tuned mechanisms. However, the cellular processes and molecular mechanisms behind this regulation are poorly understood. Exo-endocytic processes undoubtedly play a major role in controlling these vital physical properties of the membrane. Here we have explored the role of multiple endocytic pathways in the maintenance of membrane homeostasis and its mechanism. We have used multiple ways to modulate membrane tension, including a PDMS based cell stretching device, osmotic shocks or deadhering of substrate attached cells, followed by and optical or magnetic tweezers to measure membrane tension.

We find that a specific endocytic pathway, the dynamin-independent CLIC/GEEC (CG) endocytic pathway is transiently up regulated during change of membrane tension by stretch-induced relaxation or by multiple other means. By contrast caveolar or clathrin-mediated endocytic pathways are not modified. The CG pathway is a high capacity pathway with properties giving it the potential to be a core regulator of membrane dynamics that can rapidly respond to changes in membrane tension. Modulating the CG pathway via perturbation of key regulatory genes correspondingly modifies the resting membrane tension and the rate of membrane retrieval after strain-induced relaxation. Further, we find a mechanotransduction machinery regulates GBF1 activity at cell surface thus modulating CG pathway in response to changes in tension. These features suggest that the CG pathway could be a vital component of the cellular machinery that sets resting membrane tension and maintains area homeostasis.

CD13 is a critical regulator of beta1 Integrin recycling, cell migration and focal adhesion turnover.
M. Ghosh¹, C. Devarakonda¹, S. Thangada¹, R. Lo¹, L.H. Shapiro¹;
¹Center for Vascular Biology, UCONN Health Center, Farmington, CT

CD13 is a multifunctional cell-surface adhesion molecule that is constitutively expressed on a variety of cells. Our recent studies demonstrated that CD13 regulates dynamin-mediated internalization of receptors of disparate classes to control downstream signal transduction pathways, implicating a fundamental role for CD13 in cellular endocytic processes. In the present study, we investigated mechanisms of CD13-mediated endocytic regulation in the context of the well-characterized program of integrin trafficking. Integrins are trans-membrane receptors mediating interactions between the extracellular matrix (ECM) and the actin cytoskeleton via focal adhesions (FAs), which are dynamic structures that form and dissolve in tightly regulated steps to enable cell migration. In Murine Embryonic Fibroblasts (MEFs), CD13 localizes with β1-integrin at FAs and at cell-cell junctions in epithelial cancer cells, prompting our exploration of potential contributions of CD13 in integrin function. Phenotypically, FAs in CD13KO fibroblasts are elongated and irregular with displaced FA accessory proteins, markedly reduced actin stress fibers and fewer microtubule extensions, indicating that FA formation and cytoskeletal organization is defective in the absence of CD13. This disrupted cytoskeletal organization in CD13KO cells was accompanied by reduced FA kinase phosphorylation, consistent with a link between CD13 and the control of FA dynamics. Importantly, in WT MEFs, CD13 and β1-integrin co-internalize, traffic to EEA1+ and Rab5+ early endosomes and recycle to the plasma membrane together.
via Rab11a+ recycling endosomes. Conversely in CD13KO MEFs, internalized β1-integrin is again found in early endosomes but rather than recycling, integrin aberrantly traffics to Rab7+ late endosomes/lysosomes. Pulse-chase assays confirmed that CD13 is necessary for β1-integrin recycling to the cell surface. Functionally, lack of CD13 led to reduced cell spreading and cell-ECM migration in a wound-healing assay. While CD13 accumulated at the cell leading edge of migrating cells and co-localized with scaffolding protein IQGAP1, deficiency of CD13 led to reduced accumulation of these proteins at the migrating front, suggesting that CD13 is necessary for guiding IQGAP1 localization to regulate directional migration. Mechanistically, CD13 is in a complex with the IQGAP recycling regulator ARF6 GTPase and this interaction is necessary for proper integrin trafficking. This study defines a critical role for CD13 in controlling β1 integrin focal adhesion dynamics and actin cytoskeletal organization in association with ARF6 and its regulator IQGAP1, thereby directing the fundamental cellular processes of FA turnover, receptor trafficking and cell migration.

Clathrin-independent endocytosis coordinated with filopodial formation in the growth cone, revealed by superresolution microscopy.
M. Igarashi1, M. Nozumi1;
1Dept Neurochem Mol Cell Biol, Niigata Univ Grad Sch Med Dent Sci, Niigata, 951-8510, Japan

The growth cone is a highly motile structure at the growing axonal tip at the time of the neuronal development/regeneration. The continuous reorganization of actin cytoskeletons and membrane trafficking should be performed in its leading edge. These two events are essential to the precise navigation of an axon, however, the relationship between them is not clearly understood. To observe their coordinating movements, we analyzed the dynamics of clathrin, a BAR domain protein, endophilin A3 (Endo3), and F-actin in the growth cone of NG108-15 cells using a superresolution microscopy 3D-SIM, and TIRFM (ref. 1). Whereas clathrin mainly accumulated in the basal membrane in the central domain, Endo3 emerged in the dorsal surface at its leading edge. Accumulation of Endo3 coincided with the F-actin bundling. When actin polymerization was inhibited by cytochalasin B or CK-666, intensity of Endo3 reduced markedly. Knockdown of fascin, a protein F-actin cross-linker, also reduced the numbers of Endo3 at the leading edge. Synaptophysin (Syp), like Endo3, arose near the filopodial bases, and most of them were retrogradely moving along the actin bundles. The retrogradely moving Syp puncta were colocalized with Endo3 and dynamin 1 (Dnm1), at the leading edge, but not with clathrin. Endo3 knockdown reduced Syp puncta from the leading edge whereas a clathrin inhibitor, Pitstop2, did not affected the Syp distribution. Interestingly, in the mouse cortical neurons, Endo3-RNAi showed the inhibited axonal growth, the reduced growth cone size, and the diminished intensity of its F-actin. We also showed the lipid raft domains, in which signaling proteins are enriched with cholesterol and sphingolipids, were endocytosed with Syp, and Gpm6a, a lipid raft protein involved in neuronal polarity determination (ref. 2), were specifically detected on the apical surface from epifluorescence images acquired using TIRFM. These results suggest that the Syp(+)-vesicles by Endo3-, Dnm1-dependent and clathrin-independent endocytosis, occurring at the apical membrane of the leading edge, coincides with filopodial formation. Actin control of endosomal sorting in neurons: impact on Alzheimer's disease.
C. Guimas Almeida¹, L. Salavessa³, L. Oliveira¹;
¹CEDOC - Chronic Diseases Research Center, NOVA Medical School, Lisboa, Portugal

Endosomal sorting has been implicated in Alzheimer’s disease (AD). β-amyloid (Aβ) is generated in endosomes depending on the endocytic trafficking of the β-amyloid precursor protein (APP) and of APP cleaving enzymes, mainly of BACE1. We previously established that Aβ causes dysfunction of endosomal sorting for degradation (Almeida et. al, J Neurosci 2006). Moreover, we and others found that genetic risk of AD is associated with deregulation of endosomal sorting potentiating Aβ generation. One of these genes, CD2AP, is an actin-capping protein. Actin dynamics controls intracellular trafficking mainly by shaping cellular membranes. Actin helps to drive membrane invagination for endocytosis and shape membrane tubules for secretory trafficking (eg. Almeida et al, NCB 2011). However, a role for actin dynamics in endosomal sorting is not well established. We are investigating endosomal actin function in neurons, its (de)regulation by an Alzheimer’s risk factor, and its role in endosomal Aβ generation. We recently established that CD2AP is polarized to neuronal dendrites, where it controls the translocation of APP away from the endosomal limiting membrane during early endosome maturation into multivesicular endosomes (Ubelmann et. al, EMBO Reports 2017). Now we have found by dSTORM that perinuclear actin foci are more associated with early than late endosomes in neuronal cells. CD2AP localizes to endosomes independent of endosomal F-actin. Loss of function of CD2AP leads to a decrease in actin-positive endosomes and to the disruption of endosomal actin dynamics in neurons. Interference with a specific subunit of the F-actin polymerizing Arp2/3 complex depletes endosomal actin and increases Aβ. These results indicate that endosomal actin regulation by CD2AP is implicated in endosomal sorting. Dysfunction of endosomal CD2AP and actin potentiates amyloidogenesis and potentially contributes to Alzheimer’s disease development.

Synaptojanin 1 (SJ1) is a major presynaptic phosphatase that couples synaptic vesicle endocytosis to the dephosphorylation of PI(4,5)P2, a reaction needed for the shedding of endocytic factors from their membranes. While the role of SJ1’s 5-phosphatase module in this process is well established, the contribution of its Sac phosphatase domain, whose preferred substrate is PI4P, remains unclear. Recently a homozygous mutation in its Sac domain was identified in early-onset Parkinsonism patients. We show that mice carrying this mutation developed neurological manifestations similar to those of human patients. Synapses of these mice displayed endocytic defects and a striking accumulation of

Tuesday-271
clathrin coated intermediates strongly implicating Sac domain's activity in endocytic protein dynamics. Mutant brains had elevated auxilin (PARK19) and parkin (PARK2) levels. Moreover, dystrophic axonal terminal changes were selectively observed in dopaminergic axons in the dorsal striatum. These results strengthen evidence for a link between synaptic endocytic dysfunction and Parkinson's disease.

Cell repulsion driven by EphB2 is regulated by Eps15R-mediated endocytosis.
E. Evergren¹,², H.T. McMahon³;
¹Centre for Cancer Research and Cell Biology, Queen's University Belfast, Belfast, United Kingdom,
²Neurobiology Division, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

EphB receptors and their ligands are important for formation of tissue boundaries during development and in adult tissue, and are also involved in cancer cell invasion. This form of contact-mediated cell-cell repulsion is dependent on removal of EphB receptors from the cell surface. The molecular mechanism for trans-endocytosis of EphB/ephrinB is largely uncharacterised and we therefore set out to identify novel components of this mechanism. First we investigated the role of clathrin-mediated endocytosis in EphB2-mediated cell repulsion using overexpression of dominant negative constructs of AP180 and dynamin-1. To assess EphB2-mediated cell repulsion we quantified the patterning of EphB2- and ephrinB1-expressing cells in a co-culture assay. Both expression of AP180 C terminus and dynamin1-T65A significantly inhibited EphB2-mediated patterning. Secondly, we identified Eps15R and Eps15 as binding partners of Numb, a known adaptor protein for EphB2. In the co-culture assay knockdown of Eps15R, but not Eps15, resulted in an inhibition of EphB2-mediated patterning. To investigate the function of Eps15R further, the lifetime of AP2sigma2-EGFP was assessed using live cell imaging in BSC1 cells. The mean lifetime was 47s in the Eps15R knockdown cells compared to 26s in the control, suggesting a significant slowing of clathrin-coated pit maturation. Morphological analysis of clathrin-coated pits using electron microscopy showed that Eps15R knockdown cells had fewer but larger pits. In particular the neck diameter of the pits was significantly increased compared to control. This led us to investigate whether Eps15R associates directly with clathrin using biochemical techniques. Immunoprecipitation and pull-down assays showed that the motif domain of Eps15R bound clathrin heavy chain terminal domain directly. The binding motif was mapped using alanine scanning mutagenesis and pull-downs and found to be, DPFxLDPF. An additional LDPF motif in the motif domain contributed further to clathrin binding. Finally, we used the EphB/ephrinB co-culture assay as a functional assessment of the Eps15R-clathrin interaction. Knockdown of Eps15R resulted in a reduced EphB2-patterning. This was rescued by expression of wild type Eps15R, but not by the clathrin-binding mutant, thus demonstrating the significance of the Eps15R-clathrin interaction for EphB trans-endocytosis. As a control wild type Eps15 was expressed, which does not contain a clathrin-binding motif. Eps15 could not rescue the loss of Eps15R in the EphB/ephrinB co-culture assay. These results provide the first evidence that Eps15R together with clathrin control EphB/ephrinB trans-endocytosis and thereby cell repulsion.

Tetraspanins TSP-12 and TSP-14 function redundantly to regulate the trafficking of the type II BMP receptor in Caenorhabditis elegans.
Z. Liu1, H. Shi2, J. Liu1;
1Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY

Tetraspanins are a unique family of four-pass transmembrane proteins that play important roles in a variety of cell biological processes. One of their roles is to regulate the trafficking of their associated proteins. We have previously shown that two paralogous tetraspanins in C. elegans, TSP-12 and TSP-14, function redundantly to promote bone morphogenetic protein (BMP) signaling [1]. To dissect the functions of TSP-12 and TSP-14 in BMP signaling, we used the CRISPR/Cas9 system to tag the endogenous TSP-12 and TSP-14 proteins with different colored fluorescent proteins. These analyses showed that TSP-12 and TSP-14 share overlapping expression and localization patterns in multiple tissues, including the hypodermis, where the BMP receptors function to regulate one of the phenotypic outputs of the BMP pathway, worm body size. TSP-12 and TSP-14 are both localized to the cell surface and intracellular vesicles. We found that inside the cell, TSP-12 and TSP-14 are partially co-localized and that TSP-14 primarily localizes to the early endosomes, with some TSP-14 proteins also present in the late endosomes. We further showed that TSP-12 and TSP-14 are required for the intracellular recycling of the type II BMP receptor DAF-4, but not the type I receptor SMA-6. Together with previous findings by Gleason et al. showing that the type I receptor SMA-6 is recycled via the retromer complex [2], our work demonstrates the involvement of distinct recycling pathways for the type I and type II BMP receptors, and highlights the importance of intracellular trafficking in the regulation of BMP signaling in vivo.

The expression and function of transforming growth factor-beta superfamily receptors are regulated by multiple molecular mechanisms. The type II BMP receptor, BMPRII, is expressed as two alternatively spliced forms, the long and short forms (BMPRII-LF and -SF), which differ by a ~500 amino acid C-terminal extension, unique among receptors from the TGF-beta superfamily. Whereas this extension was proposed to modulate BMPRII signaling output, its contribution to the regulation of receptor expression was not addressed. To map regulatory determinants of BMPRII expression we compared the synthesis, degradation, distribution and endocytic trafficking of BMPRII isoforms and mutants. Our findings identify translational regulation of BMPRII expression and the contribution of a 3' terminal
coding sequence to this process. BMPRII-LF and -SF differed also in their steady state levels, kinetics of degradation, intracellular distribution and internalization rates. A single di-leucine signal in the C-terminal extension of BMPRII-LF accounted for its faster clathrin-mediated endocytosis relative to BMPRII-SF, accompanied by mildly faster degradation. Higher expression of BMPRII-SF at the plasma membrane resulted in enhanced activation of Smad signaling, stressing the potential importance of the multi-layered regulation of BMPRII expression at the plasma membrane.

Mutations of the N-terminal TIR domain tyrosine result in loss of TLR9 function by directing autophagic elimination of the mutant protein.
C. Biswas1, S. Rao1, D. Dersh1, P.W. Zoltick1, Y. Argon1, M.S. Marks1, E.M. Behrens1; 1Pediatrics/Rheumatology, Children's Hospital of Philadelphia, Philadelphia, PA

Nucleic acid sensing Toll-like receptors (TLRs) are important for host defense against pathogens but are also potent immunomodulators, thus help shape innate and adaptive immune responses. The cytosolic TIR domain of the TLRs acts as the platform for assembling the signalosome that translates ligand binding by pathogen motifs to intracellular transcriptional events. In the case of TLR9, the ligand is hypomethylated double-stranded DNA from pathogens, and results in the production of inflammatory cytokines such as TNFα and IL-6. Prior studies in TLR4 suggested that the ligand-mediated phosphorylation of the N-terminal tyrosine of the TIR domain was critical mediating downstream TLR signals. In this study, we examined the role of the N-terminal TIR domain tyrosine in TLR9 function, which unlike TLR4 requires an additional step of cleavage from a 160 kDa proprotein to an 80 kDa active form in the endosome prior to signaling. We substituted the N-terminal TIR domain Y870 of TLR9 with phenylalanine (Y870F) or with alanine (Y870A), and expressing them retro-virally in the TLR9 knockout bone marrow derived dendritic cells (BMDCs), and measured cleavage of the TLR9 pro-protein into active form, intracellular localization of TLR9, and ligand induced TLR9 cytokine production. Y870F, which still possessed the aromatic ring of tyrosine but lacks the phosphorylation site, had diminished TNFα and IL-6 production upon ligand binding, while Y870A had complete loss of cytokine production. These results correlated with a partial loss of the active 80 kDa in Y870F such that the diminution of cytokine production could be completely accounted for by the amount of 80kDa protein made suggesting the phosphorylation at this residue is not needed for signaling. Accordingly, there was a total loss of 80kDa protein in the Y870A mutant. Y870A TLR9 was able to bind to its normal chaperoning proteins GRP94 and Unc93b1. It was also capable of forming dimers with itself and wild type TLR9 as normally expected. However, while, wild type TLR9 was found within Lamp1+ endosomes within 4 hours of expression, Y870A TLR9 instead localized with LC3BII positive structures consistent with autophagic vesicles that become Lamp1+ after 24 hours, suggesting evolution into an autolysosome to presumably degrade and dispose of the mutant protein. These results suggest that the N-terminal TIR domain tyrosine is not important for phosphorylation as previously reported, but rather for proper targeting of the蛋白 to its correct subcellular location. Furthermore, binding to the normal ER chaperones, GRP94 and Unc3b1, is insufficient to target TLR9 to the endosome in the presence of such a mutation. Mutations of the N-terminal TIR domain tyrosine rather appear to result in targeting of mutant

How membrane trafficking and cellular signaling are interconnected is a fundamental question in cell biology. We recently discovered a clear example of such reciprocal control between signaling and endocytosis through the study of β-arrestin, a critical player in the signaling and trafficking of G protein-coupled receptors (GPCRs), the largest signaling receptor family. All of the many known functions of β-arrestin were previously thought to require β-arrestin to be scaffolded with its activating GPCR and remain in a stable physical complex. Using live-cell quantitative fluorescence imaging, we recently found that β-arrestin, previously thought to exclusively function in an obligate physical complex with its activating GPCR, can also function as an independent downstream transducer molecule by trafficking to clathrin-coated structures (CCSs) after dissociating from its upstream activating GPCR (Nature Cell Biology, March 2016). This requires an alternate cycle of β-arrestin activation in which the GPCR acts as a catalyst rather than co-scaffold, but how this is possible remains unknown. We now show that catalytic activation of β-arrestin is widespread, occurs for both β-arrestin isoforms and is triggered by a variety of GPCRs. Formation of the catalytic GPCR / β-arrestin complex does not require the GPCR cytoplasmic tail nor tail phosphorylation, distinguishing it from classical complex formation that requires both. Catalysis instead uses the GPCR core structure and involves destabilization of a salt bridge between the base of the β-arrestin finger loop and C-lobe that acts as an ‘ionic lock’ stabilizing the inactive state. Once dissociated from the catalytic complex, β-arrestin can operate apart from receptor by binding to plasma membrane phosphoinositides and to the CCS lattice. We propose a β-arrestin activation cycle catalyzed by transient interaction with the GPCR core and energetically driven through a network of non-receptor allosteric interactions. These results define a new framework for understanding cellular β-arrestin function and the signaling consequences of clathrin-mediated endocytosis.

Eukaryotic cells are organized into spatially and functionally distinct membrane-bound organelles, whose functions are defined by their lipid and protein composition. Accurate and robust sorting of membrane components between these compartments is necessary for the maintenance of organelle identity. For most membrane proteins, the determinants of their steady-state subcellular localization remain unknown. Lateral membrane domains known as lipid rafts provide an ideal platform for membrane sorting processes, and have been widely implicated in post-Golgi sorting and endocytosis/recycling. However, the structural determinants of protein association with such domains are almost entirely unknown. We have developed and characterized a robust experimental system for
direct, quantitative measurements of raft affinity in intact plasma membranes and used it to explore the determinants of transmembrane protein recruitment into raft domains and the consequences of this recruitment on subcellular traffic. We identified several structural features associated with raft affinity, and established a quantitative and functional relationship between raft association and subcellular protein localization. Specifically, we observed that raft association is fully sufficient for PM recycling of certain proteins, and that abrogation of raft partitioning for these proteins led to their degradation in the lysosomes. These findings identify structural determinants of raft affinity for transmembrane proteins and support the conclusion that ordered membrane domains mediate recycling of specific membrane components from the endosomal compartments to the PM. We have proceeded to define the molecular machinery that mediates raft lipid and protein sorting and recycling to the PM. Using a set of orthogonal transmembrane proteins as probes of raft and non-raft domains, we developed a high throughput siRNA screen to dissect the molecular machinery and dynamics for raft-mediated sorting. We identified a number of validated hits including known players of the early endocytic traffic (Rab5 and EEA1), but also novel players that appear to define a distinct class of trafficking mediators specific for raft-associated proteins. This pathway is not dependent on the classical recycling pathways defined by Rab4 and Rab11, rather defining a novel route for PM recycling of raft-prefering cargo.

Endocytosed PAM, MPR and EGF traverse a dynamic multivesicular body network together.

N. . Back1, K. Kanerva1, K. Vishwanatha2, A. Yanik2, E. Ikonen1, R.E. Mains2, B.A. Eipper2;

1Department of Anatomy, University of Helsinki, Helsinki, Finland, 2Department of Neuroscience, University of Connecticut Health Center, Farmington, CT

In the endocytic pathway the epidermal growth factor (EGF)/EGF receptor complex is conveyed to lysosomes for degradation while the secretory granule membrane protein peptidylglycine α-amidating monoxygenase (PAM) and the lysosomal enzyme transporter cation independent mannose-6-phosphate receptor (MPR) are recycled to the trans-Golgi network and evade degradation. We studied the conserved mechanisms for endocytic trafficking of PAM by overexpressing PAM in HEK293 cells and comparing the endocytic trafficking of PAM, MPR and EGF. As expected, all three cargoes accumulated on intralumenal vesicles in multivesicular bodies. 10 and 20 min after uptake of labeled PAM and MPR or EGF more than 80% of labeled endosomes contained all three cargoes, at least partially on the same intralumenal vesicles. Live video imaging of the uptake of labeled cargoes demonstrated frequent contacts between endosomes: 20 min after uptake a PAM containing endosome made an average of 5.2+0.4 contacts/min lasting 2.9+0.4 s with other PAM containing endosomes of the same age, thus being connected to another endosome of the same age for approximately 25% of the time. In addition, uptake of Alexa 555 conjugated PAM antibody versus Alexa 488 conjugated PAM antibody introduced 10 min later showed frequent contacts and material exchange between early and late endosomes. Prelabeling of lysosomes with fluorescent dextran revealed contacts between PAM containing endosomes and lysosomes with approximately the same frequency (5.8+0.4 contacts/min of 2.3+0.2 s duration). Similar contacts were not seen by conventional electron microscopy. With the use of high pressure freezing tubular contacts and direct membrane apposition between multivesicular bodies and between multivesicular bodies and lysosomes could be observed. In conclusion, the same population of multivesicular bodies transports PAM, MPR and EGF, at least partially on the same intralumenal vesicles. The endosomal pathway is highly dynamic; a PAM containing endosome is most of the time briefly connected to another endosome or a lysosome. The mechanism of further sorting of cargo from intralumenal vesicles is obscure and probably involves back fusion of intralumenal vesicles with the limiting membrane of the multivesicular body.

Proteomics reveals novel protein associations with early endosomes in an EGF-dependent manner.
J.A. Gosney¹, M.L. Merchant², D.W. Wilkey², B.P. Ceresa¹;
¹Pharmacology Toxicology, University of Louisville, Louisville, KY, ²Medicine, University of Louisville, Louisville, KY

The epidermal growth factor receptor (EGFR) is a receptor tyrosine kinase that is an integral component of proliferative signaling. When activated by a ligand at the plasma membrane, EGFR dimerizes with another ErbB family receptor, leading to kinase domain activation and transphosphorylation of C-terminus tyrosine residues. These phosphotyrosines act as crucial regulators of EGFR signaling as effector proteins dock to the receptor at these sites. The receptor undergoes clathrin-mediated endocytosis into early endosomes, where it can then be trafficked to a lysosome for degradation. However, the kinase domain of EGFR retains its activity during trafficking, suggesting that EGFR can continue to elicit signaling cascades after internalization. Unfortunately, there is no consensus as to how EGFR spatial regulation affects its signaling or interaction with downstream effectors. We hypothesize that EGFR localization in early endosomes permits unique interactions with downstream effectors. In an effort to identify proteins that uniquely associate with the internalized EGFR, we have developed a strategy for isolating early endosomes and analyzed the protein make-up of these compartments. HeLa cells were stimulated with and without EGF (10 ng/ml) for 15 min, and the post-nuclear supernatant (PNS) was loaded onto a 17% Percoll gradient which separates endosomes based on density. The gradient was fractionated, and fractions containing early endosomes were pooled and immunoprecipitated with an EEA1 monoclonal antibody. The morphology of isolated compartments was monitored using transmission electron microscopy, which revealed intact vesicles with an average diameter of 68.63 ±26.74nm. Endosomes were subjected to liquid chromatography/tandem mass spectrometry (LCMS) for proteomic analysis. The purification protocol yields a highly enriched population of early endosomes, as evidenced by immunoblot and LCMS analyses. The isolation method precipitates early endosome marker proteins, but not marker proteins specific to other organelles. Five proteins were detected in endosomes in a ligand-dependent manner: EGFR, RUFY1, STOML2, PTPN23, and CCDC51. We have developed a rapid and high-throughput isolation technique to collect early endosomes from HeLa cells that can be analyzed by LCMS to detect a distinct proteome. These data provide evidence that endocytic trafficking of the activated EGFR changes the protein composition and signaling potential of the early endosome.

A molecular mechanism to recruit galectin-3 into multivesicular bodies for polarized exosomal secretion.
S. Bänfer¹, D. Schneider¹, J. Dewes¹, M.T. Strauss²,³, S.A. Freibert¹, H. Elsässer¹, R. Jungmann²,³, R. Jacob¹;
¹Department of Cell Biology and Cell Pathology, Philipps University Marburg, Marburg, Germany,
²Department of Physics and Center for Nanoscience, Ludwig Maximilian University, Munich, Germany,
³Max Planck Institute of Biochemistry, Martinsried, Germany

Galectin-3 (Gal3) plays a role of fundamental importance in the extracellular space, however the exact secretion pathway remained elusive. Lacking a canonical signal sequence for translocation into the endoplasmic reticulum (ER), Gal3 is exported independently of the secretory pathway by a not yet defined non-classical mechanism.

Here, we found Gal3 in the lumen of exosomes. Super-resolution and electron microscopy studies visualized Gal3 recruitment and sorting into intraluminal vesicles (ILVs). Computer simulations mimicking the experimental conditions depicted identical Gal3 recruitment to multivesicular bodies (MVBs), confirming the ability to discriminate between distinct Gal3 sorting stages into ILVs. Exosomal Gal3 release depends on the ESCRT-1 component Tsg101 and functional Vps4a. Either Tsg101 knockdown or expression of dominant-negative Vps4a¹²28Q causes an intracellular Gal3 accumulation at MVB formation sites. In addition, we identified a highly conserved tetrapeptide P(S/T)AP motif in the amino-terminus of Gal3 that mediates a direct interaction with Tsg101. Mutation of the P(S/T)AP motif results in a loss of interaction and a dramatic decrease in exosomal Gal3 secretion. We also found evidence for a functional role of Gal3 in the sorting process of exosomal proteins and ILV biogenesis. We conclude that Gal3 is the first member of endogenous ESCRT-independent proteins which are P(S/T)AP-tagged for exosomal release. In summary, this study identifies a functionally relevant PSAP-mediated direct Tsg101-interaction with an endogenous cargo molecule and provides a unique model of how proteins destined for exosomal secretion can be recruited and opens new avenues for polarized unconventional secretion of cytoplasmic proteins.

Ist1 regulates ESCRT-III assembly and function during multivesicular endosome biogenesis.
E. Frankel¹, A. Audhya³;
¹Biomolecular Chemistry, University of Wisconsin-Madison, Madison, WI

Degradation of most integral membrane proteins is directed by the endosomal sorting complex required for transport (ESCRT) machinery, which selectively targets ubiquitin-modified cargoes into intraluminal vesicles (ILVs) within multivesicular endosomes (MVEs). To define mechanisms underlying ESCRT-mediated formation of ILVs, we exploited the rapid, de novo biogenesis of MVEs during the oocyte-to-embryo transition in C. elegans. In contrast to previous models suggesting that ILVs form individually, we demonstrate that they remain tethered to one another subsequent to internalization, arguing that they bud continuously from stable subdomains. Additionally, we show that membrane bending and ILV formation are directed specifically by the ESCRT-III complex in vivo in a manner regulated by Ist1, which promotes ESCRT-III assembly and inhibits the incorporation of upstream ESCRT components into ILVs.

Tuesday-278
Our findings underscore essential actions for ESCRT-III in membrane remodeling, cargo selection, and cargo retention, which act repetitively to maximize the rate of ILV formation.

**Renitence vacuoles facilitate protection against phagolysosomal damage in activated macrophages.**

A.O. Wong1,2, M. Marthi3, B. Gregorka3, M.S. Swanson3, J.A. Swanson1,3;

1Immunology Graduate Program, University of Michigan, Ann Arbor, MI, 2Medical Scientist Training Program, University of Michigan, Ann Arbor, MI, 3Department of Microbiology and Immunology, University of Michigan, Ann Arbor, MI

As professional phagocytes, macrophages are susceptible to endolysosomal membrane damage inflicted by the pathogens and noxious particles they ingest. Whether macrophages have mechanisms for limiting such damage is not well understood. Previously we reported a phenomenon, termed “inducible renitence,” in which LPS activation of macrophages protected their endolysosomes against damage initiated by phagocytosis of silica beads. To gain mechanistic insight into the process, we analyzed the kinetics of renitence and morphological features of LPS-activated versus resting macrophages following silica bead-mediated injury. We discovered novel vacuolar structures that form in LPS-activated but not resting macrophages following silica bead phagocytosis. Because of their correlation with renitence and damage-resistant nature, we termed these structures “renitence vacuoles.” Renitence vacuoles formed coincident with silica bead uptake in a process associated with membrane ruffling and macropinoscyosis. However, unlike normal macropinosomes, which shrink within 20 minutes of formation, renitence vacuoles persisted around bead-containing phagosomes. Renitence vacuoles fused with lysosomes, and, after fusion, maintained their acidity. Phagosomes associated with renitence vacuoles, however, did not fuse with lysosomes. As damage-resistant, persistent macropinosomes, renitence vacuoles act as structural barriers to prevent fusion between damaged phagosomes and intact lysosomes and thereby preserve endolysosomal integrity.

Phagocytosis and degradation of microorganisms or debris by macrophages is crucial for pathogen clearance and resolution of inflammation. Alveolar macrophages are central for pulmonary host defense because they are responsible to survey the exposed airways. Alveolar macrophages from COPD (chronic obstructive pulmonary disease) patients demonstrate defective phagocytosis and their inability to clear respiratory pathogens could contribute to disease pathogenesis. However, the molecular drivers of this phagocytic defect are unknown. Human rhinovirus (HRV) and non-typeable Haemophilus influenzae (NTHi) are frequently isolated during COPD exacerbations. We hypothesised that HRV infection(s) of alveolar macrophages are key drivers of phagocytic defect observed in COPD. Alveolar macrophages isolated from bronchoalveolar lavage or monocyte derived macrophages (MDMs) were pre-challenged with HRV16. Following viral challenge, we analysed phagocytosis, phagosome maturation, reactive Tuesday-279
oxygen species generation and cytokine production. Alveolar macrophages or MDMs pre-challenged with HRV16 demonstrated deficient phagocytosis towards a range of targets. In AM derived from COPD patients, HRV16 further impaired phagocytosis. This inhibition was viral mediated and not observed with UV inactivated virus. We also performed RNA sequencing on HRV16 infected macrophages in the presence or absence of NTHi. We found that HRV16 treated macrophages were less able to respond to a second phagocytic trigger. Our results demonstrate that HRV16 impairs macrophage responses at multiple pathway levels.

¹Virology and Immunology, Texas Biomedical Research Institute, San Antonio, TX, ²Microbiology, The University of Texas Health Science Center at San Antonio, San Antonio, TX, ³Microbiology and Immunology, University of Maryland School of Medicine, Baltimore, MD

Macropinocytosis allows the cell to non-selectively uptake large volumes of extracellular fluid through closure of plasma membrane protrusions and formation of large endocytic vesicles called macropinosomes. Macropinocytosis is critical for a range of diverse physiological processes, including antigen capture by macrophages and dendritic cells, and is a route of cell entry for a range of pathogens. Despite being the first endocytic vesicle seen by microscope, the molecular mechanism of macropinosome biogenesis is poorly understood. Using Ebola virus (EBOV) and the fluid-phase marker, dextran, both known to require macropinocytosis for trafficking into the cell, we demonstrate that lipidation of LC3B protein, originally described to be critical for autophagosome formation, is also required for biogenesis of macropinosomes. Depleting cells of LC3B or cellular machinery coordinating LC3B processing abolished internalization, but not cell binding of EBOV and uptake of dextran. The block to macropinosome formation was at the earliest detectable step when Ankfy1 protein and phospholipid PtdIns(3,4,5)P3 mark sites of macropinocytic cups. Both unprocessed and lipidated forms of LC3B interacted with Ankfy1 by immunoprecipitation and colocalization assays. This interaction appeared at the cell surface, suggesting that although various forms of LC3B possess an inherent ability to associate with forming macropinosomes, it is the lipidated form that drives closure of macropinocytic cups and, therefore, EBOV and dextran internalization. Based on these findings, we speculated that pharmacological inhibition of LC3B lipidation would interfere with macropinosome internalization. Indeed, PIK-III, a potent inhibitor of LC3B processing, efficiently blocked dextran uptake and replication-competent EBOV infection in human immortalized cell culture and blood-derived primary macrophages. Our findings demonstrate a clear role for LC3B in controlling macropinocytosis as well as identify novel targets for treatment of diseases dependent on it. This work was funded by the Douglass and Ewing Halsell Foundations.

University, Toronto, ON, 4Chemistry and Biology, Ryerson University, Toronto, ON

Phagocytosis is a process that is critical for immunity, as well as for tissue development and repair. Circulating and tissue resident phagocytes continuously capture dead cells and invasive pathogens, which are degraded in phagolysosomes. The phagosome maturation pathways that convert phagosomes into microbicidal and hydrolytic compartments are highly regulated processes that have been extensively studied and consequently known in great detail. On the other hand, the fate of phagolysosomes, after their cargo is digested, is poorly understood. Utilizing phagosomal markers and fluorescent bacteria such as *E. coli* and filamentous *Legionella* as traceable and degradable phagosomal cargo, we followed mature phagolysosomes to their resolution. Unlike the assumption that phagolysosomes are exocytosed after particle degradation, our results indicate that phagolysosomes split and fragment into many vesicles. Combining pharmacological and genetic strategies, we found that this process is clathrin dependent. We then speculated that phagosome resolution is essential to recycle membranes, reform lysosomes and maintain the phagocytic appetite of macrophages. Indeed, macrophages could eat a larger number of particles 7 hours after a first round of phagocytosis. In marked contrast, interrupting the fragmentation of the phagolysosome blunted the ability of macrophages to undertake additional phagocytosis. Lastly, we provide evidence that phagolysosome vesicles seem indistinguishable from basal lysosomes in all functions examined including markers, acidification and fusogenicity with subsequent phagocytic and endocytic cargo. Thus, we propose that phagosome resolution is the mechanism by which macrophages reform lysosomes after particle degradation. Hence, the fragmentation of the phagolysosomes during the resolution phase may provide cellular resources for the continuous generation of new phagosomes and the prevention of this phase will critically impair the immune and housekeeping functions of the phagocytes.

Dissecting Atg27 Function in Budding Yeast Autophagy and Membrane Traffic.
M.C. Penton1, V.A. Segarra1;
1Biology, High Point University, High Point, NC

Eukaryotic cells use membrane trafficking to transport molecules, like lipids and proteins, to their designated location inside cells. Intracellular protein transport is dependent on the formation of membrane vesicles that carry these protein cargoes from a donor to a target compartment. Protein cargos have sorting signals that are recognized by adaptor proteins. Ultimately, this allows for the formation of membrane vesicles that contain the appropriate cargo. Under stress conditions, cells activate a specialized type of membrane transport known as autophagy. During this cellular process, cellular components that are damaged or unneeded are degraded and recycled. When autophagy is not functioning properly in humans, this can lead to a variety of diseases like cancer, heart, liver, and neurodegenerative diseases. Our lab uses baker’s yeast to better understand the membrane trafficking events underlying autophagy. More specifically, we are trying to understand the function and trafficking of the yeast membrane protein, Atg27 (autophagy-related protein #27). Atg27 is composed of 3...
domains: luminal, transmembrane, and cytoplasmic. While the cytoplasmic domain is known to contain at least one sorting signal important for proper Atg27 localization, the function of the luminal domain is unknown. Our work aims to map additional sorting signals on Atg27 and determine the functions of the luminal domain. To do this, we have generated yeast expressing fluorescent Atg27 molecules lacking parts of its cytoplasmic/luminal domains. We evaluate the effects of these mutations using fluorescence microscopy and autophagy assays. Atg27 is also a potential protein cargo receptor. We are also interested in identifying protein cargo recognized by Atg27. High-throughput experiments done by other labs have identified potential binding partners for Atg27. We assess whether these proteins require Atg27 for their trafficking and localization.

GRASP55 senses energy deprivation through O-GlcNAcylation to promote autophagosome-lysosome fusion.
X. Zhang¹, Y. Wang¹;
¹Department of Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

The Golgi apparatus is the central hub for protein trafficking and glycosylation in the secretory pathway. However, whether Golgi responds to glucose deprivation is so far unknown. Here, we report that GRASP55, the Golgi stacking protein located in medial- and trans-Golgi cisternae, is O-GlcNAcylated by the O-GlcNac transferase OGT in growth condition. Glucose deprivation does not disrupt the Golgi structure, but reduces GRASP55 O-GlcNAcylation. De-O-GlcNAcylated GRASP55 forms puncta outside of the Golgi area, which colocalize with autophagosomes and late endosome/lysosomes. GRASP55 depletion reduces autophagic flow and results in autophagosome accumulation. Biochemically, GRASP55 interacts with LC3-II on the autophagosomes and LAMP2 in late endosome/lysosomes, and functions as a bridge between LC3-II and LAMP2 for autophagosome and lysosome fusion; this function is negatively regulated by GRASP55 O-GlcNAcylation. Therefore, GRASP55 senses the glucose level through O-GlcNAcylation and acts as a tether to regulate autophagosome maturation.

A switch in the specificity of an endosomal CORVET tether underlies formation of regulated secretory vesicles in the ciliate *Tetrahymena thermophila*.
D. Sparvoli¹, H. Osakada², X. Lan³, M. Iwamoto², G.R. Bowman¹, C. Kontur¹, J.K. Pritchard³, T. Haraguchi², A.P. Turkewitz³;
¹Department of Molecular Genetics and Cell Biology, The University of Chicago, Chicago, IL, ²Advanced ICT Research Institute, National Institute of Information and Communications Technology (NICT), Kobe, Japan, ³Department of Genetics, Stanford University, Stanford, CA, ⁴Howard Hughes Medical Institute, Stanford University, Stanford, CA, ⁵Department of Molecular Biology, University of Wyoming, Laramie, WY, ⁶Department of Genetics, Yale University School of Medicine, New Haven, CT, ⁷Department of Biology, Stanford University, Stanford, CA, ⁸Graduate School of Frontier Biosciences, Osaka University, Suita, Japan

In the endocytic pathway of animals, two related complexes, called CORVET (Class C Core Vacuole/Endosome Transport) and HOPS (Homotypic fusion and protein sorting), act as both tethers and fusion factors for early and late endosomes, respectively. Mutations in CORVET or HOPS lead to trafficking defects and contribute to human disease including immune dysfunction. HOPS and CORVET
are conserved throughout eukaryotes but remarkably, in the ciliate Tetrahymena thermophila, the HOPS-specific subunits are absent while CORVET-specific subunits have proliferated. As uncovered via forward genetics, a single VPS8 paralog in Tetrahymena (VPS8A) is required to synthesize prominent secretory granules called mucocysts. More specifically, Δvps8a cells fail to deliver a subset of cargo proteins to developing mucocysts, instead accumulating that cargo in vesicles also bearing the mucocyst sorting receptor, Sor4. Surprisingly, although this transport step relies on CORVET, it does not appear to involve early endosomes. Instead, Vps8a associates with the late endosomal/lysosomal marker Rab7, indicating target specificity switching occurred in CORVET subunits during the evolution of ciliates. Mucocysts belong to a markedly diverse and understudied class of protist secretory organelles called extrusomes. Our results underscore that biogenesis of mucocysts depends on endolysosomal trafficking, revealing parallels with invasive organelles in apicomplexan parasites and suggesting that a wide array of secretory adaptations in protists, like in animals, depend on mechanisms related to lysosome biogenesis.

The effect of endomembrane transport inhibitors on octanoic acid resistance in Drosophila.
Z.A. Drum¹, J.D. Coolon¹;
¹Department of Biology, Wesleyan University, Middletown, CT

Drosophila sechellia, a species of fruit fly that is endemic to the Seychelles islands has evolved dietary specialization to the fruit of Morinda citrifolia. The fruit from M. citrifolia produces octanoic acid as a defense mechanism at levels that are lethal to dietary generalist species of Drosophila including sister taxa D. melanogaster and D. simulans. Drosophila sechellia has developed resistance to octanoic acid allowing it to specialize on M. citrifolia and eat its fruit without lethality. The cellular mechanisms involved in D. sechellia resistance to M. citrifolia are unknown, but genetic analysis has alluded to a difference in endomembrane function between octanoic acid resistant D. sechellia and the more susceptible Drosophila species. To elucidate the potential cellular mechanisms that provide D. sechellia resistance to octanoic acid, D. simulans, D. melanogaster, and D. sechellia were given several drugs that inhibit specific routes of endomembrane transport. After exposure to each drug, the flies were introduced to food containing octanoic acid and death rates were measured and compared within and between species. Exposure to Retro-2, an inhibitor of retrograde transport from the early endosome to the endoplasmic reticulum through the trans-Golgi network, increases survivorship of individuals upon exposure to octanoic acid in all three species tested. These experiments are beginning to provide insight into the cellular mechanisms that confer toxin resistance in D. sechellia.

Major Facilitator Superfamily Domain-Containing 12 (MFSD12) regulates melanin synthesis from lysosomes.
S.L. Bowersox¹,², S.A. Tishkoff³, M.S. Marks¹,²;
¹Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA, ²Pathology and Laboratory Medicine, Children’s Hospital of Philadelphia, Philadelphia, PA, ³Genetics, University of Pennsylvania, Philadelphia, PA

Mammalian hair, skin, and eye color arise from the presence and distribution of melanin pigments. Melanins are synthesized by pigment cell melanocytes in specialized subcellular organelles, named
melanosomes. Humans produce both eumelanin (brown and black) and pheomelanin (yellow and red) pigments. Melanin synthesis is disrupted in a number of human genetic diseases that cause skin and eye hypopigmentation, often associated with vision defects, for example oculocutaneous albinism (OCA). Variations in gene products that control melanin synthesis affect melanin quantity and distribution in humans and animal models. While hundreds of pigmentation genes have been identified, few of these are directly linked to normal, physiological pigment variation in ethnically diverse humans. Through genome-wide association studies, our collaborators have identified a novel gene that correlates with pigmentation levels in humans, Major Facilitator Superfamily Domain-containing 12 (MFSD12). Our preliminary data show that depletion of MFSD12 from immortalized mouse melanocytes increases melanin content. MFSD12 is a putative membrane transporter of unknown function, and our preliminary data show that it localizes predominantly to lysosomal membranes, not to melanosomes, and may regulate maintenance of lysosomal pH. This suggests that MFSD12 regulates melanin synthesis indirectly from lysosomes.

Studying human ATG4 homologs using ATG4 quadruple knockout (QKO) cells.
S. Yu¹, K. Kauffman¹, J. Jin¹, N. Nguyen¹, A. Lystad¹, T.J. Melia¹;
¹Department of Cell Biology, Yale University, New Haven, CT

Macroautophagy is a conserved cellular degradation process hallmarked by the covalent attachment of the ubiquitin like LC3/GABARAP family proteins to phosphatidylethanolamine (PE) on growing autophagosomes. One of the important regulators of this reaction is ATG4. It first primes LC3/GABARAP to expose the conserved carboxyl-terminal glycine to facilitate lipidation, while it also delipidates to release LC3/GABARAP for recycling. How does one protein family control both the production and removal of LC3/GABARAP-PE to ensure functional autophagy has been a central question in studying LC3/GABARAP and ATG4. Here, by utilizing a ATG4 quadruple knockout (QKO) HEK293 cell line generated by CRISPR/Cas9 in our lab, we aim to understand how the four human ATG4 homologs cooperate to exert priming and delipidation activities on seven LC3/GABARAP family proteins to regulate autophagy activity.

We first validated the ATG4 QKO by immunoblotting all four ATG4 homologs and saw complete loss of protein levels. We next examined four LC3/GABARAP homologs and observed complete loss of priming and lipidation, further supporting functional KO of all ATG4s. Notably, we can now robustly identify the pro-forms of LC3B and GABARAPL1 in our QKO. By rescuing the QKO with individual ATG4 homologs, we found that ATG4B alone can restore priming and lipidation of LC3/GABARAP family proteins when expressed at low levels comparable to endogenous levels. QKO rescued with a mutant ATG4B depleted of its carboxyl-terminal LC3 interacting region (LIR) showed accumulation of lipidated LC3/GABARAP, strongly suggesting it as an important delipidation-specific regulatory motif. In contrast, ATG4A is more specific to the GABARAP subfamily and can only partially restore GABARAPL1 priming when overexpressed. Lipidated GABARAPL1 also seems to accumulate, indicating ATG4A cannot fully support GABARAPL1 delipidation. In addition, lipidated GABARAPL1 does not accumulate after lysosomal inhibition, suggesting ATG4A alone cannot support functional autophagy. Lastly, ATG4C and ATG4D only showed very little priming activity towards GABARAPL1 when overexpressed individually. In summary, by systematically analyzing individual ATG4s in QKO, together with previous efforts examining their activity in vitro, we establish the framework of how different ATG4 homologs act on various LC3/GABARAP substrates to regulate autophagy.

Delipidation of mammalian LC3 proteins by each of the four Atg4 proteases.
K. Kauffman1, S. Yu1, B. Mugo1, A. O’Brien1, S. Nag1, T.J. Melia1;
1Cell Biology, Yale University, New Haven, CT

Autophagy is a bulk cellular degradation process where material to be degraded is encapsulated in an organelle called the autophagosome which grows de novo. The covalent conjugation of LC3 proteins to lipids in the growing membrane is required for proper autophagosome maturation. During this process, LC3 proteins undergo two proteolytic cleavage events. First, pro-form LC3 is cleaved at the COOH-terminus to reveal a glycine residue required for the lipidation reaction. The second event releases LC3 from the membrane, allowing for recycling of the LC3 and to facilitate fusion of the autophagosome with the lysosome. The Atg4 family of proteases, containing Atg4A, Atg4B, Atg4C, and Atg4D, drives both cleavage events but how Atg4 proteases are able to distinguish between soluble and lipid-anchored LC3 is not well-understood. By reconstituting the lipidation reaction in vitro, we are able to produce lipidated LC3 allowing us to directly test the delipidation activities of these four proteases. We show that Atg4B cleaves soluble LC3 orders of magnitude faster than the lipidated form, which is directly impacted by the anchoring of LC3 into the membrane, rather than the attachment of a lipid moiety. Further, although Atg4B is very efficient at cleaving soluble LC3, Atg4A displays more activity on lipidated substrates. Additionally, Atg4C and Atg4D can be activated by the removal of their expanded N-terminal domains to process lipidated LC3, which may also suggest roles for these homologs in specialized forms of autophagy. These results show that while all four Atg4 family members can be activated to similar enzymatic activities on lipidated substrates, only Atg4B efficiently processes the soluble form. Further, through mutagenesis of Atg4B, we have shown that the recognition of the lipidated form, but not the soluble form, is sensitive to a COOH-terminal LC3-Interacting Region. This differentiation is particularly notable with members of the LC3 substrate family. We suggest a model whereby Atg4B drives very fast priming of LC3 proteins while delipidation is inherently slow and regulated by Atg4 homologs.

Temperature-dependent sorting of fluorescent protein-tagged tyrosinases to the melanosome.
S.M. Joseph1, A.C. Theos1;
1Human Science, Georgetown University, Washington, DC

Tyrosinase is a type I integral membrane glycoprotein that catalyzes melanin biosynthesis in mammals. Oculocutaneous Albinism Type 1B is caused by mutations that render human tyrosinase temperature-sensitive (ts). We used the murine tyrosinase Himalayan mutant as a model to study ts tyrosinase variants. Our main objective was to characterize the temperature-sensitive melanosomal targeting of full length murine tyrosinase-FP chimeras. To this end, we epistope-tagged the protein with a C-terminal EGFP or monomeric RFP and used epitope-directed antibodies for biochemical detection. Non-pigmented COS-7 and melanized 1011-mel human melanoma cells were transfected and selected for stable constitutive expression of FP-tagged Himalayan and wild type tyrosinases. Indirect immunofluorescence microscopy results showed that, while the wild type tyrosinase-FPs sort efficiently to the lysosome or mature melanosome in non-pigmented and pigmented cells respectively, both Himalayan tyrosinase-EGFP and -mRFP accumulate within the endoplasmic reticulum (ER) when
expressed at the nonpermissive temperature (37°C), as evidenced by coincident staining with ER markers. In contrast, the mutant variant is able to exit the ER and be transported to the lysosome/melanosome at the permissive temperature (31°C). Endoglycosidase treatment followed by immunoblotting with FP-directed antibodies showed that Himalayan tyrosinase-EGFP retained high mannose oligosaccharides, failing to reach maturity, which confirms ER retention at 37°C. We then assessed whether this ER retention of Himalayan-FP tyrosinase expressed at the nonpermissive temperature is reversible or irreversible. Cells were grown at 37 °C and then incubated with cycloheximide for 30 min, limiting subsequent analysis to polypeptides accumulated at the nonpermissive temperature by blocking new protein synthesis. Cells were then either maintained in cycloheximide at 37°C or shifted to 31°C, and analyzed by western blotting and indirect immunofluorescence microscopy. Our data suggest that some of the Himalayan-tyrosinase-EGFP variant may be rescued by a subsequent reduction in temperature. The reversible nature of this potential misfolding is consistent with increased substrate-induced melanization seen in Himalayan-expressing melanocytes and may open new avenues for the development of molecular therapeutics targeting the molecular changes associated with temperature-sensitive albinism. In addition, this FP-tagged tyrosinase may be used as a tool for kinetic experiments in live cells aimed at the further dissection of membrane trafficking pathways involved in the biogenesis of lysosome-related organelles.

The role of canonical and non-canonical autophagy in bone resorption by osteoclasts.
A.N. Tran1, S. Segeletz2, E. McDermott1, J.J. Rochford3, M.H. Helfrich1;
1Institute of Medical Sciences, University of Aberdeen, Aberdeen, United Kingdom, 2Biotechnologisches Zentrum (BIOTEC), Technische Universität Dresden, Dresden, Germany, 3 Rowett Institute of Nutrition and Health, University of Aberdeen, Aberdeen, United Kingdom

Osteoclasts are cells specialized in the degradation of bone. To do this, osteoclasts form a lysosome-like membrane domain called the ruffled border (RB) that is contained within an actin-rich attachment site, called the sealing zone (SZ). Lysosomal vesicles fuse to the RB, thereby releasing their content into the extracellular space to degrade the underlying bone matrix. LC3, a marker of autophagic vesicles, localises to the RB, alluding to a potential role of autophagy in the resorptive function of osteoclasts. In vitro, 25% of osteoclasts from mice deficient in autophagy, through FIP200 deletion, still expressed GFP-LC3 at the RB. Through live cell imaging, GFP-LC3 was found to localise to the RB in a time-dependent manner, with osteoclasts in earlier stages of SZ formation having a strong concentration of GFP-LC3 within the SZ, which eventually dissipated as the SZ collapsed. The localisation of LC3 to the RB may be analogous to LC3-associated phagocytosis (LAP) in macrophages, an autophagy-independent pathway whereby LC3 is recruited to phagosomes to enhance phagosome maturation. In mice, autophagy deficiency through FIP200 deletion led to a modest decrease in bone density, which corresponded to an increase in bone resorption as measured in vitro.

LAP is critically dependent on the protein, Rubicon. In osteoclasts generated from the RAW 264.7 macrophage cell line, siRNA knockdown of Rubicon resulted in a modestly increased (13%) resorption of mineralized substrate compared to controls. Studies in Rubicon knockout mice are required to confirm this leads to a change in bone mass. Using live cell imaging with LysoTracker and GFP-ezrin, we examined lysosomal vesicle targeting to the RB and sealing zone dynamics, respectively. We observed no significant differences between Rubicon knockdown osteoclasts and controls.

Earlier studies in bone diseases, such as Paget’s disease of bone, have illustrated that dysregulation of autophagy in osteoclasts can result in serious bone pathology. Our data add to this by suggesting that
both canonical autophagy and LAP-like pathways modulate the resorptive capacity of osteoclasts during normal bone homeostasis.

**Host cells degrade the*H. pylori*pore-forming toxin, VacA, to resist cell death.**

N.J. Foegeding¹, K. Raghunathan¹, T.L. Cover³⁴⁵, M.D. Ohi⁶;  
¹Cell and Developmental Biology, Vanderbilt University, Nashville, TN, ²Pediatrics, Children's Hospital of Pittsburgh. University of Pittsburgh Medical Center, Pittsburgh, PA, ³Medicine, Vanderbilt University School of Medicine, Nashville, TN, ⁴Pathology, Microbiology, Immunology, Vanderbilt University School of Medicine, Nashville, TN, ⁵Veteran Affairs Tennessee Valley Healthcare Syste, Nashville, TN, ⁶Cell and Developmental Biology, University of Michigan Ann Arbor, Nashville, TN

Helicobacter pylori persistently colonizes the gastric mucosa of more than half of the world population, with prevalence as high as 90% in developing nations. Infection with*H. pylori*causes chronic gastric inflammation and is the leading cause of stomach ulcers and gastric cancer. Both the ability of*H. pylori*to colonize the stomach and the risk of developing*H. pylori*-mediated disease is directly associated with the secretion of a pore-forming virulence factor called vacuolating cytotoxin A (VacA). VacA has been reported to trigger a wide range of cellular responses including cellular vacuolation, plasma membrane permeability, disruption of mitochondrial membrane permeability, and apoptosis. The mechanisms by which these processes occur are not yet fully understood. During our investigation into VacA toxicity, we observed that host cells recover from VacA-induced vacuolation and grow to confluency. Furthermore, we found that VacA-induced cell death is dependent on the presence of supplemental ammonium chloride (NH₄Cl), a commonly used autophagy inhibitor. Therefore, we hypothesized that host cells are able to degrade VacA via autophagy. By assessing the intracellular levels of VacA both by western blot and light microscopy, we have shown that host cells degrade VacA and that supplemental NH₄Cl and chloroquine inhibit VacA degradation. We found that, over time, VacA colocalizes with late endosomes and autophagosomes, suggesting that VacA is trafficked to autophagosomes. Additionally, in contrast to a proposed model where VacA is trafficked to mitochondria to induce apoptosis, we do not observe VacA localization to mitochondria. We propose a model in which host cells traffic VacA to autophagosomes to be degraded by autophagy, thereby permitting cellular recovery from VacA-induced toxicity.

**Single Cell Analysis of Vacuolar pH Using Confocal Microscopy.**

J.D. Campos¹, R.C. Segura¹, Y.M. Chan¹;  
¹Biology, San Francisco State University, San Francisco, CA

Vacuole and lysosome functions—including ion storage and protein degradation—play large roles in human diseases such as lysosomal storage disorders and Alzheimer’s. In order for these functions to occur properly, vacuolar pH must lie within a specific range. Due to the breadth of the vacuole’s function, pH regulation has direct implications in cellular age. Despite this, the relationship between vacuolar pH and the size and shape of the vacuole has remained understudied. The proton pump for vacuoles, the V-ATPase, is a protein complex that spans the vacuole membrane. An increase in the vacuole’s membrane surface will increase the number of proton pumps present on the vacuole, and should therefore lower the pH. To test our hypothesis about the relationship between vacuole...
morphology and vacuolar pH, we use confocal microscopy to collect single cell data comparing the surface area and volume of yeast vacuoles to their pH. The dye, BCECF will be used to measure pH within yeast vacuoles. At the same time, the lipophilic dye, FM-4-64 will be used to stain the vacuole membrane. Then, using computational image analysis, we will reconstruct three-dimensional models of vacuoles to measure their volume and surface area. If our hypothesis is accurate, we predict that there would be an inverse relationship between vacuolar pH and the surface area of the vacuole.

Rab11/Fip5 regulates formation of the terminal web and is necessary for microvilli stabilization during zebrafish intestinal development.
C.E. Jewett¹, B. Appel², R. Prekeris³;
¹Department of Cell and Developmental Biology, University of Colorado Anschutz Medical Campus, Aurora, CO, ²Department of Pediatrics, University of Colorado Anschutz Medical Campus, Aurora, CO

Formation of a hollow tube of cells, or lumen, is an essential morphogenetic event that occurs repeatedly throughout development and results in the formation of many organ types, including the gut, kidneys, trachea, and neural tube. A crucial first step in lumen formation is establishment of apical-basal cell polarity, such that opposing cellular domains are specialized for unique functions. In the gut, the apical side of intestinal cells are lined with specialized membrane protrusions called microvilli that enhance the cell surface area and aid in nutrient absorption. These microvilli are anchored in an actin- and intermediate filament-rich cytoskeletal network, known as the terminal web, located just below the apical cell surface. Despite the importance of microvilli in intestinal cell function, the molecular machinery that governs apical microvilli formation remains largely unclear. Here we use zebrafish as a model system to determine the role of a Rab11 effector, Fip5, in apical lumen formation and microvilli establishment during gut development. Using CRISPR gene editing, we created loss-of-function mutations for both fip5a and fip5b (zebrafish have two paralogs of fip5). Alone, neither fip5a nor fip5b homozygous mutant fish show a strong phenotype, suggesting that they can compensate for one another. However, transmission electron microscopy analysis on the gut of homozygous fip5a and fip5b double mutant fish revealed severe defects in apical trafficking and microvilli stability. At 3 days post fertilization, the gut cells of embryos show structures that resemble microvilli inclusion bodies, which are cleared by 6 days post fertilization and replaced with an accumulation of enlarged apical endosomes up to several microns in size. By 11 days post fertilization, the fish have progressively worsened, now showing large gaps between cells, suggesting defects in cellular junction integrity and deformed apical cell caps. These defects appear to be caused by a disruption in targeting Rab11-endosomes to the apical plasma membrane since Rab11 is mislocalized to the basolateral side in fip5a;fip5b double mutant fish. Significantly, we also found that cytokeratin, a major component of the terminal web, is mislocalized from the apical side of cells suggesting that Rab11/Fip5 endosomes may play an essential role in formation of the terminal web and stabilization of microvilli throughout gut development.

Vangl1/2 function in neural tube convergence and extension.
M. De Oliveira Melo1, A.E. Sutherland1;
1Department of Cell Biology, University of Virginia, Charlottesville, VA

Anterior-posterior elongation of the embryo is fundamental for early vertebrate development and body plan formation. Tissue elongation is driven by convergence and extension (CE), in which the tissue undergoes narrowing along one axis and extension along the perpendicular axis. In the mouse embryo, morphogenesis of the early neural tube involves CE, driven by epithelial cell intercalation where neighbor cells move between each other in a polarized way, as well as bending and closure of the neural plate into a tube, driven by epithelial cell shape change and cytoskeletal reorganization. At the genetic and molecular level, components of the planar cell polarity (PCP) pathway have been shown to regulate these polarized cell behaviors. Mutations of the Van Gogh like 2 (Vangl2) gene, lead to mice with a short body axis and open neural tube in the hindbrain and spinal cord regions, known as craniorachischisis (CRN). Previous data from our lab showed that the Vangl2 Loop tail (Lp) mutant, which corresponds to a point mutation in the C-terminal end of Vangl2, affects cell intercalation efficiency but not polarity of neural plate cells. As the close homolog Vangl1 has a similar localization to Vangl2 in the neural plate, our hypothesis is that Vangl1 may compensate to maintain normal polarity in the absence of Vangl2. Using a line carrying knockout alleles of both Vangl genes we find that loss of Vangl1 and 2 (Vangl1gt/gt;Vangl2ko/ko) affects the polarity and the efficiency of cell intercalation, while the presence of one copy of Vangl1 (Vangl1gt/+;Vangl2ko/ko) rescues both polarity and efficiency. In contrast, the polarity of intercalation is lost in embryos lacking Vangl1 (Vangl1gt/gt;Vangl2ko/+), and one copy of Vangl2 is not sufficient to rescue this effect. The apical area of neural cells is significantly increased in both Vangl1gt/+; Vangl2ko/ko and double mutant embryos, compared to the double het (Vangl1gt/+; Vangl2ko/+), and the actin filament organization is disrupted, suggesting a role of Vangl2 in apical constriction. These data show that Vangl1 and Vangl2 together cooperate to maintain cell behavior and to drive neural tube morphogenesis. Furthermore, they suggest that the polarity of CE is primarily regulated by Vangl1 while Vangl2 is responsible for regulate the apical changes that drives neural tube bending and closure.

Perturbations of intracellular flows explain and invert the transport-dependent PAR polarization of C. elegans zygotes.
M. Mittasch1,2, P. Gross3, M. Nestler4, A.W. Fritsch1,2, A. Voigt2,4, S.W. Grill2,3, M. Kreysing1,2;
1Max Planck Institute of Molecular Cell Biology and Genetics, Dresden, Germany, 2Center for Systems Biology Dresden, Dresden, Germany, 3Biotechnology Center, Technische Universität Dresden, Dresden, Germany, 4Department of Mathematics, Technische Universität Dresden, Dresden, Germany

Throughout the last decades, access to genetic and chemical perturbations boosted our molecular-level understanding of cell biological processes. However, it was suggested that the spatio-temporal organization of cells and developing embryos also depends on physical transport processes such as diffusion, cytoplasmic streaming, and cortical flows. And thus far, it remains a challenge to unravel the function of physical transport during morphogenesis due to the lack of suitable perturbation methods for in vivo systems.
Here, we exploit thermoviscous pumping (Weinert & Braun, J. Appl. Phys. 2008) to induce intracellular flows in single cells and developing embryos. This firstly allows to systematically dissect the role of flows during PAR polarization. We find that i) cytoplasmic flows towards the membrane drive PAR loading locally, ii) cytoplasmic flows parallel to the membrane efficiently couple to the actomyosin cortex, causing long range cortical flows. iii) These induced cortical flows move pre-established PAR domains. iv) While small displacements of PAR domains are being self-corrected and cells divide normally, asymmetric cell division is inverted as soon as PAR domains were rotated across the anterior-posterior axis.

Taken together, these perturbation experiments directly show that intracellular hydrodynamics are essential for PAR polarization and reveal a robust mechanism by which flows alter the entire body axis of the embryo. Furthermore, our findings suggest that asymmetric cell division is mediated by a self-amplifying, binary decision process with high robustness against imperfect PAR positioning. Finally, we emphasize more general opportunities to dissect the principles of transport-dependent organization of living systems in space and time.

Counter-rotational cell flows drive morphological and cell fate asymmetries in mammalian hair follicles.
M. Cetera1, L. Leybova1, B. Joyce1, D. Devenport1;
1Molecular Biology, Princeton University, Princeton, NJ

Organ morphogenesis is a complex process dependent on the interplay between cell fate specification, epithelial-mesenchymal interactions, and tissue polarity. The emergence of the regularly spaced, globally aligned pattern of hair follicles across the mammalian skin is a striking example of organ morphogenesis that arises through coordinate epidermal-dermal signaling and planar polarized morphogenesis controlled by the planar cell polarity (PCP) pathway. Here, using a combination of live imaging, automating cell tracking, mouse genetics, and laser ablation, we discover a novel program of PCP-dependent cell rearrangements that drive planar polarization and polarized cell fate specification of mammalian hair follicles. Upon specification, hair placode epithelial cells undergo dramatic cell rearrangements that generate a counter-rotational pattern of cell flows. These movements reposition placode cells along the anterior-posterior axis such that posterior cells converge toward the center of the placode and flow anteriorly, while anterior and lateral cells flow outward and posteriorly toward the placode rear. Counter-rotational cell flows are driven by myosin-dependent, spatially polarized cell neighbor exchanges where asymmetric PCP protein localization correlates with junction shrinkage and disassembly. Strikingly, this pattern of cell rearrangements generates not only the morphological polarization of the hair follicle, transforming the placode from vertical to anterior-directed growth, but also directs the planar polarized organization of progenitor fates upon which the future hair follicle is built. Specifically, Shh-expressing hair germ progenitors shift from a central to anterior location while an outer ring of Sox9-expressing stem cell progenitors moves posteriorly toward the placode rear. Cell fate specification also feeds into polarized morphogenesis, as counter-rotational movements are lost in the absence of radially symmetric cell fates. Further, we show that PCP-dependent cell rearrangements displace a crucial stromal signaling center - the dermal condensate - toward the anterior, where it is necessary for the maintenance of polarized hair germ and stem cell progenitor fates. Our results define the cellular mechanisms that generate planar polarity in complex multicellular structures and demonstrate how a simple pattern of local cell rearrangements directs both morphological and cell fate asymmetries.

The ciliary GTPase Arl3 maintains tissue architecture by directing Planar Cell Polarity (PCP) dependent mitotic spindle orientation during epidermal morphogenesis.
S. Bhattarai¹, S. Begum¹, E.J. Ezratty¹;
¹Pathology and Cell Biology, Columbia University, New York, NY

Planar cell polarity (PCP) can modulate mitotic spindle orientation in the context of tissue morphogenesis, but the underlying regulatory mechanisms are largely unknown. During mammalian skin development, oriented cell divisions are biphasic. Well-established polarity pathways drive asymmetric cell division (ACD), positioning the mitotic spindle perpendicular to the tissue plane in conserved process essential for epidermal differentiation. Basal stem cells (SCs) must also undergo self-renewing planar cell divisions during skin development and regeneration, but it is unknown whether defects in this process can have detrimental consequences for the maintenance of tissue architecture. Using in utero gene targeting in developing mouse embryos, here we show that depletion of ciliary GTPase Arl3 from basal SCs causes severe defects during skin development: abnormal expansion of progenitor cell populations, loss of epidermal integrity and skin barrier deficiency. Interestingly, Arl3 KD resulted in unexpected defects to mitotic spindle orientation: planar cell divisions, specifically along the anterior-posterior (A-P) tissue plane, were significantly diminished. Loss of self-renewing planar cell divisions in basal SCs depleted of Arl3 was balanced by increased ACD, hyper-proliferation of progenitor cell populations and expansion of suprabasal cell layer. These observations suggest that an Arl3-dependent mechanism maintains cell division polarity along the A-P tissue axis, and that disruption of planar spindle orientation has detrimental consequences to epidermal architecture. We hypothesized that loss of planar mitotic spindle orientation could be a consequence of defective PCP signaling. In Arl3 KD epidermis, PCP signaling molecule Celsr1 fails to maintain its polarized distribution at cellular junctions across the A-P tissue plane. This resulted in defective hair follicle angling, a hallmark of disrupted PCP during skin development. Clonal analysis in mosaic embryos revealed that Arl3 is required for the maintenance of Celsr1 polarity and transduction of PCP to neighboring basal cells. In the absence of Celsr1, Frizzled 6 loses its asymmetrical distribution in the plane of the tissue and becomes abnormally segregated to the apical cortex of basal SCs. Celsr1 and transferrin internalization experiments suggest that Celsr1 is normally endocytosed during mitosis, but that Arl3-dependent recycling of PCP components may be required for their polarized membrane segregation. We propose that Arl3 regulates polarized endosomal trafficking of PCP components to orient cell divisions in the plane of the epithelium. Cell-cell communication via small GTPase signaling likely plays a crucial role specifying planar mitotic spindle orientation during tissue morphogenesis.

TRANSCRIPTIONAL DYNAMICS OF SINGLE-CELL REGENERATION IN THE CILIATE STENTOR COERULEUS.
P. Sood¹, R.M. McGillivary¹, W.F. Marshall¹;
¹Biochemistry and Biophysics, University of California, San Francisco, San Francisco, CA

In many multicellular organisms, the ability to regenerate tissue is lost through the course of development. Some organisms—including flatworms, salamanders and zebrafish—retain regenerative potential throughout their lifetimes and are powerful systems for uncovering mechanisms of tissue

Tuesday-291
regeneration, particularly in regards to cell-to-cell signaling. Repair at the single cell scale is also critical for an organism’s wound healing response; however, little is known about regeneration at the level of an individual cell. Here, I present our efforts to develop a unicellular model for studying regeneration and wound repair in the ciliate, Stentor coeruleus. In addition to its remarkable size (cells can reach up to 1 mm in length) and subcellular complexity, Stentor has incredible regenerative abilities: almost any portion of the cell, when removed through excision, will give rise to a normally proportioned cell with intact subcellular organization. Pioneering studies of Stentor elucidated many morphological principles of its regeneration (Morgan, 1901; Tartar, 1961), but we have much to learn about the molecular basis of Stentor’s regenerative and healing abilities. To gain a molecular foothold into the process, we have recently sequenced and annotated the genome of Stentor coeruleus. Now, using RNA-seq I am describing the transcriptional dynamics underlying the regeneration of a key organelle in the cell -- the oral apparatus (OA). This complex organelle is one of the most prominent features of the cell, composed of thousands of cilia. Cells can be induced to shed and regenerate the OA upon osmotic shock. Preliminary results indicate that after shedding, conserved genes involved in centriole production are expressed in two temporal waves, separated by an hour. Using this approach, we can identify novel genes involved in the process of centriole and cilia biogenesis. The detailed transcriptional time course, in combination with RNAi manipulations, will further reveal the genetic networks that regulate OA regeneration, and will help elucidate the fundamental principles of cell regeneration and healing at the scale of a single cell.

The DEP domain protein LET-99 regulates spindle positioning downstream of multiple polarity cues in C. elegans.
M.J. Liro1,2, K.L. Price1,2, L.S. Rose1,2;
1BMCDB Graduate Program, University of California, Davis, Davis, CA, 2Molecular and Cellular Biology, University of California, Davis, Davis, CA

Asymmetric divisions produce daughter cells with different fates, and thus are critical for animal development. During asymmetric divisions, the mitotic spindle must be positioned on a polarized axis to ensure the differential segregation of cell fate determinants into the daughter cells. Spindle positioning is also important in symmetrically dividing cells to produce specific cell arrangements. In many cell types a cortically localized complex consisting of Gα, GPR, and LIN-5 (Gα/Pins/Mud, Gα/LGN/NuMA) mediates the recruitment of dynein, which exerts pulling forces on astral microtubules to physically position the spindle. In the C. elegans one-cell embryo, the conserved PAR polarity proteins organize into anterior and posterior domains, which regulates the asymmetry of cortical GPR/LIN-5 to align the spindle on the anterior-posterior (AP) axis. In contrast, at the 4-cell stage in the endomesodermal precursor cell (EMS), the PAR proteins are localized to inner/outer domains. Nonetheless, EMS divides asymmetrically with its spindle oriented on the AP axis, and this alignment depends on partially redundant Wnt and MES-1/SRC-1 signaling pathways initiated from a neighboring cell. The mechanisms connecting cell signaling to the spindle positioning machinery remain to be determined. We previously identified LET-99, a DEPDC1 family protein, as a key intermediate for spindle positioning. LET-99 is localized to the cortex/membrane and is restricted to a posterior lateral band by the PAR proteins in the one-cell; genetic and biochemical data suggest that LET-99 may be a target of the PAR kinases PAR-1 and PKC-3. LET-99 in turn inhibits the cortical recruitment of GPR/LIN-5 to Gα and is essential for the dynamic asymmetric localization of GPR/LIN-5. More recently, our analyses of fast-inactivating temperature sensitive mutants revealed that LET-99 also acts in the MES-1/SRC-1 pathway for EMS
spindle positioning; LIN-5 is required for EMS spindle positioning as well, potentially in a Ga independent manner. To further elucidate the MES-1/SRC-1 pathway and test the hypothesis that PAR proteins regulate spindle orientation in the EMS cell, we examined division patterns using temperature sensitive par-1 and pck-3 mutations. The data suggest that PAR-1 may act in the Wnt pathway, but we found no role for PKC-3. In addition, we found that the PAR-1 related kinase PIG-1 acts in the MES-1/SRC-1 pathway, as does the small G protein Rac. LET-99 is also needed (redundantly) for membrane furrowing during cytokinesis. Rac regulation is important during cytokinesis and LET-99 has a domain with weak homology to RhoGAP proteins. We are currently testing the hypothesis that LET-99 associates with Rac and that this is important for cytokinesis and/or EMS spindle orientation.

Par3 interacts with Prickle3 to maintain planar cell polarity (PCP) in the vertebrate neural plate. I. Chuykin1, O. Ossipova1, S. Sokol1;
1Cell Developmental and Regenerative Biology, Icahn School of Medicine at Mount Sinai, New York, NY

The planar cell polarity (PCP) coordinates cell orientation in embryonic epithelia and controls vertebrate neural tube closure. In the Xenopus neural plate, the core PCP proteins Prickle3/Vangl2 localize to the anterior apical domain of each cell, but the significance of this apical localization has been unclear. We show that the apical polarity protein Par3/Pard3 is also planar-polarized in the neural plate, pointing to a possible role of Par3 in PCP. Supporting this view, interference with Par3 function inhibited neural plate PCP and neural tube closure. Mechanistically, Par3 physically associated with Prickle3 and promoted its apical localization. Overexpression of a Prickle3-associating Par3 fragment disrupted PCP in the neural plate. Moreover, a Par3 construct lacking Prickle3 binding lost the ability to inhibit body axis elongation commonly associated with PCP defects. Based on these results, we propose a new mechanistic link between Par and PCP components that is essential for neural tube closure.

Protein palmitoylation as a mechanism of asymmetric protein localization during cell division. E. Stypulkowski1, E. Witze1;
1Cancer Biology, University of Pennsylvania, Philadelphia, PA

Asymmetric cell division results in two distinctly fated daughter cells to generate cellular diversity during development and tissue homeostasis. A major molecular hallmark of an asymmetric division is the unequal partitioning of cell-fate determinant proteins. However, the mechanisms driving the asymmetric targeting and localization of these determinants to the membrane remains unclear. Protein palmitoylation is a dynamic post-translational modification which regulates protein localization between the cytosol and membrane domains. We have previously established that Wnt5a-mediated signaling promotes protein depalmitoylation to foster polarized protein localization. We present protein palmitoylation as a key mechanism for the asymmetric partitioning of the cell-fate determinants Numb (Notch antagonist) and β-catenin (canonical Wnt regulator). Using point mutants, we show specific palmitoylated residues on proteins are required for asymmetric membrane localization. Furthermore, we find that palmitoylation components can restrict Notch and Wnt transcriptional activity to one daughter cell. Moreover, we show altering the expression of the depalmitoylating enzyme, APT1, changes the transcriptional signatures of human breast cancer cells to those resembling that of Notch and β-catenin. Together, these findings demonstrate that palmitoylation is a key mechanism of
asymmetric cell division regulating Notch and Wnt-associated protein dynamics, gene expression, and cellular functions.

Rapid diffusion state switching underlies stable cytoplasmic gradients in the C. elegans zygote.
Y. Wu¹, B. Han¹, E.E. Griffin¹;
¹Biological Sciences, Dartmouth College, Hanover, NH

Shortly after fertilization of the C. elegans embryo, the cytoplasmic RNA-binding proteins MEX-5 and PIE-1 rapidly form opposing concentration gradients that span the 50-um length of the cell. PAR-1, a conserved cell polarity regulator localized on the posterior cortex, phosphorylates MEX-5 and increases its diffusion in the posterior cytoplasm, leading to the preferential retention of MEX-5 in the anterior (Tenlen 2008, Daniels 2010, Griffin 2011). Through mechanisms that are not understood, high concentrations of MEX-5 in the anterior increases the diffusion of PIE-1, giving rise to posterior-rich concentration gradient of PIE-1 (Daniels 2009, Wu 2015).
In this study, we use Near-TIRF imaging and single-particle tracking to characterize the reaction/diffusion dynamics that maintain the MEX-5 and PIE-1 gradients. We find that both proteins interconvert between fast-diffusing and slow-diffusing states on time scales that are much shorter (seconds) than that of gradient formation (minutes). We have estimated the kinetics of MEX-5 and PIE-1 switching between slow and fast-diffusing states from the appearance rate of slow-diffusing particles and by smPReSS analysis (Robin 2014). We find that the kinetics of diffusion-state switching are strongly polarized along the A/P axis by the PAR polarity system such that fast-diffusing MEX-5 and PIE-1 particles are ~symmetrically distributed whereas slow-diffusing particles are highly enriched in the anterior and posterior cytoplasm, respectively. Using mathematical modeling, we demonstrate that our estimates for the kinetics of MEX-5 and PIE-1 diffusion-state switching are sufficient to account for their respective concentration gradients. The reaction/diffusion mechanisms characterized here provide a quantitative framework for understanding how polarity cues at the cortex control the partitioning of factors in the cytoplasm.

Basal cell shape influences division orientation in the mammalian epidermis.
K. Box¹, B. Joyce¹, D. Devenport¹;
¹Molecular Biology, Princeton University, Princeton, NJ

The ability to control cell fate through oriented cell division is imperative for the proper development of many organs, such as the stratified epidermis. Basal stem cells of the epidermis can divide in two ways: 1) perpendicularly to the epithelial plane to produce one basal and one suprabasal daughter that goes on to differentiate, and 2) parallel to the epithelial plane, which generates two basal daughter cells and expands the stem cell pool. While mechanisms leading to perpendicular divisions are known, those orienting planar divisions have not been explored. Late in embryonic skin development, apical-basal polarity factors align the spindle to promote perpendicular divisions. Thus, we hypothesized that parallel cell divisions might be controlled by planar cell polarity (PCP), which relies on a set of cortical “core” transmembrane components that are asymmetrically localized along the epithelial plane. The goal of this project was to determine a potential role for planar cell polarity in orienting basal cell divisions that occur within the plane of the epidermis. In the absence of PCP, such as in the Vangl2Δp/Δp mutant,
embryos exhibit increased perpendicular, asymmetric divisions at the expense of planar, symmetric divisions. This defect was not due to increased proliferation rates, nor to mislocalization of cortical spindle anchoring proteins like LGN. Rather, we link the reduction in planar divisions to alterations in cell shape, which are indirectly caused by the neural tube defects characteristic of PCP mutants. We demonstrate that early in epidermal stratification, there is a close relationship between interphase cell height and mitotic spindle orientation. Moreover, failure of the epidermis to close over the neural tube in PCP mutants leads to cell crowding and a lower frequency of planar cell divisions. We propose a model in which basal epidermal cells utilize shape, rather than cortical PCP cues, to inform planar division orientation.

Oligomerization mediates self-stabilizing cortical asymmetry of the keystone polarity protein PAR-3.
C.F. Lang¹, A. Anneken², E.M. Munro¹²;
¹Committee on Genetics, Genomics, and Systems Biology, University of Chicago, Chicago, IL, ²Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL

The PAR proteins constitute a highly conserved biochemical module that forms and stabilizes cellular asymmetries in a wide variety of contexts and in response to a wide variety of cues. During polarization of the C. elegans zygote, a transient cue triggers the dynamic segregation of PAR proteins into complementary anterior and posterior domains. Mutual antagonism between anterior and posterior PAR proteins plays a central role in stabilizing this pattern. However, the anterior PAR protein PAR-3 is unique in that it is required for all other PAR asymmetries, but remains stably asymmetric when all other PAR proteins are either absent or uniformly distributed. A key property of PAR-3 is its ability to oligomerize, which is required for its cortical localization. Here we show that oligomerization mediates dynamically self-stabilizing PAR-3 asymmetries in the absence of mutual antagonism. Combining single-molecule imaging and particle tracking, we show that PAR-3 monomers bind weakly to the membrane where they assemble rapidly and reversibly into oligomers. We show that oligomer dissociation rates decrease sharply with oligomer size. We further show that recruitment rates of PAR-3 monomers are five-fold higher on the anterior cortex where PAR-3 oligomers are enriched and that this bias depends strongly on the ability of PAR-3 to oligomerize implying positive feedback in which cortical PAR-3 oligomers directly bind/recruit cytoplasmic monomers. Using a quantitative model with parameter values constrained by experimental measurements, we find that weak membrane binding of PAR-3 monomers, reversible assembly into slowly-dissociating cortical oligomers, and positive feedback on monomer recruitment is sufficient to explain the stable persistence of a PAR-3 enriched cortical domain. Our model predicts that the PAR-3 domain will self-focus over time through dynamic competition among PAR-3 oligomers for a finite pool of PAR-3 monomers. However, the domain size will be effectively stable over the timescale of polarization given a sharp decrease in oligomer mobility with oligomer size and sufficiently slow exchange of oligomer subunits, which we confirm experimentally. Our results reveal a novel mechanism that underlies the dynamic stabilization of cortical polarity in the C. elegans zygote. We hypothesize that variants of this mechanism, involving dynamic exchange and oligomerization of membrane-associated proteins, may operate in other cells to stabilize polarized states.
In the vertebrate retina, the different neuronal cell types required for visual perception are organized within specific layers. Light is detected by rod and cone photoreceptors (PRs) located in the outer nuclear layer (ONL), which then convey visual information to interneurons located in the Inner Nuclear Layer (INL) via synapses that form in the outer plexiform layer (OPL). Amacrine cells located in the basal-most region of the INL modulate the stimulation of ganglion cells of the Ganglion Cell Layer (GCL) mediated by bipolar cells. How each neuron is stereotypically segregated in specific layers and wires into a functional circuitry remains largely unknown. Here we hypothesized that regulators of cell polarity might be involved. Among the major polarity pathways, the partitioning defective (Par) proteins have the broadest function in a multitude of cell types and organisms. Since some Par proteins, such as Par3, are sufficient to induce polarization in isolated cells, they are classically referred to as cell intrinsic regulators of polarity. In the mammalian retina, Par3 localizes in tight junction at the apical membrane of retinal progenitor cells (RPCs) during development, and in tight junctions formed between PRs and Müller cells in the adult retina. To investigate the mechanisms of spatial segregation of neurons, we conditionally knocked-out Par3 in RPCs using the alpha-Pax6:Cre mouse line. Par3 cKO showed an early disruption of the retinal apical membrane and displaced mitosis at E14 and P0. By P14, Par3 cKO displayed a disrupted apical membrane and OPL. Apical distribution of PR, bipolar and horizontal cell nuclei was disturbed but, surprisingly, Par3 inactivation did not affect lamination of the basally-located amacrine cells, Müller glia, or Ganglion cells, or the formation of the inner plexiform layer (IPL), suggesting that the molecular mechanism regulating lamination of the inner retina is different and independent from outer retina lamination. Although the retina was dramatically disorganized, cell fate determination did not seem affected, but PRs rapidly degenerated, with a 90% decrease between P14 and P60, indicating that Par3 is required for photoreceptor survival. To refine the cellular mechanism mediating Par3 function, we lineage-traced Par3 KO RPC clones using the GlastCreERT2 mouse line induced at E14.5. Surprisingly, clonal deletion of Par3 did not lead to PR, bipolar or horizontal cell displacement, indicating that Par3 functions cell non-autonomously to regulate lamination in the outer-retina. Together, these results identify Par3 as a regulator of retinal lamination and photoreceptor survival.

Peripheral nervous system changes during senescence in MDX mice.

T.M. Augusto1, A.D. Assis2, N.P. Biscolla2, A.L. Oliveira2, G.F. Simoes2;

1Morphology and Basic Pathology, Faculty of Medicine of Jundiai - FMJ, Jundiaí, Brazil, 2 Structural and Functional Biology, University of Campinas, Campinas, Brazil

Duchenne muscular dystrophy (DMD) is an X-linked genetic disorder caused by mutations in the dystrophin gene, generating critical protein malfunction. The dysfunctional dystrophin leads to degeneration of skeletal muscle fibers which causes retrograde changes that affect the peripheral...
nervous system (PNS). Further degeneration may occur with the aging process, what has been poorly investigated. In this sense, the present work evaluated the motor function and sciatic nerve microenvironment during senescence in MDX mice. C57BL/10 mice were used as the control strain. Thus, we used fifteen mice from each strain (control and mutant), which were evaluated at six, twelve, and eighteen months old. The motor function was monitored using the walking track test (Catwalk system). The animals were sacrificed and the sciatic nerves processed for immunohistochemistry (neurofilament and p75NTR antisera). The results showed that MDX mice present a significant motor deficit (two-fold decrease) as compared to six months old control animals. Such decreased SFI, although less intense, was detected at twelve months (172%) and eighteen months (117%). The Max Contact Max Intensity decreased 13%, 19% and 21% in MDX mice as the result of aging (6, 12 and 18 months old). p75NTR immunolabeling increased 77%, 79% and 72% in MDX mice and Neurofilament immunolabeling decreased 30%, 46% and 56% in MDX mice throughout the lifespan. Overall, the results herein indicate that the constant cycles of muscle degeneration/regeneration in MDX mice cause retrograde structural changes in the sciatic nerve microenvironment, directly affecting the homeostasis of the PNS during the course of DMD.

Protective effects of pregabalin in the spinal cord microenvironment in MDX mice submitted to sciatic nerve axotomy.
A.D. Assis¹, F.D. Oliveira¹, T.M. Augusto², A.L. Oliveira¹, G.F. Simoes¹;
¹ Structural and Functional Biology, University of Campinas, Campinas, Brazil, ² Morphology and Basic Pathology, Faculty of Medicine of Jundiaí - FMJ, Jundiaí, Brazil

Duchenne muscular dystrophy (DMD) causes degeneration of skeletal muscle fibers resulting in retrograde changes that affect the central nervous system (CNS). In turn, spinal motoneurons show the typical signs of chromatolysis and loss of synapses in the early stages of the disease. Pregabalin was designed as a potent successor to a related drug, gabapentin. Pregabalin binds to the alpha2-delta subunit of the voltage-gated calcium channel in the CNS. Among its neuroprotective effects are modulation of excitatory neurotransmitters, anti-apoptotic and anti-inflammatory effects and downregulation of astrogliosis and microglial reaction in the central nervous system. In this sense, the present work studied the effects of pregabalin in the spinal cord microenvironment in MDX mice (experimental model for the study of DMD) during disease. C57BL/10 mice were used as the control strain. MDX (n=10) and C57BL/10 (n=5) were submitted to the axotomy of the left sciatic nerve in the sixth week of life, stimulating retrograde reaction and glial reaction in the spinal cord microenvironment. The mice were treated with 30 mg/kg/day of pregabalin i.p, seven days before the nerve injury and seven days after the injury until euthanasia. Vehicle counterparts received saline injections. The spinal cords were obtained and processed for immunohistochemistry (GFAP and synaptophysin antisera). The results showed a 60% reduction in GFAP expression in the MDX group treated with pregabalin relative to the MDX saline group (MDX+pregabalin contralateral – 9,082±599, MDX+saline contralateral – 15,070±487, p<0.005; MDX+pregabalin ipsilateral – 12,293±535, MDX+Saline ipsilateral – 19,195±360, p<0.005 – integrated density of pixels at spinal cord lamina IX of Rexed). Also, an increased expression of synaptophysin was obtained (MDX+pregabalin contralateral – 9,836±122, MDX+saline contralateral – 7,979±131, p<0.005; MDX+pregabalin ipsilateral – 7,447±271, MDX+saline ipsilateral – 5,153 ± 212, p<0.005). The comparison of MDX and C57BL/10 mice showed that pregabalin ameliorates the effects of DMD on motoneurons. Overall, the present results indicate that a pregabalin can be used to protect the CNS from the chronic degenerative processes during the course of DMD.
Prions are unconventional infectious agents that cause invariably fatal neurodegenerative diseases including Creutzfeldt-Jakob disease in humans, scrapie in sheep and goats, and chronic wasting disease in deer and elk. These diseases are caused when a host-encoded GPI-anchored glycoprotein, mammalian prion protein (PrP), misfolds from its cellular form (PrP\(^c\)) into a disease-associated, aggregation prone, self-replicating conformation (PrP\(^\Delta\)). While prions (PrP\(^\Delta\)) are unorthodox infectious agents since they lack coding nucleic acids, like traditional infectious agents, interspecies transmission of prions via natural routes occurs efficiently and is characterized by high infectivity titers. Interestingly, the efficiency of interspecies prion infection varies widely among mammalian species even though the primary sequence of PrP\(^\Delta\) is highly conserved between species. At the extreme ends of this spectrum, rabbits are nearly resistant to infection, while the bank vole (Myodes glareolus) appears to be a uniquely universal recipient. Previous work has shown that the conversion of native PrP\(^\Delta\) into PrP\(^\Delta\) in vitro requires species-specific glycosylation patterns and cofactor molecules. Here, we test the hypothesis that specific glycosylation and cofactor requirements play an important role in determining the host range of prion replication using the bank vole model.

Approximately 1.5 million Americans suffer from traumatic brain injury (TBI), which may lead to Alzheimer’s disease (AD) like condition. An estimated 56 billion dollars are spent as a result of TBI and about 90,000 Americans suffer from long-term disability. Uprising stress, busy lifestyle and unhealthy food habits are the major causes of traumatic brain injury. The majority of the treatment strategies are based on the improvement of cholinergic function in the brain and one of the emerging therapeutic target is to enhance the acetylcholine level in the brain. Standardized botanical extracts including Huperzia serrata, Convolvulus pluricaulis (Shankhapushpi; SP) and Celastrus paniculatus (Jyotismati; JY) are long been known to attenuate brain function and well-being. Research studies have demonstrated the versatile roles of these novel phytochemicals as natural acetylcholinesterase inhibitors and neuroprotectants, and exhibited their efficacy in the management of neurological or memory impairment, dementia, Parkinson’s and Alzheimer’s disease. In the recent past, we developed a novel, standardized Huperzia serrata extract, CogniUp\textsuperscript{TM} enriched with 1% Huperzine A, which demonstrated broad spectrum safety and neuroprotective abilities. In this study, we developed a unique
combination of CogniUp, SP and JY (MZ001), which can effectively and synergistically inhibit acetylcholinesterase (AChE) inhibition. Based on our initial assessment, concentration-dependent AChE inhibition kinetics was assessed individually using 0, 3.0, 6.0, 9.0, 12.0 and 24.0 mg SP/ml, while AChE inhibition kinetics was assessed individually using 0, 0.5, 1.0, 2.0, 4.0 and 8.0 mg JY/ml. Simultaneously, concentration-dependent AChE inhibition kinetics was assessed individually using 0, 0.0625, 0.125, 0.25 and 0.5 μg CogniUp/ml. Several combinations were assessed and ultimately, we found that a combination of SP, JY and CogniUp (12 mg/ml, 4 mg/ml and 0.125 μg/ml) provided the most efficacious and synergistic AChE inhibition. No significant adverse events were observed. Further studies are in progress to establish the therapeutic efficacy of our unique proprietary combination- MZ001 containing SP, JY and CogniUp.

RARβ agonist induces endodermal differentiation by inhibiting Hoxa1 in differentiating mouse ES cells.
A. Shrestha1, E.M. Cevallos1;
1BIOLOGY, Southern University, Baton Rouge, LA

Mouse Embryonic Stem (ES) cells are pluripotent in nature and can be differentiated in culture into all three cell lineages: ectoderm, mesoderm, and endoderm. In ES cells, retinoic acid (RA, a derivative of vitamin A) induces differentiation acting through the Retinoic Acid Receptors (RARs) and their isoforms (RARα, RARβ, RARγ). In previous research, RARβ has been shown to repress the expression of Hoxa1, a homeobox Transcription Factor (TF) required for ES neuronal differentiation, and induce endodermal differentiation in mouse ES cells. However, the mechanism by which endodermal induction interferes with neuronal differentiation has yet to be determined. Therefore, this work is aimed at identifying the RARβ target genes induced by a commercial RARβ agonist, AC55649 (AC), that may interfere with the neuronal differentiation. For this purpose, we performed transcriptome analyses on mouse ES cells treated with RA versus RA plus 5 micromolar AC for 48 hours. Our results indicate that about 80 genes were differentially expressed by 2-fold or more in mouse ES cells treated with RA plus AC as compared to cells treated with RA only. Validation by quantitative Polymerase Chain Reaction (qPCR) was performed for RARβ targets such as Zscan4, Coro6 and Mettl26. Zscan and Coro6 were found to be downregulated by AC plus RA compared to RA alone, while Mettl26 was found to be upregulated by AC. Analyses at the protein level were performed by Western blot and immunofluorescence. The overall result indicates that RARβ activation promotes endodermal differentiation by acting as repressors of neuronal differentiation.

Herpes simplex virus -1 (HSV-1) infections of the central nervous system (CNS) may result in devastating encephalitis characterized by altered astrocyte reactivity and activation. Regulation of the astrocyte secretome critically influences the outcome of a brain injury. Inflammatory cytokines are initially beneficial for clearance of virally infected cells but become detrimental if activated for too long. Neurotrophic factors secreted by activated astrocytes are crucially involved in regulation of inflammatory response and repair mechanisms. In this study, we employed primary murine cortical cultures containing astrocytes and neurons to study neurotrophic factor signaling in HSV-1 infected CNS cells. Interestingly, fibroblast growth factor 4 (FGF-4), a paracrine neurotrophic factor, was dramatically up-regulated by a switch-on mechanism and induced neurotrophic signaling in neighboring cells. This effect was specific to HSV-1 infection and independent of innate immunity signaling indicating a virus induced mechanism. We thus propose that during the course of an HSV-1 brain infection, FGF-4 shifts astrocytic responses from inflammation to repair, thereby promoting viral spread in the CNS.

Mutation of the Drosophila RNA-binding protein Muscleblind, causes accumulation of rhodopsin, ER stress and retinal degeneration.
I. Tekin1,2, J.D. Ni1,2, A. Gurav1,2, D. Acosta-Alvear2, C. Montell1,2;
1Neuroscience Research Institute, University of California, Santa Barbara, Santa Barbara, CA,
2Department of Molecular, Cellular and Developmental Biology, University of California, Santa Barbara, Santa Barbara, CA

Many inherited retinopathies result from the loss-of-function mutations in genes required for phototransduction, such as the gene encoding the light-sensitive receptor rhodopsin (Rh). Defects in the biosynthesis, folding, and/or trafficking of Rh result in insufficient protein levels in the photoreceptor cell membrane, which can lead to retinal degeneration and blindness. As in humans, mutations that reduce functional Rh levels in the fruit fly, Drosophila melanogaster, recapitulate clinical manifestations of retinopathies. Through a genetic screen for Drosophila genes required for phototransduction, we identified a mutation in one isoform of the evolutionarily conserved muscleblind-like (MBL) family of proteins. MBL is a member of a family of RNA-binding proteins that regulates the splicing, transport and stability of tissue-specific RNAs. In humans, the loss of function of either one of two isoforms of MBL (MBNL1/2) cause myotonic dystrophy. We found that mutations in one Drosophila Mbl isoform results in defects in phototransduction, and in progressive degeneration of the photoreceptor cells. The mutant flies also display a profound reduction in the levels of Rh1 and other phototransduction proteins, such as the TRP and TRPL cation channels, without discernible effects on their respective mRNA levels. We found that the Rh1 protein accumulated in the endoplasmic reticulum (ER) of the photoreceptor cells of mutant animals. Moreover, there was a significant increase in the mRNA levels of the transcription factor Xbp1, a major regulator of the ER stress response. Our results suggest that Mbl regulates the biosynthesis, folding, transport, or stability of Rh1. We suggest that the retention of Rh1 in the ER results in unmitigated ER stress, which consequently leads to photoreceptor cell death and retinal degeneration. We are currently conducting analyses aimed at revealing the specific mechanisms by which this Mbl mutation affects ER function in fly photoreceptor cells. By circumventing the developmental defects associated with the complete loss of Mbl, the mutation we identified allows us
to dissect the homeostatic functions of Mbl in adult photoreceptor cells, and the specific molecular mechanisms that result in photoreceptor degeneration.

**Neurons survive and regenerate after simultaneous injury to axons and dendrites.**
M. Shorey¹, J. Mandel¹, M.M. Rolls¹; ¹BMMB, Penn State, University Park, PA

After axon injury, neurons recover function by regenerating the damaged process. It has recently been shown that neurons can also survive dendrite severing and can regenerate these processes. It is not known how well neurons in vivo survive simultaneous injury to axons and dendrites, even though this scenario is likely to occur during stroke and traumatic brain injury. If neurons can survive simultaneous injury to both compartments it is not known whether they would initiate one type of regeneration first, axon or dendrite, or would regrow both types of processes simultaneously. To address these questions we used an in vivo system in which we can use a pulsed UV laser to induce controlled injury to specific regions a neuron. Axons, dendrites, or all processes of ddaE sensory neurons in whole living larvae were severed with a laser and responses were tracked over time. As previously described removing the axon or all the dendrites resulted in regeneration. However, when the axon and all the dendrites were removed to leave an isolated cell body very little regrowth was observed although the cells did survive over the 72h period analyzed. We considered two hypotheses that could account for this failure after complete severing: 1) loss of contact between the neuron and surrounding cells made it difficult to regenerate, or 2) the axon and dendrite regeneration programs are mutually inhibitory and cannot run at the same time. To distinguish between these hypotheses, we cut the axon and all of the dendrites except for one, which would allow the cell to remain in contact with surrounding cells. In this case rapid outgrowth was initiated, and our initial analysis suggested that both axonal and dendritic compartments were regenerating. To elucidate whether induction of either regeneration pathway would halt regeneration that has already begun, we performed the injuries 24h apart. Again, our results suggested that both pathways are able to run in parallel. We conclude that, at least this neuron type, can survive injury of both axons and dendrites and can regenerate both types of processes simultaneously.

**Microglia activation in animal model of post-traumatic stress disorder.**
M. Sidorova¹, O. Tuchina¹, I. Vakolyuk¹; ¹School of Life Sciences, Immanuel Kant baltic Federal University, Kaliningrad, Russia

The central nervous system has historically been considered immune-privileged; however this privileged position mostly consists of adaptive immune responses with restricted access of infiltrating lymphocytes into the brain parenchyma, while cells of the innate immune system — microglia — are abundant in the brain. Microglia is also considered a key player in many neuroinflammatory conditions. Microglial cells respond to infectious agents such as LPS with reactive phenotype and changes in expression of certain markers such as Iba1. Reactive microglia are also found in the brain during neuroinflammatory processes in depression, bipolar disorder, post-traumatic stress disorder (PTSD). We used animal model of PTSD in order to test how chronic stress affects the neurogenesis, reactivity of microglial cells as well as their density in the dentate gyrus of the hippocampus and whether hippocampal volume is changing during PTSD. According to our results, 10 days after stress onset the
number of Iba1+ microglial cells in the dentate gyrus of the hippocampus increased substantially compared to the control group (Mann–Whitney, p=0.028). However, we did not see any inflammatory foci, i.e. microglial nodules. The intensity of Iba1+ staining of as well as the size and shape of cells did not differ from the control group. The hippocampal volume did not change significantly. We propose that neurotoxic or neuroprotective role of microglia cells can change depending on the microenvironment, such as in presence of certain cytokines, interleukins, hormones that lead to corresponding changes in the molecular profiles of glial cells. The particular mechanisms of microglia activation and its role in neurogenesis is discussed. This work was supported by Contract №14.575.21.0036, unique identifier of applied scientific research and experimental development RFMEFI57514X0036.

Novel Single nucleotide polymorphism in the exon 3 of MYOC gene enhance the risk of Glaucoma.
S. Nazir1, M. Mukhtar1, M. Shahnawaz1, S. Farooqi2, N. Fatima1, R. Mehmoond1, N. Sheikh1; 1Deaprtment of Zoology, University of the Punjab, Lahore, Pakistan, 2Department of Biomedical Engineering Center, Kalashahkaku Campus, , University of Engineering and Technology,, Lahore, Pakistan

Genetic polymorphism on MYOC gene alters the myocilin protein leading to the interruption in normal regulation of Intraocular pressure (IOP) that ultimately causes glaucoma. The present study was conducted with an aim to identify the polymorphism on exon 3 of MYOC gene in glaucoma patients of Lahore division. For this purpose a case control study was conducted with 100 patients and 100 controls subjects. DNA was extracted from each blood samples and targeted DNA fragment was amplified by PCR. Polymorphisms were identified through sequencing. It was observed that allelic and genotypic frequency of rs74315341 and rs879255525 were significantly associated with glaucoma in studied population. The polymorphism on rs74315341 polymorphic site led to the change of Arginine into Serine whereas rs879255525 transforms Lysine into Asparagine. Haplotype TGAAGCCATTTC was found to be significantly associated with disease onset whereas the haplotype GGAAGCCATTTC was found to be protective against disease development. In conclusion MYOC gene polymorphisms were identified as susceptible regions for glaucoma onset in population of Lahore division. Our paper is the first report to identify a novel mutation rs879255525 for glaucoma on exon 3 of MYOC gene.

The fusogen EFF-1 drives phagosome sealing during cell process clearance.
P. Ghose1, A. Rashid1, P. Insley1, M. Trivedi1, P. Shah2, A. Singhal1, Y. Lu1, Z. Bao2, S. Shaham1; 1Developmental Genetics, The Rockefeller University, New York, NY, 2Developmental Biology, Sloane Kettering Institute, New York, NY

Programmed cell death and cell process pruning are common in metazoan development and homeostasis. Dismantling of morphologically complex cells, sporting long processes, poses a particularly interesting problem, as different regions of a cell are often in different microenvironments, and contact different cells. We have used the *C. elegans* tail-spike cell (TSC) to understand the death and clearance of a morphologically complex cell. The TSC extends a microtubule-laden process towards the tail tip during embryonic morphogenesis and then dies. Tracking of death using still images and long-term light-sheet microscopy reveals that the TSC undergoes three distinct degeneration/clearance...
events. The proximal TSC process is dismantled first, and undergoes Wallerian degeneration-like beading. The cell soma then dies and is cleared in a manner resembling other apoptotic cells. The distal process retracts and accumulates in a distinct varicosity. All three mechanisms depend independently on CED-3/caspase. Importantly, a similar sequence accompanies the demise and clearance of embryonic and sexually dimorphic CEM neurons. Thus, the TSC death program may represent a general mechanism for dismantling morphologically complex cells, including neurons.

Clearance of the proximal and distal TSC fragment is independent of known apoptotic engulfment proteins, except for SAND-1/MON1, which promotes phagosome maturation, suggesting that novel mechanisms are at play. From a genetic screen for mutants disrupting TSC clearance, we identified two mutants with lesions in eff-1, encoding a previously-described C. elegans fusogen. These mutants and one carrying a canonical allele, are defective in TSC distal process varicosity clearance, and do not display cell body or proximal process clearance defects. EFF-1 is expressed in and functions in hyp10 cells, which surround and engulf TSC process remnants. While hyp10 appears to recognize the distal process varicosity in eff-1 mutants, the phagosome that is formed remains open, suggesting that EFF-1 may mediate the fusion event required for membrane scission and phagosome sealing. Supporting this idea, the phagosome is labeled with PLCδ-PH::mKate2, a reporter for unsealed phagosomes. FRAP data also suggest that the eff-1(−) phagosome is open. Fusion-dead EFF-1 fails to rescue distal process clearance. EFF-1 also localizes to the tips of phagosome arms, consistent with a function in phagosome sealing.

Direct mediators of membrane scission that promote the formation of endosomes, phagosomes, and other plasma membrane-derived organelles are not known. Our data reveal a novel paradigm for complex cell dismantling that may be broadly conserved, and suggest a novel role for EFF-1 in the scission event promoting phagosome sealing.

Cell biology of functional axon regeneration.
C. Ding1,2, M. Hammarlund1,2;
1Neuroscience, Yale School of Medicine, New Haven, CT, 2Genetics, Yale School of Medicine, New Haven, CT

Functional axon regeneration requires a regenerating neuron to form new synapses onto relevant targets, thus rebuilding an effective circuit. To model this process in vivo, we developed an assay in C. elegans that links regeneration of a single, specific axon (DA9) with regained activation of its post-synaptic targets and recovery of relevant behavior. By imaging DA9 axon morphology and synaptic components during functional axon regeneration, we can analyze the process of rebuilding circuits in molecular detail. DA9 normally has synapses only in a specific region of its axon in the dorsal nerve cord. Surprisingly, we find that axon injury initially results in the formation of transient synaptic vesicle clusters in the DA9 dendrite. These clusters form independently of the injury-sensing DLK pathway. DA9 microtubule polarity is not altered by axotomy, suggesting that injury may trigger minus end-directed transport of vesicle clusters. Optogenetic stimulation of DA9 during this early phase of regeneration results in dendritic vesicle release, activation of ventral cells, and aberrant behavioral response. Later, as the DA9 axon regenerates into its former dorsal synaptic area, new synapses are formed in the correct dorsal region. This remodeling enables activation of dorsal cells when DA9 is stimulated, restoring largely normal circuit function and behavior. Together, these data reveal a surprising amount of circuit plasticity during functional axon regeneration, and establish an in vivo system to investigate its mechanisms.

Pharmacologically increasing microtubule acetylation corrects stress-exacerbated effects of organophosphates on neurons.
A. Patil1, A.N. Rao1, Z.D. Brodnik1, L. Qiang1, R.A. Espana1, K.A. Sullivan2, M.M. Black3, P.W. Baas1;
1Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA, 2Environmental Health, Boston University School of Public Health, Boston, MA, 3Anatomy and Cell Biology, Temple University, Philadelphia, PA

Many veterans of the 1990-1991 Gulf War contracted Gulf War Illness, a multi-symptom disease that primarily affects the nervous system. Here we treated cultures of human or rat neurons with diisopropylfluorophosphate (DFP), an analog of sarin, one of the organophosphate toxicants to which the military veterans were exposed. All observed cellular defects produced by DFP were exacerbated by pretreatment with corticosterone or cortisol, which, in the rat and human neurons respectively, serves in our experiments to mimic the physical stress endured by soldiers during the war. To best mimic the disease, DFP was used below the level needed to inhibit acetylcholinesterase. We observed a diminution in the ratio of acetylated to total tubulin that was correctable by treatment with tubacin, a drug that inhibits HDAC6, the tubulin deacetylase. The reduction in microtubule acetylation was coupled with deficits in microtubule dynamics, which were correctable by HDAC6 inhibition. Deficits in mitochondrial transport and dopamine release were also improved by tubacin. Thus, various negative effects of the toxicant/stress exposures were at least partially correctable by restoring microtubule acetylation to a more normal status. Such an approach may have therapeutic benefit for individuals suffering from GWI or other neurological disorders linked to organophosphate exposure. (AP and ANR are co-first authors. ANR is supported by an NRSA from the NIH. This work was supported by grants from the DOD to PWB and KAS, and a grant from the NIH to PWB.)

TRPV4 mediated neuronal hyperexcitability and disrupted mitochondrial axonal transport in a Drosophila model of inherited neuropathy.
B.M. Woolums1, M. Tabuchi1, H. Sung1, J.M. Sullivan1, B.A. McCray1, M.N. Wu1, C.J. Sumner1, T.E. Lloyd1;
1Neurology, Johns Hopkins University, Baltimore, MD

Dominant missense mutations in the gene encoding the cation channel transient receptor vanilloid, family member 4 (TRPV4) cause inherited neuropathies including Charcot-Marie-Tooth disease 2C (CMT2C). in vitro, mutations in TRPV4 that cause CMT2C cause a gain of TRPV4 channel function and increased intracellular calcium which subsequently leads to cellular toxicity. However, the mechanisms by which CMT2C causing mutations in TRPV4 lead to neuronal dysfunction in vivo remain poorly understood. We generated transgenic Drosophila that express either wild-type or a CMT2C causing TRPV4 mutant (TRPV4R269C) to assess the effect of TRPV4R269C on neuron function in vivo. Selective expression of TRPV4R269C in Drosophila CCAP neurons (NCCAP) results in a failure of Drosophila wing expansion that is blocked by genetically inactivating the channel pore, demonstrating the requirement of channel function in mediating this phenotype. Perforated patch clamp analysis of NCCAP reveals that TRPV4R269C causes a calcium-dependent increase in NCCAP neuronal excitability which is rescued by application of a TRPV4 selective antagonist. High level expression of TRPV4R269C causes synaptic and dendritic degeneration, both of which are rescued genetically by inactivating the channel pore or

Tuesday-304
pharmacologically by feeding larvae a TRPV4 selective antagonist. We conducted a genetic screen in NCCAP and found that CaMKII knockdown potently suppresses the TRPV4R269C mediated wing expansion phenotype and selectively rescues degeneration of synapses but not dendrites. We also find that TRPV4R269C, but not controls, inhibits the processivity of both anterograde and retrograde mitochondrial transport in axons. Induction of TRPV4R269C expression after eclosion causes progressive locomotor impairment, suggesting TRPV4R269C can disrupt adult neuron function leading to a progressive neuropathy. Our data demonstrate that TRPV4R269C causes neuropathy through elevated neuronal intracellular calcium which disrupts mitochondrial transport and mediates neurodegeneration through compartment-specific calcium-mediated signaling pathways and supports further investigation of TRPV4 antagonists as potential therapeutics for the treatment of CMT2C.

1Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA; 2Physiology and Biophysics, Albert Einstein College of Medicine, New York City, NY, 3Dermatology, George Washington School of Medicine and Health Sciences, Washington DC, DC

Microtubule-stabilizing drugs have gained popularity for treating injured adult axons, the rationale being that increased stabilization of microtubules will prevent the axon from retracting and fortify it to grow through inhibitory molecules associated with nerve injury. We have posited that a better approach would be not to stabilize the microtubules, but to increase labile microtubule mass to levels more conducive to axonal growth. Recent work on fetal neurons suggests this can be accomplished using RNA interference to reduce the levels of fidgetin, a microtubule-severing protein. Methods to introduce RNA interference into adult neurons, in-vitro or in-vivo, have been problematic and not translatable to human patients. Here we show that a novel nanoparticle approach, previously shown to deliver siRNA into tissues and organs, enables siRNA to gain entry into adult rat DRG neurons in culture. Knockdown of fidgetin is partial with this approach, but sufficient to increase the labile microtubule mass of the axon, thereby increasing axonal growth. The increase in axonal growth occurs on both a favorable substrate and a growth-inhibitory molecule associated with scar formation in the injured spinal cord. The nanoparticles are readily translatable to in-vivo studies on animals and ultimately to clinical applications. (TOA and AJM are co-first authors. PWB and DJS are co-senior authors. This work was supported by a grant to PWB from the Craig H. Neilsen Foundation, a grant from the DOD to DJS, and NIH grants to PWB and DJS. TOA is supported by an NSF GRFP.)

Differential effects of oxidative stress on neurons cultured from different regions of the embryonic chick brain.
E. Beyrent1, M. Galardi1, G. Gomez1;
1Biology, University of Scranton, Scranton, PA

It has been suggested that oxidative stress-induced damage to proteins and lipids within neurons may underlie the cellular etiology in neurodegenerative diseases such as Alzheimer’s or Multiple Sclerosis.
Due to the number and complexity of interactions among cytosolic proteins involved with neuronal function, neurons are particularly susceptible to the effects of oxidative stress. For example, oxidative stress-induced hyperphosphorylation of microtubule-associated protein tau causes their aggregation into non-functional clumps, and eventual degradation of the microtubule network; thus aggregates of hyperphosphorylated tau have commonly been seen in post-mortem tissue from individuals afflicted with Alzheimer’s disease. However, these effects appear to vary in different brain regions. Our laboratory has therefore employed neurons cultured from different regions of the embryonic chick brain at embryonic day 10 through 14 to study the differential effects of oxidative stress at the cellular level. Neurons isolated from the different brain regions were grown in mixed-cell cultures and treated with hydrogen peroxide or tert-butyl hydroperoxide (from 1 to 100 μM) for up to five days. In vitro, cerebral neurons generally grow longer neurites, while neurons derived from the cerebellum or optic tectum grow shorter processes but with more extensive branching. Oxidative stress induces more extensive process retraction and detachment in the cerebellar and tectal neurons, as well as decrease in overall cell adhesion protein expression and localization to the cell membrane. In contrast, cerebral neurons subjected to oxidative stress show decreased expression and localization of the cytoskeletal support protein neurofilament-68. In untreated cerebral neurons, tau protein tightly colocalizes with the microtubule network. Increasing levels of oxidative stress induces a lower correlation between tau and the cytoskeleton, coupled with reductions in neural process length. In addition, oxidative stress induces redistribution of phospho-tau from dispersal through axonal processes to localization in the cell body. These results suggest that oxidative stress induces hyperphosphorylation of tau protein in live cells, causing them to form aggregates that lead to cytoskeletal degradation and neuronal retraction. Collectively, our results suggest differential susceptibility of neuronal subpopulations to oxidative stress, which may offer potential avenues for investigation for the cellular mechanisms affected by different neural disorders.

**A new microtubule-based approach for augmenting nerve regeneration.**

A.J. Matamoros¹, D. Wu¹, L.A. Baker², D.J. Sharp², V.J. Tom¹, P.W. Baas¹;

¹Neurobiology Anatomy, Drexel University College of Medicine, Philadelphia, PA, ²Physiology Biophysics, Einstein College of Medicine, New York, NY

Most studies on microtubules in the nervous system have focused on the dynamic properties of the microtubules, with stabilization by taxol and related drugs being proposed as a therapeutic for nerve injury. However, while initial indications were hopeful, more recent observations have called into question whether such drugs directly help nerves to regenerate or if they only provide a small advantage by reducing proliferation of the glial scar. In particular, there is concern that microtubule-stabilizing drugs will impede the ability of the regenerating axon to navigate to its target, given that microtubule dynamics are known to be important for growth cone guidance. Even so, microtubules remain a worthy target, given that they are downstream of many of the growth factors and cell signaling pathways that have already been shown to be relevant to nerve regeneration. We hypothesize that a better approach than microtubule stabilization may be to boost the levels of the more dynamic component of the microtubule mass, which is more akin to how axons grow and navigate during development. Previously we showed in work on fetal neurons that fidgetin is a microtubule-severing protein that pares down the dynamic portions of microtubules in the axon, such that depleting fidgetin results in an increase in dynamic microtubule mass and faster axon growth. Using AAV5 to transduce adult dorsal root ganglion neurons with fidgetin shRNA, we have now tested whether fidgetin knockdown assists axon regeneration in a novel in-vitro system in which the cells are plated on a laminin...

HIV-1 Nef induced inflammation, astrogliosis, and chromatolysis can be reversed by inhibiting TGFβ.

N. Martinez-Orengo1, M.L. Cruz1, R.J. Noel1;
1Basic Sciences, Ponce Health Sciences University, Ponce, PR

Astrocytes and neurons play a major role in the maintenance and proper function of the brain. Learning and memory can be compromised if either of these cell types are affected. The human immunodeficiency virus (HIV) has the capacity of damaging the nervous system. Although viral replication in astrocytes is limited and neurons are not infected, early viral proteins can be produced in astrocytes and affect nearby cells. Keeping the virus under detectable levels does not exempt patients from developing HIV-associated neurocognitive disorders (HAND) which still affect near 50% of the people living with HIV. When viral particles enter the brain, cytokines can induce an inflammatory state leading to neurotoxicity. The transforming growth factor β (TGFβ) is a cytokine important for several cell characteristics and neuron viability. Our group has demonstrated that the HIV early protein Nef causes learning impairment when expressed by astrocytes. We have seen that Nef by itself can increase trafficking of immune cells into the brain and promote inflammation as well as increased expression of TGFβ. In this study we aim to understand how astrocytes expressing HIV-1 Nef promote inflammation, astrogliosis, and affect neuron viability. To demonstrate this, astrocytes were transfected with Nef or GFP (control) plasmids and treated with rTGFβ or a TGFβ inhibitor. Lysates were collected at 24, 48, and 72 hours to measure protein expression. Sprague Dawley rat brains were infused with astrocytes expressing Nef and treated daily by giving an oral dose of either placebo or a TGFβR inhibitor. Immunofluorescence for target proteins was performed in tissues collected at days 1 and 5 after surgery. Our results show that astrocytes expressing Nef have increased levels of TGFβ and GFAP. In rat brain tissues, Nef inhibits astrocyte proliferation, increases astrogliosis and chromatolysis. These effects seem to be reversed as soon as one day after surgery with the use of the TGFβR inhibitor. We also have preliminary data suggesting a reduction in tight junction protein in the Nef treated group when compared to naïve rats. Previously, we have also seen changes in spine density related to Nef expression. Thus, our future studies include looking at the blood brain barrier (BBB) permeability and measuring pre and post synaptic proteins. Immune responses in the brain can vary depending on the insult. A better characterization of the effect of Nef in the brain and the role of TGFβ pathway in these responses is relevant for understanding neuropathologies currently disturbing HIV patients.

Investigating the neuroprotective functions of TLDc proteins.
D.M. Svistunova1, M.J. Finelli1, P.L. Oliver1, K.E. Davies2;
1Department of Physiology, Anatomy and Genetics, The University of Oxford, Oxford, United Kingdom

Neurodegenerative disorders are becoming more prevalent with increased life-expectancy, yet the mechanisms of disease initiation and progression are still to be unraveled. Oxidative stress (OS) is one of the key factors implicated in the neurodegenerative process and organisms have developed multiple mechanisms to neutralise the potential damage that reactive oxygen species can cause. Oxidation resistance 1 (Oxr1) has been identified by our group as one of the proteins responsible for neuronal cell protection against OS. We discovered that mice lacking Oxr1 display progressive ataxia, death of cerebellar granule neurons and only survive for 24 days. Oxr1 can effectively reduce cellular OS levels, although the molecular mechanisms of action remain unclear. Oxr1 is a member of a protein family that share a highly conserved C-terminal TLDc domain. Importantly, mutations in TLDc domain-containing protein TBC1D24 are associated with seizures, deafness and neurodegeneration in humans. Therefore, understanding the function of TLDc proteins will shed light on mechanisms of cellular stress response and role of these proteins in disease.

In order to identify pre-symptomatic pathways in Oxr1 knockout mouse, transcriptomic analysis has been carried out. These data revealed that genes involved in neuroinflammation were up-regulated when Oxr1 was deleted in vivo, but interestingly no genes related to the OS response were significantly altered. This led us to hypothesise that Oxr1 might be regulating the activity of antioxidant machinery at the protein rather than mRNA level. Using an unbiased protein interaction screen in the brain, several key antioxidant enzymes were identified as putative interactors of Oxr1. Using a combination of in vitro methods and in vivo assays in neuronal cells we are currently investigating the functional interaction between Oxr1 and these enzymes in the regulation of cell sensitivity to OS. Our results indicate that Oxr1 may be influencing important post-translational modifications of antioxidant proteins to modulate their function. Further investigation will provide a better understanding of neuronal OS defense system and role of TLDc proteins in this process.

The NINDS Repository: Publicly available DNA and Cell Lines sampled from individuals diagnosed with neurological disorders.
L. Scheinfeldt1, S. Heil1, A. Green1, J. Santana1, A. Amberson1, A.M. Resch1, R. Zhang2;
1Coriell Institute for Medical Research, Camden, NJ, 2National Institute for Neurological Disorders and Stroke-NIH, Bethesda, MD

Neurological disorders present serious health concerns and challenges to health and health-related quality of life in the United States. Most neurological disorders are complex diseases involving genetic and environmental risk factors, many of which are not yet clearly understood. The identification of reliable genetic risk markers will, therefore, contribute to preventive efforts, earlier diagnoses, disease management options, and new targeted therapeutics. To this end, The National Institute of Neurological Disorders and Stroke (NINDS) Repository offers a public resource containing DNA and lymphoblastoid cell lines with corresponding de-identified clinical and demographic data representing a diverse set of neurological disorders and neurologically normal controls. To date, NINDS Repository samples have been used in over 300 peer-reviewed scientific publications, including genome-wide association studies,
case-control studies, whole-genome and whole-exome sequencing studies, structural variation studies, and candidate gene studies. The genetic and genomic data collected by these studies have been deposited in the Database of Genotypes and Phenotypes (dbGaP), a NIH/NLM sponsored repository for restricted-access data from studies investigating the contributions of genetic variation to phenotypic variation and disease (http://www.ncbi.nlm.nih.gov/gap). Since its establishment, specimens from over 37,000 individuals have been successfully banked and can be accessed through an online catalog (http://catalog.coriell.org/NINDS): individuals diagnosed with cerebrovascular diseases (N>10,800), Parkinsonism (N>5,600), motor neuron diseases (N>2,500), epilepsy (N>6,000), Tourette syndrome (N>4,100), Dystonia (N>2,200), and neurologically normal controls (N>6,100).

Hyperglycemia upregulates calpains expression and promotes sodium channels proteolysis in rat brain.

A.V. Vega1,2, L.M. Arratia-Cortés3, M. Calderón-Torres1;
1UBIMED, FES Iztacala UNAM, Los Reyes Iztacala, Tlalnepantla, Mexico, 2Carrera de Médico Cirujano, FES Iztacala UNAM, Los Reyes Iztacala, Tlalnepantla, Mexico, 3Posgrado en Ciencias Quimicobiológicas, ENCB-IPN, Mexico City, Mexico

Calpains play an important role in neurological pathologies, cardiovascular diseases and diabetes. In several populations it has been observed that single nucleotide polymorphisms in the calpain 10 gene increases the risk of developing diabetes, and its expression in increased in pancreas of diabetic patients. Sustained hyperglycemia triggers cellular damage in neurons, including alterations in voltage-dependent sodium channels (NaV) function that are related to chronic pain. Interestingly, in animal models of chronic pain calpain 1 proteolysed NaV. Despite that neuropathic pain is a common comorbidity of diabetes, it is unknown whether calpains expressed in neurons (calpains 1, 2, 5, 7 and 10) are susceptibles to glucose up rise and if that may affect sodium channels integrity. We analyzed the expression of calpains in normo and hyperglycemic rats by sqRT-PCR and western blot and studied the proteolysis pattern of sodium channels, using whole brain total RNA and protein samples. Hyperglycemia was induced by a single injection of streptozotocin (STZ, 60 mg/kg) and glucose concentration was measured 72h afterwards; CN rats were injected with vehicle. Half of each group was also exposed to the calpain inhibitor MDL28170 (3mg/ml), applied intraperitoneally daily for 3d after hyperglycemia onset (>250 mg/dL). We did not find differences on mRNA levels for CAPN 1, 2, 5, 7 and 10 between groups. However, at protein level we found that hyperglycemia induced increases of calpain 1, 2 and 5 of 2-fold or more, which were reverted by MDL28170 to control levels. Calpain 10 and calpain 7 expressions were insensitive to treatment with STZ or MDL28170 alone. However calpain 10 became sensitive to MDL28170 after hyperglycemia onset. Regarding the proteolysis of sodium channels, we found that hyperglycemia increases proteolysis of several NaV isoforms, including NaV1.1, NaV1.2 and NaV1.8. Isoform NaV1.6 was not affected by hyperglycemia. By immunofluorescence assay we found that calpains 1 and 10 colocalize with sodium channels in hippocampus and there is a tendency to increase his colocalization in hyperglycemic brains. All together our results suggest that calpains expression is stimulated by hyperglycemia and can be partially responsible for degradation of NaV1.2 of sodium channels. They also suggest that other proteases may be involved. Proteolysis of NaV by calpains may alter the kinetics of NaV, accounting for the misfunction of these channels in chronic pain. Alteration in NaV function or expression may also be involved in development of neurological comorbidities of diabetes such as cognitive dysfunction. Supported by PAPCA 2013-38 FESI-UNAM and PAPIIT-DGAPA-UNAM IN223116.

Investigating a role of TOR-2 in controlling ER export of AMPA receptors to regulate synaptic excitability in C. elegans.
C. Xu¹, B. Parker¹, K.A. Caldwell¹, G.A. Caldwell¹;
¹Biological Sciences, University of Alabama, tuscaloosa, AL

Human torsinA is an ER-resident protein, which is a member of large and structurally diverse family of AAA+ proteins that hydrolyze ATP to release energy for remodeling substrates. Mutation or deletion in DYT1 gene, is responsible for a dominantly inherited human movement disorder called early-onset torsion dystonia. DYT1 dystonia is an autosomal disorder, characterized by painful, involuntary sustained muscle contractions and abnormal postures. While clinical manifestations are well-documented, underlying molecular mechanisms by which torsinA modulates neuronal activity remain to be fully elucidated. Biochemical and in vivo evidence suggest that torsinA, like other AAA+ proteins, has molecular chaperone activity (Caldwell et al., 2003; Burdette et al., 2010). A quantitative readout for endoplasmic reticulum (ER) stress response in the nematode, Caenorhabditis elegans, indicates that torsinA functions as a homeostatic regulator of ER stress (Chen et al., 2010). Likewise, overexpression of human wild-type (WT) torsinA and related invertebrate orthologs can suppress the accumulation of misfolded proteins (McClean et al., 2002; Caldwell et al., 2003). Based on torsinA chaperone activity at the ER, we are interested in exploring its role in neurotransmitter receptor trafficking from ER to plasma membrane in C. elegans. C. elegans tor-2 is a homologue of human torsinA that is expressed in a few neurons in the adult hermaphrodite, including the AVE interneurons. These neurons are responsible for driving backwards movement which is regulated by AMPA type glutamate receptors. Changes in synaptic AMPA receptor levels have been proposed to be a key regulatory event in synaptic plasticity (Wang et al., 2010). Our preliminary data show that tor-2 mutation or pan-neuronal RNAi knockdown of tor-2 in C. elegans caused defects on backwards movement and nose touch response, a phenotype indicative of glutamatergic involvement. We also found that pan-neuronal tor-2 RNAi in C. elegans caused a significant decrease in abundance of the AMPA type glutamate receptor, GLR-1 in the ventral nerve cord. Interestingly, the Human Liver Proteome Project determined that human cornichon 4 physically interacts with torsinA. Cornichons are a family of ER-localized transmembrane proteins) that directly interact with AMPARs immediately after translation in the ER to promote export from the ER and Golgi complex (Haering et al., 2014; Drummond et al., 2012). We propose that TOR-2 activity modulates the trafficking of AMPA-type glutamate receptors and further regulate synaptic excitability in C. elegans.

Expression and distribution pattern of Pnn in ischemic cerebral cortex and cultured neural cells exposed to oxygen–glucose deprivation.
S. Mukda¹, S. Leu²;
¹Research Center for Neuroscience, Institute of Molecular Biosciences, Mahidol University, Nakornpathom, Thailand, ²Institute for Translational Research in Biomedicine, Kaohsiung Chang Gung Memorial Hospital, Kaohsiung, Taiwan

Pnn, a multifunctional protein, participates in embryogenesis as well as in apoptosis, proliferation, and metastasis in tumor cells through regulating gene transcription and mRNA alternative splicing. However,
the role of Pnn in non-dividing cells, particularly regarding stress response, remains unknown. In the present study, we applied primary cultured rat neural cells and mice with middle cerebral artery occlusion (MCAO)-induced ischemic stroke to examine the alternation of Pnn in the stress response to ischemic insults. In cultured primary cortical neurons with normoxia, Pnn is mainly localized in the nuclear speckle. The expression level of Pnn was increased immediately after exposure to oxygen-glucose deprivation (OGD) and then declined in the reoxygenation period. Moreover, the nuclear speckle Pnn was gradually translocated to the cytosol during the reoxygenation period in a time-dependent manner. The apoptosis-associated proteins in the primary cortical neurons were also found to be increased with OGD/reoxygenation. In primary astrocytes, Pnn is localized mostly in the nuclear speckle both under the normoxia and the OGD condition. Unlike that in neurons, the Pnn expression in astrocytes was decreased immediately after OGD and then gradually up-regulated during the reoxygenation period. Three days post induction of ischemic stroke in mice, the neuronal expression of Pnn in the peri-ischemic region was reduced. However, the Pnn expression in astrocytes was not altered. Moreover, the nuclear speckle distribution of Pnn in neurons was also diminished following ischemic stroke. In conclusion, the Pnn expression and distribution after OGD and during reoxygenation showed distinct manner in neurons and astrocytes, implying that Pnn may play different roles in different neural cells in the stress response to ischemic injury.

Human tryptophan hydroxylase-2 expression in S. cerevisiae results in cytotoxicity.
F.A. Mohamed¹, M.P. Torrente¹;
¹Department of Chemistry, Brooklyn College, the City University of New York (CUNY), Brooklyn, New York, NY

Major depressive disorder is a debilitating neuropsychiatric illness that has been projected to affect approximately one in six Americans in their lifetime. Conventional methods of pharmaceutical treatment, most recently including selective serotonin reuptake inhibitors (SSRIs), have been known to ameliorate symptoms; however, these treatments are slow-acting and present a range of side effects. Thus, it is necessary to reevaluate how depression is managed in an effort to develop rapid-acting and robust methods of treatment. Tryptophan hydroxylase-2 (TPH2) has been discovered to be responsible for the majority of serotonin biosynthesis in the mammalian brain, and developing an understanding of this enzyme, its molecular structure, and regulation would be the prime target for novel therapeutic methods. Intriguingly, 300 single nucleotide polymorphisms (SNPs) have been identified in human TPH2 and proven to induce the onset of select neuropsychiatric illnesses, including uni- and bipolar depression. These disease-associated mutations enhance the natural aggregation propensity of TPH2, reducing the pool of functioning TPH2, and consequently, serotonin, in the brain. In order to assess if TPH2 misfolding underlies serotonergic dysfunction, we seek to use S. cerevisiae as a model to screen for cytotoxicity upon exogenous expression of TPH2. We are actively screening three TPH2 galactose-inducible constructs, 303, 416, and 426. The 303 construct is integrating, whereas 416 and 426 are non-integrating. Our yeast spotting assay results thus far have indicated that 416 and 426 yield the greatest cytotoxicity in yeast. We anticipate conducting further study with known TPH2 mutations in order to screen for their cytotoxicity. Developing the molecular characterization of TPH2 will allow us to harness its enzymatic capacity and discover ways to enhance serotonin production in individuals who experience depression and other debilitating neuropsychiatric disorders.

Disruption of Tuba1a leads to neurodegeneration that can be rescued by Mg++.  
G. Buscaglia¹, J.E. Aiken¹, J.K. Moore³, E.A. Bates¹;  
¹Pediatrics, University of Colorado School of Medicine, Aurora, CO, ²Cell and Developmental Biology, University of Colorado School of Medicine, Aurora, CO

In neurons, the microtubule network stabilizes axons and dendrites, and facilitates protein trafficking. Mutations that disrupt the TUBA1A α-tubulin isotype cause developmental brain malformations. Indeed, we showed that an Asparagine to Aspartic acid substitution at residue 102 (Tuba1aND) results in developmental brain abnormalities and perinatal death in homozygous Tuba1aND mice. Our data from yeast and mice showed that the Tuba1aND mutation compromises the stability of microtubules. Interestingly, mice heterozygous for this mutation (Tuba1aND/) develop abnormal motor phenotypes as adults, suggestive of neurodegeneration, despite apparently normal brain development. Microtubule networks are lost and disorganized in many neurodegenerative diseases, but it is not clear whether microtubule dysfunction causes neurodegeneration or is a result of loss of neuron health. Our data suggests that compromising microtubule function can cause neurodegeneration. The Tuba1aND/+ mutation is located adjacent to a magnesium (Mg2+) binding site in alpha tubulin and Mg2+ stabilizes αβ-tubulin heterodimers. We demonstrate that Mg2+ supplementation can partially attenuate the Tuba1aND/+ motor phenotypes. Therefore, we can manipulate the scale of microtubule dysfunction within the brain at different developmental and post-developmental time points using Mg2+. The Tuba1aND allele allows us to dissect the mechanism of microtubule function in neurodegeneration.

Leucine rich glioma activated 1 (LGI1) is a neuronal protein that forms a trans-synaptic bridge linking pre- and post-synaptic transmembrane proteins (ADAM22 and ADAM23) and helps to organize a multimeric complex at the synapse including AMPAR and voltage-gated potassium channels [1]. LGI1 autoimmune encephalitis is a severe neuropsychiatric disorder related to epilepsy. It is an antibody-mediated pathogenesis where the patients produce autoantibodies against LGI1, which alter synaptic plasticity. However, the molecular mechanisms that lead to the observed problems in patients still remain largely unknown. To elucidate early molecular changes at the synaptic level in LGI1 encephalitis, we used multi-color super-resolution microscopy (STORM) [2]. Using well-characterized synaptic markers (Homer and Bassoon) as molecular standards, we determined the positioning of LGI1 and 4 other related proteins (AMPA, ADAMS and voltage-gated potassium channels) within the synaptic space at nanoscale resolution. Further, we compared this molecular architecture in healthy neurons.
versus neurons treated with antibodies from patients suffering from LGI1 autoimmune encephalitis. Our results show that LGI1 auto-antibodies impact the nanoscale organization of pre-synaptic proteins, while the post-synaptic protein organization is more subtle. These results suggest a loss of LGI1 interaction with pre-synaptic proteins upon antibody binding and give further insight into early changes in pathology.

The anti-N-methyl-D-aspartate receptor (NMDAR) autoimmune encephalitis is a neuropsychiatric disorder mediated by NMDAR autoantibodies. Patients’ antibodies cause NMDAR internalization but the early events at the synaptic level that lead to the depletion of surface NMDARs are poorly understood. Here, using super-resolution microscopy and Monte Carlo simulations, we studied the effects of NMDAR autoantibodies on the nanoscale distribution of NMDAR subpopulations. Our results show an early, antibody-induced clustering of synaptic and extrasynaptic receptors. This clustering is subunit specific and mainly affects GluN2B-containing NMDARs. Following receptor internalization, the remaining surface NMDARs return to control clustering levels but are preferentially retained at the synapse. These results are recapitulated by Monte Carlo simulations if a model is considered by which antibodies induce NMDAR cross-linking and disruption of NMDAR-protein interactions within and outside the synapse. Finally, activation of ephrin-B2 receptor partially restores the nanoscale surface distribution of NMDARs.

Autism is a genetically complex neurodevelopmental disorder in which patients exhibit social deficits in verbal and non-verbal forms of communication and display restricted and repetitive behaviors. Emerging evidence suggests that altered neural connectivity, particularly at the level of synaptic connections, contributes to disease pathology. Dynamic rearrangements of the actomyosin cytoskeleton drive neural circuit formation, including neurite extension and the development of actin-enriched spines at excitatory synapses. Actomyosin regulatory pathways are also one of the major molecular mechanisms disrupted by both Autism-associated copy number variants (CNVs) and de novo mutations. Yet, it is still unknown how actomyosin regulation shapes developing cortical circuits and the impact of specific actomyosin regulatory pathways on Autism pathology. To understand the cytoskeletal
mechanisms that lead to altered neural circuitry in Autism, we develop cortical brain organoids from patient induced pluripotent stem cells (iPSC). Our Autism-derived cortical organoids exhibit increased excitatory synapse formation, similar to post-mortem patient samples and mouse models of Autism. To address whether myosin-II activity contributes to this observed increased in excitatory synapse area, we acutely treated 3-month old neurotypic cortical organoids with the RhoA kinase (ROCK) inhibitor, Y-27632. We confirmed that Y-27632 treatment reduced ROCK-driven myosin-II activation in the cortical organoids through reduced phosphorylation of the myosin regulatory light chain (RLC) at Ser19. Intriguingly, acute Y-27632 treatment mimicked Autism pathology by significantly increasing excitatory pre-synaptic surface area as labeled by vGlut-1. We hypothesize that a corresponding increase in synaptic Rac1 activity mediates this increase in excitatory synaptic surface area. In support of this hypothesis, we observe increased phosphorylation of the Rac1 downstream target, coflin, at Ser3 in Y-27632-treated cortical organoids. These results suggest that Rac1 activity dysregulation could be a driving mechanism underlying Autism synaptic pathology, leading us to investigate which Rac1 activity regulators are present during cortical development. For example, in neurotypic cortical organoids, we found that the Rac1 inactivator, ArhGAP23, is enriched at excitatory synapses. Through the use of a human cortical organoid model, we demonstrate that coordinated myosin-II and Rac1 activity underlie excitatory synapse development, and that alterations in the balance between these actomyosin pathways can promote Autism pathology.

**Remodeling of the postsynaptic plasma membrane during neural development.**

K. Tulodziecka¹, B.B. Diaz-Rohrer², N.M. Waxham¹, I. Levental³;

¹Integrative Biology and Pharmacology, University of Texas Health Science Center at Houston, Houston, TX

Neuronal synapses are the fundamental units of neural signal transduction, and must maintain exquisite signal fidelity while also accommodating the plasticity that underlies learning and development. To achieve these goals, the molecular composition and spatial organization of synaptic terminals must be tightly regulated; however, little is known about the regulation of lipid composition and organization in synaptic membranes. Here, we quantify the comprehensive lipidome of rat synaptic membranes during post-natal development and observe dramatic developmental lipidomic remodeling during the first 60 post-natal days, including progressive accumulation of cholesterol, plasmalogen, sphingolipids, and lipid containing w-3 polyunsaturated fatty acids (e.g. DHA). Further analysis of membranes associated with isolated post-synaptic densities (PSDs) suggests the PSD-associated post-synaptic plasma membrane (PSD-PM) as one specific location of synaptic remodeling. We analyze the biophysical consequences of developmental remodeling in reconstituted synaptic membranes and observe remarkably stable microdomains, with the stability of domains increasing with developmental age. Remarkably similar changes were observed during in vitro development of cultured hippocampal neurons, suggesting a cell-autonomous program for developmental lipidomic remodeling in neurons. Disruption of lipidomic remodeling leads to reduced efficiency of synaptogenesis. We rationalize the developmental accumulation of microdomain-forming lipids in synapses by proposing a mechanism wherein palmitoylation of the immobilized scaffold protein PSD-95 nucleates domains at the postsynaptic plasma membrane. These results reveal developmental changes in lipid composition and palmitoylation that facilitate the formation of post-synaptic membrane microdomains, which may serve key roles in function of the neuronal synapse.

Competition in the postsynaptic density for PDZ domains of PSD-95.
T. Mastro¹, A. Preza¹, P. Kind², M.B. Kennedy¹;
¹Biology and Biological Engineering, Caltech, Pasadena, CA, ²Centre for Integrative Physiology, The University of Edinburgh, Edinburgh, United Kingdom

Molecular mechanisms of synaptic plasticity are of great interest because derangement of synaptic plasticity contributes to neural diseases such as autism, schizophrenia, cognitive impairment, neuropathic pain, epilepsy, and stroke. This work addresses the molecular mechanisms underlying NMDA-type glutamate receptor-triggered plasticity at excitatory synapses. A critical step in this process is a change in the rate of trapping of AMPA-type receptors (AMPARs) in the postsynaptic density (PSD), which increases the number of AMPARs and strengthens the electrical signal at the synapse. Our work aims to determine whether trapping of AMPARs in the PSD is mediated by rearrangement of the PSD scaffold caused by changes in the affinity of different PSD proteins for the PDZ domains of the major synaptic scaffold protein, PSD-95. Our earlier publication (1) supports this notion by showing that: 1. Phosphorylation of the abundant PSD protein synGAP by CaMKII reduces its affinity for the PDZ domains of PSD-95; and 2. The composition of the PSD is altered in synGAP deficient mice such that AMPAR-binding proteins with PDZ ligands, including TARPs and LRRTM2, are increased in concentration relative to PSD-95. We have now replicated these finding in synGAP-deficient rats. These findings suggest that the extent of binding of particular synaptic proteins to the PDZ domains of PSD-95 is regulated by activity-dependent phosphorylation of synGAP. We are testing this hypothesis in cultured rat neurons. We have isolated PSDs from neuronal cultures before and after induction of synGAP phosphorylation by pharmacological activation of NMDARs. The ratios of AMPAR-associated proteins to PSD-95 in the PSDs are determined by quantitative immunoblotting. We have found that the ratio of TARPs to PSD-95 is consistently increased in PSDs after chemical activation of synaptic NMDARs. We are using cultures from synGAP-deficient rats to determine if synGAP deficiency alters the composition of the PSD in rat cultures. We plan to transfect with a variety of synGAP mutant proteins in order to determine which domains or phosphorylation sites on synGAP are important for regulating PSD composition.

Nuclear Factor One (NF1)-Dependent Developmental Program Directs the Timing of Gene Expression in Maturing Neurons.
B. Ding¹, P. Dobner¹, D. Kilpatrick¹;
¹Dept. of Microbiology and Physiological Systems and Program in Neuroscience, University of Massachusetts Medical School, Worcester, MA, ²Dept. of Molecular Biology, University of Texas Southwestern Medical Center, Dallas, TX

Developmental timing mechanisms play an essential role in nervous system development, and their disruption during synapse maturation is implicated in neurodevelopmental disorders. To examine how the timing of gene expression related to synapse formation is regulated during neuronal maturation, we used cerebellar tissues from gene knockout mouse and lentiviral transduction of mouse cerebellar
granule neuron (CGN) cultures together with microarray, qRT-PCR, chromatin immunoprecipitation, immunocytochemistry and immunohistochemistry assays. We found that Nuclear Factor One (NFI) regulates the temporal expression of genes required for dendrite and synapse formation via its delayed binding to their promoters in developing CGNs. Further, several other regulatory factors of NFI-dependent developmental program were also identified. (1) Calcineurin/NFAT signaling pathways suppress the program at early development stage via preventing NFI occupancy of late mature genes. (2) Transcription factor ETV1 direct binds to and is required for the NFI occupancy and expression of target genes, including ETV1 itself. This sequential transcription factor interactions and subsequent binding to downstream promoters form an auto-regulatory loop to rapidly upregulate mature gene expression at a critical developmental window. (3) Neurotrophin BDNF induced phosphorylation and accelerated the departure of the trans-repressor NFATc4 from NFI late-gene promoters, accelerating the initial onset of NFI binding in early maturing CGNs. BDNF dismissal of NFATc4 from late-genes was linked to MEK5/ERK5-dependent sequestration of NFATc4 in the cis–Golgi. These results reveal a developmental timing mechanism for dendrite/synapse gene expression in maturing neurons. NFI temporal occupancy together with Calcineurin/NFAT signaling pathways, ETV1, BDNF and NFATc4 extra-nuclear sequestration form an auto-regulatory gene network and precisely regulate the temporal gene expression in maturing neurons.

Determining the molecular basis of ultrafast endocytosis.
Y. Imoto¹, Q. Gan¹, L. Mamer², S. Markert³, I. Milosevic⁴, P. De Camilli⁵, C. Rosenmund⁶, E. Jorgensen⁶, S. Watanabe³;
¹Department of Cell Biology, John Hopkins University School of Medicine, Baltimore, MD, ²Institute of Neurophysiology, Charité Universitätsmedizin Berlin, Berlin, Germany, ³Division of Electron Microscopy, University of Würzburg, Würzburg, Germany, ⁴European Neuroscience Institute, Goettingen, Germany, ⁵Departments of Neuroscience and Cell Biology, Program in Cellular Neuroscience, Neurodegeneration and Repair, Kavli Institute for Neurosciences, Howard Hughes Medical Institute, Yale University School of Medicine, New Haven, CT, ⁶Department of Biology, University of Utah, Salt Lake City, UT

Ultrafast endocytosis is a novel clathrin-independent endocytic pathway that recycles synaptic vesicles under physiological conditions. In mouse hippocampal neurons, vesicle membrane is retrieved within 100 ms after fusion via this endocytic pathway. However, molecular mechanism underlying ultrafast endocytosis remains elusive. To reveal molecular mechanisms, we coupled molecular perturbation with flash-and-freeze approach that visualizes membrane dynamics in electron micrographs with millisecond temporal resolution. Our data have shown that actin polymerization is required for the initial membrane curvature. The transition from shallow to deep pits is mediated by synaptojanin, phosphatidylinositol phosphate phosphatase. This transition requires the conversion of plasma membrane PI4,5P2 to PI4P. The steep negative curvature at the base of the endocytic pit is then stabilized and further constricted by endophilin. Finally, Dynamin-1 severs the vesicle from the plasma membrane. Furthermore, pharmacological inhibition of lipid binding of Dynamin-1 does not abolish ultrafast endocytosis, suggesting that the PH domain may be dispensable for ultrafast endocytosis. Thus, despite its speed, ultrafast endocytosis is mediated through coordinated actions of multiple proteins.

Long-term adaptation of G-protein signalling in the brain is facilitated by active G-proteins' feedback control of the amount of RGS proteins.
M.E. Fina1, S.R. Tummala2, N. Vardi3, A. Kashina4, D.W. Dong1,3,4;  
1Biomedical Sciences, University of Pennsylvania, Philadelphia, PA, 2Department of Bioengineering, University of Pennsylvania, Philadelphia, PA, 3Department of Neuroscience, University of Pennsylvania, Philadelphia, PA, 4Institute for Biomedical Informatics, University of Pennsylvania, Philadelphia, PA

Regulation of G-protein signaling is essential for the brain. This regulation is mediated primarily by a class of proteins called Regulators of G-protein Signaling (RGS). With two dozens of RGSs regulating thousands of G-protein signaling cascades, this regulation mechanism is involved in virtually every known physiological process and plays a major role in neural signal processing. Much of what we know about RGS is derived from the retina. In the first stage of visual processing, RGS9 accelerates the recovery of photo-transduction in both rods and cones. In the second stage, RGS7 and RGS11 accelerate the light-on response of majority of bipolar cells—the Depolarizing Bipolar Cells. For a given receptor activity, decreasing or increasing the amount of RGS proteins leads to more or less active G-proteins, respectively. This allows the signal transduction to change the overall gain without the need to change other components of the cascade. This regulation is believed to be especially important during long-term adaptation such as from daylight to night vision. Much less known is what mediates the change of RGS levels during long-term adaptation. Recent data on dark adaptation in rods and light adaptation in rod bipolar cells indicate that a long-term decrease in a ligand's stimulation of a G-protein signaling cascade should lead to a decrease of RGS protein level in the cascade, and vice versa. Using knockout mouse models, we showed that the decrease of the amount of active G-proteins lead to the decrease of RGS7 and RGS11 level in rod bipolar cells. Therefore the RGS protein level and the active G-protein level reach a steady state through their feedback interactions, after a long-term adaptation to a given receptor activity. We developed a computational model of the feedback regulation of G-protein signaling cascades, which provides an over arching principle that reconciles a lot of controversial data in the literature and explains G-protein-dependent regulation in a variety of biological systems.

The role of the sub-complex α-syntrophin and α-dystrobrevin on the stability of postsynaptic AChR dynamics at the NMJ.
I. Martinez-Pena1, P. Chen1, M. Akaaboune1,2;  
1Molecular Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI, 2College of Sciences and Engineering, Life Science Division, Hamad Bin Khalifa University, Doha, Qatar

The sub complex α-syntrophin and α-dystrobrevin, components of the dystrophin glycoprotein complex, is critical for the stability of the neuromuscular junction. Mice deficient in either α-syntrophin (α-syn-/-) or α-dystrobrevin (αdbn-/-) exhibit severe abnormal synaptic phenotypes, including a dramatic decrease in the postsynaptic receptor density (more than 70% of AChRs are lost), high turnover rate of AChRs, and abnormal synaptic structure. In contrast to muscles deficient in α-syntrophin, muscles deficient in α-dystrobrevin show ~ 50% of muscular dystrophy. Here, we wanted to investigate whether both genes could act in parallel or within similar signaling pathways on the maturation and maintenance of synaptic structure. Analyses of NMJs of asyn+-/- αdbn+-/- heterozygous mice showed that the number/density of AChRs, turnover rate of AChRs, and synaptic structure are normal, similar to wild
type NMJs. Analyses of homozygous double mutant αsyn/-/αdbn/- showed that the abnormal synaptic phenotype of NMJs (abnormal synaptic structure, ~ 70% of AChRs are reduced with a high turnover rate) is no more severe than the synaptic phenotype of NMJs deficient in either α-syn/- or α-dbns/- alone. When α-dbns-GFP was electroporated into mice deficient in α-syntrophin, the synaptic phenotype was partially restored. However, electroporation of α-syntrophin into mice deficient in α-dystrobrevin has no effect on the abnormal synaptic phenotype. Altogether these results suggest that α-syntrophin and α-dystrobrevin work within the same pathway and that α-syntrophin acts upstream of α-dystrobrevin in the sequential recruitment of proteins involved in postsynaptic AChR stability.

Spontaneous rhythmic electrical activity of the tentacular apparatus of Mnemiopsis leidyi.
G. Dong1, A.G. Moss1;
1Biological Sciences, Auburn University, Auburn, AL

Ctenophores have attracted considerable attention regarding their role in the evolution of nervous systems (JEB 218:598); yet we know little about their nervous systems due to limited electrophysiological data. Previous studies of Pleurobrachia pileus (Phil Trans Roy Soc B339:1) demonstrated an afferent integrative center within the tentacular bulb. The present study used extracellular recording to examine the electrical activity of tentillae and tentacular bulb of Mnemiopsis leidyi. We found spontaneous slow trains of robust biphasic action potentials (0.1-0.3 mV, 0.25-1 spike s⁻¹) in tentilla where they arise from the tentacular bulb of adult animals. Similar rhythmic firing (0.02-0.04 mV, 0.5-1 spike s⁻¹) was observed in tentacles of 4 mm pre-metamorphic cydippid larvae, i.e. bearing only two tentacles and no lobes. Lesion analysis of excised bulb/food groove complexes mapped distributed bioelectrical activity in the oral region of adults based on electrophysiological recordings from multiple locations. This effort reveals that spontaneous rhythmic spiking originated in the aboral end of the bulb. We further demonstrate through paired electrode recording, that rhythmic spiking is conducted into the food groove tentillae at approximated speed of 0.149 m s⁻¹. To our surprise, to date we have not been able to evoke propagated action potentials by application of food (Artemia nauplii), mechanical or electrical stimulation in this region of the nervous system, in adults. In conclusion, we report here for the first time that spontaneous rhythmic action potentials likely originate inside the tentacular bulb of M. leidyi and propagate into the embedded tentillae. Surprisingly, our results are in contrast to those of Moss and Tamm with P. pileus: P. pileus bulb does not exhibit spontaneous firing, yet responded to the application of food and electrical stimulation to the tentacle with trains of short duration volleys in the tentacle, that in turn drove oscillatory slow wave activity in the bulb. Although Moss and Tamm showed that oscillator activity occurs in the P. pileus bulb that can be driven by exogenous input, our data here indicate that in M. leidyi, there is a central oscillator that drives spontaneous rhythmic activity in the bulb. Future efforts will focus on the cellular source(s) of the signal, the local circuit activity, the signal conduction pathway, its chemical neurotransmitter sensitivity and its sensory and/or motor functions. Support: NSF EPS-0447675 and Chinese Scholarship Council (GD).
Sleep is an evolutionarily conserved and vital behavior. For a period of inactivity to be defined as sleep, it must be regulated by both circadian and homeostatic factors, result in an increased arousal threshold, and occur when the organism is in a restful posture. Drosophila melanogaster exhibits sleep-like states both during the day and at night making it an ideal genetic model to investigate the mechanisms of sleep. To investigate potential glial requirements for sleep and rhythmicity, a Translating Ribosome Affinity Purification (TRAP) screen was performed to identify astrocyte-enriched genes, which were then tested for those that affected rhythmicity. One of the identified genes is CG14141, hereafter referred to as Noktochor (Nkt, sleepless in Bengali). Nkt has both a neuronal and a glial requirement for night sleep. NKT protein has a single Ig domain and is predicted to be secreted. Based on genetic experiments, the neuronal requirement can be localized to the αβ' Kenyon cells of the mushroom body, an anatomical locus known to be required for memory and sleep. Knockdown of Nkt expression in the αβ' Kenyon cells in an Rdl1 GABA receptor mutant background enhanced the night sleep phenotype, suggesting that GABA signaling is involved in the neuronal requirement of NKT for night sleep. In contrast, Rdl1 partially suppressed the glial Nkt knockdown phenotype, suggesting that glial and neuronal NKT act on distinct sleep circuits. Current studies are focused on the signaling mechanisms through which NKT regulates sleep.

Ctenophores have recently attracted much attention because several multigenetic molecular analyses proposed Phylum Ctenophora to be the sister taxon to all other animals (Science 342:1242592; Nature 510:109). The common Western Atlantic ctenophore Mnemiopsis leidyi is currently the object of intense ecological and physiological study. The tentacular apparatus of ctenophores is critical to feeding and very likely bears a diversity of sensory functions. The tentacular apparatus is composed of the tentacular bulb and affiliated tentacles or tentilla, which undergoes profound changes during metamorphosis during development of the adult ctenophore. Previous studies of the cydippid Pleurobrachia pileus suggest that the tentacular bulb is an integrative center for afferent signals arising from the distal tentacle (Trans Roy Soc B 339:1). EdU analyses for cell proliferation in P. pileus revealed a broadly diffuse flow of cells from an aboral proliferation zone (Dev Biol 350:183). The tentacular apparatus of adult cydippid and lobate ctenophores are superficially similar but as we show here, are morphologically distinct. Here, we use correlative light and electron microscopy in conjunction with fine extracellular probe recording (c.f. Dong et al., this meeting) to demonstrate structure/function relationships within the M. leidyi tentacular bulb. All preparations were fixed by modification of the method of Tamm and Tamm (Cell Tiss Res. 264:151) with careful attention to osmolarity, followed by infiltration and embedment in Spurr’s Resin. Cryosectioning (Reichert 2800N) established the general outline, thereby providing a noncollapsed scaffold against which to overlay images from 0.25 μm semi-thick light microscopy and TEM of an entire tentacular bulb (~3 mm long). This method revealed several surprising
features throughout the bulb. Selected major features include: 1) unattached oral end of the bulb, including the canal; 2) what we interpret as a food absorptive layer of cells, confirming a recent report (Curr Biol 26:2814); 3) A distinct structural feature that we interpret to be bulb neuropile; 4) A region of tentillar longitudinal fission and growth (TLFG) that moves laterally to either side of the bulb to ‘feed’ tentillar structure within the feeding groove; 5) fluorescence microscopy of Hoechst-stained live tentilli reveals numerous nuclei along the length of each tentillum, providing support for the concept that the tentilli are multicellular structures; and 6) a variety of unknown cell types at different stages of differentiation. The role of DNA repair factors in developing and maintaining proper neurotransmission in Caenorhabditis elegans.
B. Mares1, J. Trujillo1, T. Li2, H. Ando2, M. Li1; 1Biology, New Mexico Highlands University, Las Vegas, NM, 2Biological Sciences, University of Alaska Anchorage, Anchorage, AK

In eukaryotes, genetic information is stored in DNA and thus, genome stability is essential for health of the cells. In reality, DNA is constantly attacked by various sources such as free radicals, UV, and chemicals. Each mutagen can cause damage to nucleotides in DNA and may produce mutations. To repair DNA damage and avoid accumulation of mutations, numerous DNA repair enzymes and pathways exist in eukaryotic cells.

DNA repair defects result in genome instability, carcinogenesis, accelerated aging and cell death. In addition, mutations of DNA repair genes are known to cause neurological disorders in humans. Based on our findings in yeast DNA repair, we began C. elegans research project to explore novel roles of DNA repair in neurogenesis and neurodegeneration. Our neuropharmacological assays revealed that four DNA repair factors and nucleases are indispensable for proper neurotransmission. Because these factors are highly conserved throughout evolution, our research outcome would contribute to understanding mechanisms of human neurological diseases and disorders.

Investigation of the FSHR-1 Receptor as a Potential Substrate of the Anaphase-Promoting Complex at the C. elegans Neuromuscular Junction.
D. Emch1, K.L. Cherry1, A. Godfrey1, A. Munneke1, E. Damler1, J.R. Kowalski1; 1Biological Sciences, Butler University, Indianapolis, IN

Healthy nervous system function requires a balance of excitatory and inhibitory (E:I) signaling. E:I balance relies upon ubiquitination, a process performed by the ubiquitin signaling system (USS). The USS employs a series of enzymes, including E3 ubiquitin ligases, which recognize and transfer ubiquitin molecules onto bound substrates, marking them for degradation or altering their localization or function. However, substrates of the hundreds of E3 ligases remain unknown. Proper function of neuronal ubiquitin ligases and their substrates is needed for regulation of E:I balance. Our previous data showed that one highly conserved ubiquitin ligase, the Anaphase Promoting Complex (APC) regulates E:I balance at the C. elegans neuromuscular junction (NMJ), a specialized synapse where muscle

Tuesday-320
contraction is regulated by excitatory motor neurons that release acetylcholine and inhibitory motor neurons that release GABA. At the C. elegans NMJ, the APC acts in GABA motor neurons to promote GABA release and prevent excess muscle contraction. However, substrates of the APC mediates its effects at this synapse are unknown. Here, we are testing the hypothesis that the conserved G protein-coupled receptor, Follicle Stimulating Hormone Receptor 1 (FSHR-1), is a substrate of the APC critical for normal NMJ signaling in C. elegans. FSHR-1 is found in the intestines and nervous system and regulates germline cell differentiation, stress responses, and innate immunity. FSHR-1 possesses a D-box sequence, a motif often recognized by the APC. Loss of function (LoF) fshr-1 mutants exhibit decreased muscle contraction and suppress the increased muscle contraction seen in APC LoF mutants, indicating FSHR-1 may act downstream of the APC at the NMJ. Current work is focused on analyzing the biochemical relationship between FSHR-1 and the APC and determining the cell types in which FSHR-1 is endogenously expressed and where it acts to control NMJ signaling. Preliminary imaging identified FSHR-1 expression in one pharyngeal neuron subclass, but further imaging is required. Rescue experiments indicate FSHR-1 expression in GABA or cholinergic neurons is sufficient to restore near wild type muscle contraction. We are now generating C. elegans strains expressing fluorescently tagged versions of FSHR-1, in which we will quantitatively measure changes in neuronal FSHR-1 concentrations when the APC is rendered non-functional. If FSHR-1 is an APC substrate at the NMJ, then APC LoF mutants should exhibit increased levels of neuronal FSHR-1 compared to wild-type worms. E:I imbalances are responsible for many neurological diseases, so a better understanding of the APC and its substrates may provide insight into the mechanisms behind diseases like Huntington’s and epilepsy.

RhoA activity regulates spine morphology and memory associated behavior.
K. Kuroda¹, X. Zhang², K. Oda¹, Y. Nakanose¹, M. Yoshikawa¹, T. Nagai², K. Kaibuchi³;
¹Cell Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan, ²Clinical Pharmacy, Nagoya University Graduate School of Medicine, Nagoya, Japan

A dendritic spine is assumed to play an important part in formation of memory, for it changes its shape or size depending on synaptic input. Rho family GTPase is a small GTP-binding protein, which regulates cytoplasm through actin cytoskeleton. Rho family is assumed to mediate spine morphology from studies in vitro. However it is still unclear what Rho family GTPase actually do to spine morphology in vivo. To elucidate this problem, we establish in vivo experimental system to express targeted protein in specific cell types by combining Cre-Flex system with Adeno Associated Virus (AAV) injection. We succeeded to express RhoA and compare dendritic spine morphology in D1 receptor expressing-medium spiny neuron (MSN) at NAc (Nucleus Accumbens). Dendritic spines shaped into broad head and short neck in constitutively active RhoA (RhoA-CA) expressing MSN, on the other hand, spines shaped into long neck in dominant negative RhoA (RhoA-DN) expressing MSN. Then we investigated behavioral phenotype of RhoA using cocaine-induced conditioned place preference (CPP) test. We confirmed their place preference was increased in RhoA-CA expressing mouse. These results suggest that dendritic spine morphology affected by RhoA activity enhances place memory in vivo.

A molecular mechanism underlying retinogeniculate convergence in mouse visual thalamus.
A. Monavarefsani\textsuperscript{1,2}, G. Stanton\textsuperscript{3}, J. Su\textsuperscript{4}, K. Su\textsuperscript{5}, J. Van Name\textsuperscript{6}, M.A. Fox\textsuperscript{7,8};
\textsuperscript{1}Virginia Tech Carilion Research Institute, Virginia Tech, Roanoke, VA, \textsuperscript{2}Biological Sciences, Virginia Tech, Blacksburg, VA

For decades, it has been thought that feature-specific visual information (e.g. color, direction, contrast, etc.) is transferred through unmixed, parallel channels from retina to visual thalamus, and then to the cortical visual centers. To avoid mixing such feature-specific information in the thalamus, each thalamic relay cell must receive inputs from only a small number of functionally similar retinal ganglion cells (RGCs). However, in contrast to this long-held belief, a high degree of RGC convergence onto the thalamic relay cells has recently been reported by several groups. This includes cellular level convergence, in which dozens of functionally distinct RGCs converge onto one relay cell, and a subcellular levels of convergence, in which axons from as many as a dozen distinct RGCs converge onto the same region of a relay cell dendrite, forming a synaptic structure called complex retinogeniculate (RG) synapse. Here, we sought to identify molecules that contribute to the development of complex RG synapses and retinal convergence in the visual thalamus. RNAseq analysis identified Leucine-Rich Repeat Transmembrane Neuronal 1 (LRRTM1) as target-derived synaptic organizer enriched in visual thalamus, but not other retinorecipient nuclei, during the emergence of complex RG synapses. To test its role in RG synapse development, we assessed RG synapses in targeted mutant mice lacking LRRTM1 (lrtrtm1/-) using serial block-face scanning electron microscopy (SBFSEM) and AAV-brainbow circuit tracing. Both analyses revealed a significant reduction in the number of complex RG synapses in visual thalamus of lrtrtm1/- mice. Since lrtrtm1/- mutants have reduced retinal convergence (without defects in other aspect of retinofugal circuitry), we used these mutants to address the functional significance of RG convergence. While these mutants exhibited normal responses to simple visual tasks in a two alternative forced swim task, they performed poorly in more complex tasks. These studies, therefore, reveal, for the first time, a significant role for retinothalamic convergence in visual function.

VER/VEGF receptor-related proteins regulate GLR-1/GluR1 surface levels and control behavior.
E.S. Luth\textsuperscript{1}, C. Riccio\textsuperscript{1}, J. Hofer\textsuperscript{1}, K. Markoja\textsuperscript{1}, P. Juo\textsuperscript{1};
\textsuperscript{1}DMCB, Tufts University School of Medicine, Boston, MA

The dynamic restructuring of glutamate synapses provides the cellular basis of learning and memory. Failure to properly form or maintain glutamate synapses can lead to a variety of neurological disorders, and controlling their abundance and activity is critical for maximizing functional recovery after stroke. However, the molecular mechanisms that regulate the formation and function of these connections in vivo during normal nervous system development are not well understood. Expression of channelrhodopsin in the glutamatergic sensory neuron ASH\textsuperscript{1} of C. elegans enabled us to combine optogenetic control of a simple glutamate-dependent behavior, the nose-touch response (NOT), with a focused RNAi screen to identify genes important for glutamate synapse function. RNAi knockdown of \textit{ver-1} or \textit{ver-4}, VEGF receptor homologs\textsuperscript{2}, resulted in a strong defect in ASH-stimulated glutamate-dependent locomotor reversals, but did not affect overall glutamate-independent locomotion based on thrashing assays. Analysis of loss of function mutants confirmed these RNAi results. The intensity and density of the presynaptic vesicle marker RAB-3::mCherry, expressed specifically in ASH, was unaltered...
in ver mutants. In contrast, GLR-1::GFP glutamate receptor puncta in the nerve ring and ventral nerve cord of ver mutants was altered, consistent with a defect in GLR-1 clustering. Confocal imaging of GLR-1 tagged with both mCherry and pH-sensitive superecliptic pHluorin (SEP::mCherry::GLR-1)\(^3\) indicated that ver mutants exhibit a preferential loss of cell surface GLR-1 and likely act downstream of UNC-11/AP180-mediated endocytosis to control receptor recycling. Both the NOT behavior and GLR-1 trafficking defects in ver mutants were restored by specific expression of VERs in GLR-1 expressing interneurons. Mutants lacking the VER ligand PVF-1\(^4\) also exhibited NOT defects and similar reductions in cell surface GLR-1 levels, suggesting that ligand binding may be required for VER activity in this system. Together, our data identify VER-1, VER-4 and their ligand as novel regulators of GLR-1 trafficking and signaling in C. elegans. Future experiments will identify the subcellular site of action of VERs and the mechanism by which PVF-1/VER signaling regulates GLR-1 trafficking.

Calcium and Calcineurin-Dependent Regulation of CaMKII Targeting to Inhibitory Synapses.
M. Malkowski\(^1\), M. Fauzan\(^1\), Z. Minas\(^1\), A. Pittar\(^1\), R.C. Carroll\(^1,2\);

Calcium/calmodulin dependent kinase II (CaMKII) plays a central role in regulating synaptic strength in the central nervous system (CNS) and is an essential mediator of processes underlying learning and memory. It has been well-established that translocation of activated CaMKII to excitatory synapses drives NMDA receptor-dependent long term potentiation at those sites. Our previous studies have found that CaMKII can also translocate to, and potentiate, inhibitory synapses; although under different stimulus conditions than those inducing excitatory LTP. An unresolved question remains as to how CaMKII can be selectively targeted to inhibitory, and not nearby, excitatory synapses upon activation. This study examined the role of two factors controlling CaMKII targeting and modulation of inhibitory synapses: the nature of the calcium stimulus driving selective translocation and the role of calcineurin in regulating this translocation. Pharmacological stimuli that have been found to drive CaMKII to excitatory synapses generated larger calcium elevations in cortical and hippocampal neurons than those that enhanced CaMKII localization at inhibitory synapses. To examine whether differences in the magnitude of calcium stimuli alone are sufficient to differentially target CaMKII to synapses, photolytic calcium caging was employed. Stimuli that generated larger calcium signals were found to localize CaMKII to excitatory synapses, with lesser calcium signals driving CaMKII to inhibitory synapses. More physiological stimuli were also found to drive CaMKII to inhibitory synapses. One Hz field stimulus-driven neuronal activity induced a moderate rise in calcium that enhanced CaMKII localization at inhibitory synapses and potentiated inhibitory currents. Additional studies examined the role of the phosphatase calcineurin, also known to affect both excitatory and inhibitory synaptic transmission, on CaMKII targeting to inhibitory synapses. Results suggest that calcineurin activity acts to restrict CaMKII from localizing to inhibitory synapses and may serve to help maintain selective targeting of the kinase to synapses.

\(^1\)NIH/NICHD, Bethesda, MD

Assembly, maintenance and function of synaptic junctions depend on extracellular matrix (ECM) proteins and their receptors. Here we report that Tenectin (Tnc) is an ECM component required for the structural and functional integrity of synaptic specializations at the Drosophila neuromuscular junction (NMJ). Tnc, a large Mucin-type protein with RGD motifs, is secreted from motor neurons and from striated muscles and accumulates in the synaptic cleft. Using genetics, electrophysiology, histology and electron microscopy, we found that Tnc selectively recruits the \(\alpha PS2/\beta PS\) integrin at synaptic terminals. In \(tnc\) mutant larvae, the levels of \(\alpha PS2/\beta PS\) integrin are significantly reduced at perisynaptic locations, adjacent to the postsynaptic densities; however, the \(\alpha PS2/\beta PS\) integrin are not disrupted at the muscle attachment sites. Our tissue specific knockdown and rescue studies revealed that the Tnc/integrin complexes have distinct pre- and postsynaptic functions: the presynaptic complexes control neurotransmitter release, while postsynaptic complexes ensure the architectural integrity of synaptic boutons. Specifically, the \(tnc\) deprived NMJs have less individualized synaptic boutons with drastically reduced levels of postsynaptic integrin, as well as \(\alpha\)-Spectrin. Electron micrographs captured a sparse SSR at \(tnc\) mutant NMJs, similarly to that observed in mutants with reduced postsynaptic \(\alpha\)-Spectrin. These results suggest that Tnc stabilizes the boutons architecture partly engaging integrin and spectrin complexes. Our ongoing work focuses on Tnc function in the organization of presynaptic active zones. We found that a mutation that abolishes spectrin dimerization, hence the formation of the spectrin-based membrane skeleton (SBMS), recapitulates the vesicle release defects seen at \(tnc\) mutant NMJs. This indicates that the SBMS is critical for the normal release of synaptic vesicles. We are currently investigating a role for Tnc/integrin complexes in the recruitment and/or anchoring of SBMS in the vicinity of presynaptic active zones. These complexes may provide a structural network that organizes the presynaptic active zones and regulates neurotransmitter release.

Neto - the obligatory subunit of glutamate receptors, functions in both pre- and post-synaptic compartments to enable synapse development and homeostasis at the Drosophila neuromuscular junction.  
T. Han\(^1\), C.I. Ramos\(^1,2\), R. Vicidomini\(^1\), Q. Wang\(^1\), M. Jarnik\(^1\), M. Serpe\(^1\);  
\(^1\)NICHD, NIH, Bethesda, MD, \(^2\)Institut de Genomique Fonctionnelle de Lyon, Lyon, France

Synapse development is a highly orchestrated process coordinated by intercellular communication between the pre- and postsynaptic compartments, and by neuronal activity itself. Here we use the Drosophila NMJ as a model system for glutamatergic synapse development to dissect the mechanisms of synapse assembly and homeostasis. In flies as in mammals, neuron arrival at its target muscle triggers formation of large synaptic aggregates of ionotropic glutamate receptors (iGluRs), and promotes expression of more iGluRs to permit synapse maturation and growth. We have recently discovered the obligatory auxiliary protein, Neto, essential for iGluRs clustering and NMJ functionality. Neto belongs to a family of highly conserved auxiliary proteins that regulate glutamatergic synapses. Drosophila neto encodes two isoforms, Neto-\(\alpha\) and Neto-\(\beta\), with different cytoplasmic domains, generated by alternative

Tuesday-324
splicing. The cytoplasmic domains are rich in putative phosphorylation motifs and docking sites and are highly divergent among Neto proteins probably reflecting cell/tissue specific roles. Our previous studies revealed that Neto isoforms (i) engage in extracellular interactions that stabilize iGluRs at synaptic sites and trigger postsynaptic differentiation, and (ii) differentially modulate the iGluRs function and gating properties. In addition, Neto-β, the predominant isoform at the fly NMJ, mediates intracellular interactions that anchor postsynaptic density (PSD) components and sculpt iGluRs postsynaptic composition. In the absence of Neto-β, the NMJs are short, with enlarged boutons, and drastically reduced levels of type-A iGluRs. Nonetheless, these mutants have normal evoked potentials due to a robust presynaptic compensatory response. In contrast, our recent studies indicate that loss of Neto-α (which represents <10% of the total Neto pool) induces mild NMJ defects, but significantly reduced basal neurotransmission. We report that Neto-α functions in both pre- and postsynaptic compartments at the Drosophila NMJ. In the absence of Neto-α, the glutamate receptors fields/ PSDs appear enlarged and the sharp boundaries between PSDs and Dlg/PSD-95 are lost. Knockdown and rescue experiments indicate that presynaptic, and not postsynaptic, Neto-α modulates neurotransmitter release. In addition, neuronal Neto-α is required for synapse homeostasis. Chronic or acute/pharmacological reduction of postsynaptic iGluRs activities trigger increased presynaptic release in control, but not in neto-α null mutants, or in animals where Neto-α is perturbed in the presynaptic compartment. Our studies demonstrate that Neto proteins function in both motor neurons and muscles to enable synapse assembly and to coordinate synapse development and function.

Vesicular transporters heterogeneity regulates vesicle dynamics, localization and synaptic transmission in mouse central synapses.
L. Guillaud1, E. Abdelmoneim1, D. Dimitrov1, T. Takahashi1;
1Cellular and Molecular Synaptic Function Unit, Okinawa Institute of Science and Technology, Onna-son, Japan

At excitatory synapses, vesicular glutamate transporters (VGLUTs) are essentially thought to play a role in the refilling of neurotransmitter into synaptic vesicles (SVs). We have recently demonstrated that over-expression of 2 different isoforms, VGLUT1 and VGLUT2, can confer distinct dynamic properties to SVs in cultured giant presynaptic terminals. However, the functional significances of these different vesicle dynamics remained to be clarified. Here we show that upon co-expression of fluorescently labelled VGLUT1 and VGLUT2 in same terminals, SVs can be sorted into at least 2 different pools: VGLUT1-containing vesicles with high mobility and VGLUT2-containing vesicles with lower mobility. In physiological conditions, proximity ligation assay also revealed that VGLUT1-containing vesicles localized more efficiently to release sites than VGLUT2-containing vesicles. Electrophysiological recording and synapto-phluorin imaging finally demonstrated that VGLUT1 over-expression increases synaptic transmission and vesicle recycling compared to VGLUT2 over-expression. Thus, we propose that VGLUTs heterogeneity might contribute to the regulation of synaptic transmission by modulating vesicle dynamics and trafficking, and controlling their accessibility to active zones.

A role for the calcium-activated protease calpain in the regulation of netrin-1/DCC-mediated cortical axon outgrowth.
P.M. Duquette1, D. Im2, D. Park3, N. Lamarche-Vane3;
1Anatomy and Cell Biology, Research Institute of the MUHC, Montreal, QC, 2Cellular and Molecular Medicine, University of Ottawa, Ottawa, ON

During embryonic development, neurons extend axons towards their appropriate synaptic targets to establish functional neuronal circuits. The growth cone, a highly motile structure at the axon tip, is capable of recognizing extracellular guidance cues and translating them into directed axon outgrowth through modulation of the actin cytoskeleton. The netrin family of guidance cues is vital for proper neuronal pathfinding. In particular, netrin-1 mediates its attractive function through the receptor deleted in colorectal cancer (DCC), which recruits proteins to mediate axon outgrowth and guidance. The calpain family of cysteine proteases is well known for its role in cleaving cytoskeletal proteins leading to cell death while playing a vital role in adhesion turnover during cell migration. Less is known about its role during brain development although some studies have highlighted its importance in the formation and maintenance of dendritic spines, and axon outgrowth. Here we identified DCC as a novel calpain substrate and we analyzed its role in the netrin-1/DCC signaling pathway during axon outgrowth. We found that calpain was able to cleave DCC in vitro. Calpain proteolysis of cytoskeletal targets is a mechanism of regulation of neurite consolidation and protrusive activity in neurons. We assessed calpain-specific spectrin cleavage, and found that netrin-1 activated calpain in embryonic cortical neurons in an Erk1/2-dependent manner. Furthermore, we demonstrated that netrin-1 stimulation promoted cleavage of DCC within the same time-frame of calpain and ERK1/2 activation. Interestingly, netrin-1-mediated Erk1/2 activation was abolished in calpain-1/2-deficient cortical neurons dissociated from Nestin-Cre;Capns1fl/fl embryos compared to control neurons. However, DCC expression was not unaffected in calpain-deficient cortical neurons. Using another calpain-specific substrate t-BOC that links calpain activity to fluorescence intensity in live cortical neurons, we showed that netrin-1 stimulated calpain activity in live cortical neurons. Interestingly, cortical neurons overexpressing calpastatin displayed longer neurites. Using an siRNA approach to diminish both calpain-1 and calpain-2 expression, neurons with reduced calpain expression also displayed longer axons and were unresponsive to netrin-1 stimulation. Altogether, we propose a novel model whereby netrin-1/DCC-mediated axon outgrowth is modulated by calpain-mediated proteolysis of DCC and cytoskeletal targets.

Calcineurin substrate protein supports reproduction and neurite caliber development by acting like the KSP domain of human neurofilament medium subunit (NEFM) in Caenorhabditis elegans.
H. Jung1,2,3, S. Durnaoglu1,2,3, Y. Hahn4, J. Ahnn1,2,3, S. Lee1,2,3;
1Department of Life Science, Hanyang University, Seoul, South Korea, 2Research Institute for Natural Science, Hanyang University, Seoul, South Korea, 3BK PLUS Life Science for BDR Team, Hanyang University, Seoul, South Korea, 4Department of Life Science, Chung-Ang University, Seoul, South Korea
Repeats in amino acid sequence confer proteins specialized structure and function, playing a critical role in evolution of proteins. The KSP repeats of neurofilament medium subunit (NEFM) regulate axonal diameter and neuronal conduction in myelinated axons through molecular extension mediated by phosphorylation. The number of the KSP repeats exhibits a positive correlation with larger axonal diameter in larger animals among some mammalian species. However, how different numbers of KSP repeats determine cellular structure and function has not been fully examined. Here, we report that a calcineurin substrate protein CNP-2 is contains a KSP-like repetitive sequences rich in Lys (K), Arg (R), Ser (S), Thr (T), Pro (P), and Glu (E), which are frequently found in proteins that display flexible architectural features. cnp-2 is highly expressed in extensively elastic tissues such as the spermatheca, the spermathecal-uterus valve, and male tail. Also, cnp-2 is critical for both hermaphrodites and male reproductive processes. Bioinformatics analyses and experiments in transgenic worms revealed that the KSP repeat domain of unc-89/obscurin (a giant sarcomeric signaling protein) is functionally homologous with CNP-2, although it is distantly related and shows low sequence similarity and identity. In addition, expression of KSP repeats from human NEFM reversed reproduction defects in cnp-2 worm mutants in a repeat-number-dependent manner; a greater number of KSP repeats showed more efficient effects with respect to morphology and activity. Taken together, the data suggest that cnp-2 be a KRSTPE-rich repeat protein that share common features with the KSP repeats of NEFM, including regulatory molecular extension to support inter-molecular interactions, and contractile and elastic cellular structures. This study also provides insight into how alterations in the number of amino acid repeats may play a role in the determination of cellular morphology and function as a molecular mechanism contributing to the evolution of species-specific traits.

Neurofilament transport impairment precedes microtubule-neurofilament segregation in axons treated with 3,3'-iminodipropionitrile (IDPN).
J. Fenn1,2, P.C. Monsma2, A. Brown1;
1Medical Scientist Training Program, Ohio State University, Columbus, OH, 2Department of Neuroscience, Ohio State University, Columbus, OH

Neurofilaments are space-filling protein polymers that are particularly abundant in large axons, where they are known to increase nerve conduction velocity by expanding axonal caliber. In addition to this structural role, neurofilaments are also cargoes of axonal transport, moving forwards and backwards along microtubule tracks in a rapid but intermittent manner. This movement is significant clinically because disruptions in neurofilament transport are thought to give rise to the abnormal neurofilament accumulations observed in neurological diseases such as amyotrophic lateral sclerosis (ALS), Charcot-Marie-Tooth disease, and hereditary spastic paraplegia, as well as in toxic neuropathies such as those induced by 2,5-hexanedione and 3,3'-iminodipropionitrile (IDPN). Intriguingly, ultrastructural studies on axons in these neuropathies have revealed a striking cytoskeletal segregation in which neurofilaments are displaced to the axon periphery surrounding a central bundle of microtubules and organelles, in sharp contrast to healthy axons in which neurofilaments and microtubules are intermixed. In addition, radioisotopic pulse labeling studies on laboratory rats have shown that IDPN selectively impairs neurofilament transport without affecting the transport of membranous organelles. Using computational modeling, we showed previously that this segregation can be explained by a disengagement of neurofilaments from their microtubule tracks, combined with a “zippering together” of the microtubules by moving organelles that engage simultaneously with two or more microtubules. This model predicts that neurofilament transport impairment precedes segregation. To test this, we
have characterized the time course of neurofilament segregation and transport impairment in adult mice exposed to IDPN. Segregation was analyzed by immunofluorescence microscopy of axonal cross-sections and transport was analyzed using the pulse-escape fluorescence photoactivation technique in peripheral nerves of Thy1-PAGFP-NFM transgenic mice, which express a photoactivatable fluorescent neurofilament protein in neurons. Our data confirm the time-dependent and dose-dependent segregation of axonal neurofilaments and microtubules induced by IDPN and show that neurofilament transport impairment precedes the segregation. This indicates that the impairment of neurofilament transport by IDPN is not simply a consequence of neurofilament separation from their microtubule tracks. These studies establish IDPN treatment as an experimentally tractable model of neurofilament accumulation in disease, and pave the way for future studies that will address the mechanisms of neurofilament transport disruption and neurofilament accumulation in disease.

Chemical and mechanical signals interact to direct axon guidance.
S.K. Foster¹, K. Franze¹;
¹Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, United Kingdom

During brain development, growing neurons navigate through a highly complex environment as they extend towards their synaptic targets. This process of axon pathfinding is controlled by a complex suite of guidance cues. Studies of axon pathfinding have focused primarily on chemical guidance signals; however, neurons also sense and respond to local tissue stiffness. To test how chemical and mechanical cues are integrated, we studied how substrate mechanics affects the response of Xenopus laevis CNS neurons to the chemical guidance cue Semaphorin3A (Sema3A). Neurons grown on soft substrates similar in stiffness to Xenopus brain tissue exhibited significantly less Sema3A-induced collapse as well as a reduced turning angle in response to a Sema3A gradient compared with neurons grown on stiffer substrates. Both calcium dynamics and cyclic GMP levels - critical regulators of Sema3A signalling - were elevated on soft substrates, and pharmacological studies further indicate that cGMP levels play an important role in the stiffness-dependent modulation of the Sema3A response. Investigating how neurons integrate different signals in complex environments will help us to better understand axon guidance during development and regeneration.

ALS-linked mutations increase the viscosity of liquid-like axonal TDP-43 RNP granules in neurons.
P.P. Gopal¹,², J.J. Nirschli³, E. Klinman³, E.L. Holzbaur³;
¹Physiology, University of Pennsylvania, Philadelphia, PA, ²Pathology and Laboratory Medicine, University of Pennsylvania, Philadelphia, PA

Ribonucleoprotein (RNP) granules, liquid-like non-membrane bound structures, are enriched in specific RNAs and RNA binding proteins (RBPs) and mediate critical cellular processes. Purified RBPs can form liquid droplets in vitro through liquid-liquid phase separation. Mutations in human RBPs, TDP-43 and FUS, are linked to ALS/FTD, but the biophysical properties of these proteins have not been studied in neurons. Whether neuronal TDP-43 RNP granules are liquid-like, and how their liquid droplet properties contribute to physiological and pathologic processes is unknown. Here we show that TDP-43 RNP
granules in the axons of primary cortical neurons display liquid-like properties, including fusion events with rapid relaxation to circular shape, shear stress-induced deformation, and rapid fluorescence recovery after photobleaching. Moreover, wild type (WT) neuronal TDP-43 RNP granules exhibit distinct motility characteristics and biophysical properties depending on their location along the axon. Mid axonal TDP-43 RNP granules are highly dynamic, motile, and susceptible to disruption by 1,6-hexanediol, suggesting they are held together by weak hydrophobic interactions. Accordingly, mid axonal TDP-43 granules show a high degree of internal molecular mobility as well as rapid exchange with the soluble pool of TDP-43. In contrast, proximal TDP-43 granules show decreased motility and partial fluorescence recovery after photobleaching, suggesting that they have a more limited mobile fraction. Unlike mid axonal TDP-43 granules, proximal granules are not susceptible to disruption of weak hydrophobic interactions. Thus, proximal TDP-43 granules appear to be more biophysically complex and display some liquid-like properties but also may have more viscous and/or stabilized regions. These data demonstrate diversity of neuronal RNP granules that may reflect different maturational states. Furthermore, disease-linked TDP-43 mutant granules display slower half-bleach recovery and increased viscosity compared to TDP-43 WT, indicating that the mutations alter the biophysical properties of the granules in neurons. TDP-43 M337V and G298S granules show slower tau values and incomplete fluorescence recovery compared to TDP-43 WT granules. In addition, TDP-43 mutant granules show an order of magnitude increase in viscosity compared to WT granules; these altered biophysical properties may confer toxic gain of function through increased propensity for pathologic transformation. Our data suggest that RNP granules must be studied within the complex morphology of neurons in order to fully appreciate their physiologic roles and the pathologic transitions of these structures in neurodegenerative disease.

*Nox2 is involved in retinotectal connections in developing zebrafish embryos.*

A. Terzi¹, C.J. Weaver¹, H.S. Roeder¹, T.M. Gurol¹, Q. Deng¹, Y. Leung¹, D.M. Suter¹;

¹Biological Sciences, Purdue University, West Lafayette, IN

The generation of precise neuronal connections during both development and regeneration of the nervous system requires growing axons to find their correct synaptic targets. This process is mediated by the neuronal growth cone that is located at the tip of growing axons and senses the environment through molecular and physical cues. Nicotinamide adenine dinucleotide phosphate (NADPH) oxidases (Nox) are multi-subunit transmembrane proteins that generate superoxide and secondarily hydrogen peroxide (H₂O₂), which both have important signaling functions. These reactive oxygen species (ROS) regulate central nervous system development, including neuronal progenitor cell maintenance, neuronal differentiation, cerebellar development, neuronal polarity, and neurite outgrowth. However, it is unclear whether Nox derived-ROS regulate axonal growth and guidance in *vivo*. To address this problem, we have investigated Nox function in the development of retinotectal connections in zebrafish embryos. Inhibition of Nox enzymes in zebrafish embryos by a chemical inhibitor, Celastrol, decreased optic nerve thickness and tectal innervation by retinal ganglion cell (RGC) axons while increasing the width of the ganglion cell layer (GCL). Next, we have established Nox isoform-specific knockouts by CRISPR/Cas9 genome editing in order to identify the specific isoform required for axonal growth and guidance along the retinotectal pathway. *nox2* mutant embryos exhibited an increased and disorganized GCL as well as mistargeted RGC axons in optic tecta. Imaging embryos expressing the H₂O₂ -specific biosensor roGFP2/orp1 revealed that *nox2* mutant embryos have higher basal ROS levels in the eye compared to wild type embryos, suggesting that *nox2* deletion could be over-compensated by other Nox isoforms. Lastly, *in vitro*, cultured RGCs exhibited Nox2-dependent axonal outgrowth.
controlled by slit2 and netrin-1. In summary, these results suggest an important role for Nox2 function in the development of retinotectal connections.

TRIMming neurons: TRIM9 and TRIM67 modulate neuronal morphogenesis.
S. Menon¹, B. Major¹, S.L. Gupton¹;
¹Cell Biology and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC

We identified the closely related neuronally-enriched E3 ubiquitin ligases TRIM9 and TRIM67 as key regulators of the membrane trafficking and cytoskeletal dynamics underlying neuronal morphogenesis. In particular TRIM9 and TRIM67 are individually critical for embryonic cortical neurons to respond appropriately to the extracellular axon guidance cue and morphogen netrin-1. Our published studies also show that TRIM9 is required for appropriate morphogenesis, migration, and synaptogenesis in adult-born neurons in the dentate gyrus of the hippocampus. As deletion of Trim9 or Trim67 results in striking behavioral deficits, including spatial learning and memory deficits, these results indicate that TRIM9 and TRIM67 are master regulators of the form and function of developing embryonic and adult-born neurons. We hypothesize this involves their ligase activity; identification of their interacting partners and/or ubiquitination substrates will better reveal how cytoskeletal dynamics and membrane trafficking are regulated downstream of the ligases. We have found that the actin polymerase VASP and the netrin receptor DCC are ubiquitinated in a TRIM9-dependent fashion, whereas the exocytic tSNARE SNAP25 interacts with TRIM9, but is not ubiquitinated in a TRIM9 dependent fashion. Here we describe a two-pronged unbiased proteomic approach to identify additional putative interaction partners and ubiquitination targets of TRIM9 and TRIM67 from murine embryonic cortical neurons. In the first, we exploit the proximity-dependent biotin identification (BioID) approach, a technique in which biotin is covalently ligated to proteins proximal to a protein of interest, such as substrates or interaction partners, which are then identified by affinity purification and mass spectrometry. The second strategy exploits the DiGly antibody, which recognizes an epitope on ubiquitinated peptides revealed by trypsin digestion, to identify proteins differentially ubiquitinated in the presence and absence of TRIM ligases or the axon guidance cue netrin-1. The overlap of proteins identified by these two distinct approaches: proteins in close proximity to the ligases, that are differentially ubiquitinated in their presence, represents high priority candidates for substrates. Results from these approaches have identified high priority candidate interaction partners and/substrates, that are potential regulators of cytoskeletal dynamics or exocytosis, which may function downstream of netrin-DCC signaling in developing neurons. We use immunoprecipitation and ubiquitination assays to validate candidates. Time-lapse TIRF microscopy of fluorescently tagged candidates then reveals alterations in candidate localization or behavior caused by netrin stimulation or deletion of Trim9 or Trim67.
Investigation of the Roles of Novel Endogenous Ligand of Aryl Hydrocarbon Receptor in Neural Development.

P. Chuang¹, Y. Chan¹, P. Wu², P. Chen³, H. Lee¹;
¹Department of Life Science, National Taiwan University, Taipei City, Taiwan, ²Institute of Cellular and Organismic Biology, Academia Sinica, Taipei City, Taiwan, ³Department of Agricultural Chemistry, National Taiwan University, Taipei City, Taiwan

Activation of aryl hydrocarbon receptor (AHR) by xenobiotic toxic chemicals such as 2,3,7,8-tetrachlorodibenzo-p-dioxin regulates a variety of cellular processes including embryogenesis, tumorigenesis and inflammation. However, the identity of endogenous AHR ligands remains elusive. A potential AHR ligand, compound X, was identified from zebrafish embryos using previous developed cell free bioassay for dioxin-like compounds. In this study, we aim to investigate the effect of compound X in AHR activation and further explore its physiological effects. Compound X induces AHR translocation into nucleus and upregulates downstream cytochrome P450 1A1 (CYP1A1) in vitro. It also promotes neuronal differentiation in neuroblastoma (NB) cells, which is consistent with our previous studies that overexpression of AHR leads to NB cells differentiation. Furthermore, compound X enhances zCyp1a, myelin-associated myelin basic protein (zMb) and SRY (sex determining region Y)-box 10 (zSox10) expression and improves the mobility of zebrafish larvae via Ah2 pathway. Therefore, our results suggest that compound X is an endogenous AHR ligand, and plays a critical role during neural differentiation.

Responses of cultured mouse cerebral cortical axons to netrin-1 depending on developmental stages: outgrowth and collateral branching starting with filopodial protrusion.

H. Matsumoto¹, M. Nagashima¹;
¹Department of Anatomy, Saitama Medical University, Saitama, Japan

Netrin-1, a multifunctional axon guidance cue, elicits axon outgrowth via one of its receptors DCC (deleted in colorectal cancer) in several types of neurons, including cerebral cortical neurons of embryonic mice. However, we and others have observed de novo formation of axon branches without axon outgrowth induced by netrin-1 in cortical culture of neonatal hamsters. These previous reports suggested the possibility that netrin-1 function might alter during development. We tested this possibility employing dissociated culture prepared from cerebral cortices of embryonic mice.</p>

Morphometric imaging analysis revealed netrin-1-induced outgrowth in embryonic day (E) 14 axons and netrin-1-induced branching in E16 axons. Morphometric analysis also showed netrin-1-evoked filopodial protrusions sprouted on the shafts of E16 axons in advance of branch formation. These netrin-1-dependent filopodial protrusions were better visualized by a novel method called atmospheric scanning electron microscopy. By contrast, netrin-1-independent protrusions were observed in E14 axons. Since E14 axons exhibited not only high density of pre-existing filopodial protrusions but also high density of spontaneously developed axon branches under basal conditions, and correlation analysis revealed that longer axons had lower density of branches in E14 axons with and without netrin-1 treatment, it is possible that netrin-1-dependent axon outgrowth is a factor in decreasing the density of branches in E14 axons. Treatment with an anti-DCC function-blocking antibody affected not only axon outgrowth but also axon collateral branching and preceding filopodial protrusion.
conclusion, we showed two distinct functions of netrin-1 in mouse cerebral cortical neurons in vitro—promotion of axon outgrowth, and promotion of axon collateral branching that involves filopodial protrusion from the shafts. As netrin-1 exhibited one of these two functions depending on the stage of embryos utilized for cortical culture, our study raised the possibility of a shift in netrin-1 function during cortical development. Our study also suggested that a netrin-1 receptor DCC may contribute to both of cortical axon outgrowth and collateral branching starting with filopodial protrusion. This work was supported by Japan Society for the Promotion of Science (JSPS) KAKENHI Grant Numbers JP23590225 and JP26460282 (Grants-in-Aid for Scientific Research (C)).

Unraveling the role of microenvironment topography on cortical interneuron migration using microfabricated substrates.

C. Leclech1,2, C. Villard2, C. Métin1;

1INSERM U839 Institut du Fer à Moulin, Paris, France, 2UMR168 Institut Curie, Institut Pierre-Gilles de Gennes, Paris, France

During embryonic brain development, cortical interneurons (INs) migrate long distances before integrating into cortical circuits. This migration step is crucial since its dysfunction can lead to the abnormal positioning of INs and to the formation of defective cortical circuits, likely responsible for neuropsychiatric diseases at adulthood. During their migration, INs cross different territories with complex chemical and physical properties. Several diffusible molecules that guide the migration of INs have been identified, but little is known about the contacts and interactions of INs with their close physical microenvironment.

**The aim of this study is to better understand how physical parameters of the environment, especially its topography, can influence the migratory behavior of INs.** This process of contact guidance has already been reported in the migration of non-neural cells and in the navigation of growing axons, but never in migrating neurons.

To address this question, we used microfabrication techniques to build PDMS migration substrates with a precisely controlled micro-topography. On these substrates coated with adhesion molecules (laminin and n-cadherin), we were able to culture, observe and record embryonic INs exhibiting a physiological migration for several hours in between the nucleus-sized structures.

With this system, we first showed that the area of migration of INs cultured on a substrate of regularly spaced pillars, either squared or round, is significantly increased when compared with the area of migration of INs cultured on a flat substrate.

In addition, by precisely analyzing the dynamic behavior of individual cells, their orientation and morphology, we observed that the shape of the structures (either square or round pillars) specifically influenced the morphology and the behavior of migrating INs. In particular, we noticed a robust alignment of cells amongst square pillars, where INs grow long, straight and unipolar leading processes.

We showed that this topography was able to efficiently guide INs migration: directional phases are stabilized and cells are more dynamic. On the contrary, round pillars promoted growth cone splitting and leading process branching.

**Migrating INs are therefore able to respond precisely and differently to distinct geometries of their close microenvironment, by specific dynamic and morphological transformations.** These results highlight the importance of the spatial arrangement of adhesive cues in the microenvironment to achieve directed neuronal migration and overall unravel a new, important role of topographical cues in the developing brain.

HDAC6 inhibition puts the brake on axon growth and microtubule invasion into peripheral growth cone.
N. Riiexinger¹, E. Gorney¹, D. Kaur¹, A. Altman¹, E.W. Hogan¹;
¹Biology, Canisius College, Buffalo, NY

In the peripheral domain of growth cones, interactions between F-actin and dynamic microtubules influence growth cone behavior and direction of axon advance. Our previous research suggested that decreasing acetylated microtubule (AcMT) levels in the axon accelerates growth cone advance by promoting invasion of dynamic MTs into the leading edge of growth cones. Here, we tested whether increasing AcMT levels in neurons would affect axon growth and microtubule dynamics. To increase the amount of AcMTs, we used tubacin, a cell-permeable inhibitor of HDAC6, an enzyme that removes acetyl groups from MTs. Analysis of cultured Helisoma neurons exposed to tubacin and subsequently stained with antibodies for acetylated tubulin showed inhibition of HDAC6 resulted in increased microtubule acetylation within the axon and cell body. Using time-lapse DIC microscopy, we found that tubacin treatment decreased the rate of growth cone advance, central domain advance, and axon advance compared to the same neuron prior to treatment. Treatment with niltubacin, an inactive analog of tubacin, did not affect growth cone behavior. Analysis of microtubule distribution within growth cones showed tubacin treatment decreased the percent of microtubules that extended into the growth cone periphery, suggesting tubacin suppressed microtubule dynamics. The inverse relationship between axonal AcMTs and dynamic growth cone MTs may reflect a role for AcMTs in regulating the distribution of MT plus end tracking proteins (+TIPS).

Activity-Dependent Modulation of Neuronal Proliferation and Differentiation in Cultured Chick Olfactory Neurons.
A.I. Kennedy¹, G. Gomez¹;
¹Biology Department, The University of Scranton, Scranton, PA

The olfactory system regenerates and produces mature neurons from non-neuronal precursors through an endogenous differentiation pathway. However, we have previously shown that differentiation of olfactory neurons can be modulated by odor stimulation: exposure to stimulatory odorants induces acquisition of structural and functional neuronal properties in cultured embryonic chick olfactory neurons. The mechanism by which odors promote neuronal differentiation remains unclear. It is known that cyclic adenosine monophosphate (cAMP) serves as a second messenger for odor signal transduction, and is thus a prime candidate for pharmacological manipulation to directly activate the signal transduction machinery. Thus, to determine if differentiation can occur in the absence of odorant stimulation, elements of the cAMP signaling cascade were directly manipulated. Cultured olfactory neurons from an 18-day old chick embryo were exposed to either an adenyl cyclase activator (forskolin) or adenyl cyclase inhibitors (MDL-12,330A or SQ 22,536) for 12-hour periods daily for five days. Neuron differentiation was determined using immunocytchemistry to stain for olfactory marker protein (stains structurally mature neurons only), Golf (stains functionally mature olfactory neurons), and -tubulin III (stains both mature and immature neurons). Our data suggest that direct activation of adenyl cyclase with forskolin increases the number of neurons but does not drive structural or
functional maturation. Inhibition of the cyclase has no effect on neuron proliferation or differentiation. These results suggest that direct activation of adenylyl cyclase upregulates neuron production, but that modulation of olfactory maturation requires stimulation of the odorant receptors themselves, implying the involvement for the activation of additional cellular elements. Our results have important implications for the study of the environmental influence on neuron development and differentiation.

The mitochondrial Rho-GTPase, Miro, is resident at peroxisomes and regulates peroxisomal trafficking.
C. Covill-Cooke¹, G. López-Doménech¹, J.T. Kittler¹;
¹Neuroscience, Physiology and Pharmacology, UCL, London, United Kingdom

Peroxisomes are single-membrane bound organelles with a multitude of functions, including reactive oxygen species metabolism, fatty acid β-oxidation and lipid biosynthesis. Patients lacking peroxisomes (Zellweger syndrome) die within the first year of life, emphasising the requirement for functional peroxisomes in cellular health. To ensure optimal functionality of peroxisome-dependent processes throughout the cell they must be trafficked; however, how peroxisomes undergo intracellular transport remains poorly characterised. Here we identify Miro, an outer mitochondrial membrane protein that is critical for mitochondrial trafficking, as a novel regulator of peroxisomal motility. We find that further to their mitochondrial localisation, Miro1 and Miro2 are localised at peroxisomes and that signalling through the first GTPase domain of Miro1 is important for peroxisomal targeting. Additionally, we find that Miro interacts with the cytosolic peroxisomal-membrane-protein chaperone Pex19, suggesting direct insertion of Miro into the peroxisome membrane from the cytosol. Utilising Miro1 and Miro2 double knockout mouse embryonic fibroblasts we show that loss of Miro leads to a significant decrease in peroxisomal motility. Coupled to this, in the absence of Miro peroxisomes are less elongated leading to a reduction in peroxisome size. These results contribute to our fundamental understanding of peroxisomal trafficking and morphology and support a complex crosstalk between peroxisomes and mitochondrial biology.

Cycling clouds of actin filaments regulate mitochondria size and distribution in mitotic cells.
A.S. Moore¹, J.J. Nirschl¹, C.L. Simpson¹², E.L. Holzbaur¹;
¹Department of Physiology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA, ²Department of Dermatology, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

In mammalian cells, mitochondria form interconnected networks that fragment prior to cell division to allow for segregation of mitochondrial mass between daughter cells. Equitable partitioning of mitochondria is critically important to prevent bottleneck effects and the potential expansion of deleterious mitochondrial DNA mutations. To date, the precise mechanism regulating mitochondria inheritance remains controversial. Previous work from our lab identified a dynamic, rotating cloud of actin filaments propagating through interphase mitochondrial networks. We observed that actin clouds move in a continuous manner, cycling onto and off of subpopulations of mitochondria, transiently inducing fission. Here, using HeLa cells and primary epidermal keratinocytes, we find that mitochondrial...
actin cycling persists through all stages of the cell cycle, but is markedly upregulated at the G2/M transition. Specifically, we observe that mitochondrial actin clouds cycle nearly three times faster in mitotic cells (interphase: 1049±201 sec/cycle; m-phase: 384±87 sec/cycle). Consistent with this observation, we find that mitotic actin clouds are 2.86 times larger, 183% faster, and display a stronger bias for persistent, unidirectional motility as compared to interphase clouds. Enhanced cycling may be dependent on CDK1, as inhibition of the mitotic kinase with either ro3306 (20µM, 1h) or CGP74514a (10µM, 1h) robustly blocks actin cloud formation. We observe that rapidly transiting mitotic actin clouds have profound effects on mitochondrial network organization. In prometaphase, actin clouds promote and maintain mitochondrial fragmentation. In metaphase, cycling actin filaments induce microtubule-independent motility of mitochondria which ensures homogenous distribution of mitochondria in both xy and z planes. Finally, in telophase, we observe selective actin assembly on mitochondria localized to the cleavage furrow. Based on these observations, we hypothesize that mitochondrial actin clouds function as a mechanism to fragment and symmetrically partition mitochondria during cell division.

Understanding the enhanced mitochondrial fusion capabilities of a Mitofusin 2 mutant allele.
N.B. Samanas1, S.C. Hoppins1;
1Biochemistry, University of Washington, Seattle, WA

A healthy mitochondrial network is vital for proper cellular function and is maintained through the opposing forces of mitochondrial fusion and division. While our understanding of mitochondrial division has been advanced by numerous studies, mitochondrial fusion occurs through a still largely unknown mechanism distinct from that of vesicle fusion or viral fusion. The protein machinery responsible for mitochondrial fusion includes the large GTPase proteins Mitofusin 1 and 2 (Mfn1 and Mfn2, respectively). This study aims to add to the understanding of the molecular mechanism of mitochondrial outer membrane fusion using disease-associated mutant alleles. Multiple disease-causing Mfn2 mutants are able to rescue mitochondrial fusion in Mfn2-null cells, indicating that a lack of fusion is not the only mechanism by which these alleles cause disease and leading to the question of how Mfn2 mutants may alter Mfn2 function without rendering the protein inactive. Previous studies have shown that mitochondrial fusion requires mitochondrial membrane potential, mitofusin proteins present on both opposing mitochondria, hydrolysis of GTP, and assembly of the mitofusin proteins. We have characterized one mutant form of Mfn2, Mfn2C390R, which appears to meet at least some of these requirements. When expressed with Mfn1, Mfn2C390R is able to fuse mitochondria in cells and in a cell-free in vitro mitochondrial fusion assay. Unexpectedly, this form of Mfn2 can fuse mitochondria in vitro even under restrictive conditions such as low temperature or no added nucleotide, which has not been reported before. We further assayed whether this enhanced fusion ability is due to a difference in assembly state of Mfn2. Indeed, our data suggest that Mfn2C390R forms different assemblies than Mfn2WT and that these assemblies may be due to increased affinity of Mfn2C390R for Mfn1. Although Mfn2C390R removes a cysteine from the protein, there does not appear to be any difference in disulfide bond formation between Mfn2WT and Mfn2C390R, indicating that changes in disulfide bonds do not contribute to the changes in assembly state of Mfn2C390R. We propose that this disease associated mutation makes fusion by Mfn2 more promiscuous, which may alter mitochondrial function by compromising quality control.

Mitofusin-2 mediated mitophagy and mitochondrial networking dynamics regulate the mesodermal differentiation of human pluripotent stem cells.

S. Krantz, L. Wang, P. Toth, G. Marsboom, J. Rehman;
1Pharmacology, University of Illinois at Chicago, Chicago, IL

Pluripotent stem cells reprogram their metabolism from predominantly glycolysis towards enhanced mitochondrial oxidative phosphorylation during differentiation in order to adapt to the metabolic needs of the mature differentiated state. To optimize mitochondrial function for this process, mitochondria elongate and form fused networks, thus allowing for the exchange of proteins and mitochondrial DNA. Mitochondrial damage results in mitochondrial autophagy or mitophagy during which mitochondrial networks fragment and damaged mitochondria marked for degradation. Importantly, a key mediator for both mitochondrial network formation and mitophagy is the GTPase Mitofusin 2 (Mfn2), located at the outer mitochondrial membrane. While Mfn2 has been shown to affect metabolism in heritable disease, its role in regulating the bioenergetics of stem cells is not fully understood. We hypothesized that Mfn2-mediated mitophagy and mitochondrial fusion is required for the differentiation of pluripotent stem cells.

Human induced pluripotent stem cells (hiPSCs) were treated with Bone Morphogenetic Protein 4 (BMP4) and CHIR99021 (Wnt activator) for 3 days to induce mesodermal differentiation as evidenced by marked upregulation of the mesodermal transcription factor Brachyury. After three days of differentiation, the mitochondrial networks demonstrated increased fusion as shown by immunofluorescent staining of the mitochondrial membrane protein TOM20 (assessed quantitatively using the Mitochondrial Fragmentation Count, p<0.001), and by a photoactivatable mitochondrial localized GFP in live cells.

To investigate the role of Mfn2 in the bioenergetics of iPSCs, an shRNA Mfn2 construct was transduced into cells. Using the ATP fluorescent biosensor Perceval HR, a significant decrease in the ATP/ADP ratio from 1.26 to 0.85 (p<0.001) was seen after Mfn2 depletion.

Because Mfn2 is also involved in the degradation of mitochondria, the ratiometric pH-sensitive fluorescent biosensor Keima was used and indicated a tripling of baseline autophagy from an autophagy index of 2.7 to 9.7 (p<0.01) within three days of differentiation. To confirm that Mfn2 mediated autophagy to occur, a shRNA construct of Mfn2 was used. Induction of autophagy in the hiPSCs with the mitochondrial inhibitors increased the autophagy index from 0.7 to 3.1. However, cells with shRNA exhibited the same autophagy index as baseline iPSCs showing that Mfn2 mediates autophagy in hiPSCs. These findings suggest that mitophagy and mitochondrial networking are Mfn2-mediated adaptive processes which are required for the metabolic reprogramming of differentiating human pluripotent stem cells.

Role of Septin 9 in mitochondrial fission.

Y. Balachandran, C. Froese, E. Branchard, M. Kim, P.K. Kim, W.S. Trimble;
1Cell Biology, The Hospital for Sick Children, Toronto, ON

Mitochondria are fundamental eukaryotic organelles in which respiration and energy production occur. They are highly dynamic organelles that undergo fission and fusion to create interconnected networks. Regulation of fission and fusion is important for maintaining proper mitochondrial function, morphology...
and abundance, and is critical for cell survival. Though key players such as Drp1, Mff, INF2, and actin have been found to contribute to mitochondrial fission, the exact mechanisms which regulate fission are still being defined. Recently, depletion of SEPT2, which belongs to the Septin family of cytoskeletal GTP binding proteins, was shown to elongate mitochondria, suggesting that SEPT2 was required for fission. Using CRISPR to knockout specific septins in HeLa cells, we have found that knockout of SEPT9 results in a more significant elongation phenotype than SEPT2 KO. SEPT9 localizes to constriction sites along mitochondria where fission occurs. In addition, we have found that p114RhoGEF is activated by binding to SEPT9 and that p114RhoGEF and RhoA, in conjunction with SEPT2, form a complex detectable by co-immunoprecipitation. Moreover, depletion of p114RhoGEF by siRNA, or inhibition of the RhoA substrate ROCK by Y27632, in wild type cells phenocopies SEPT9 knockout, suggesting that activation of ROCK by SEPT9 is critical for fission. In support of this hypothesis, the elongated mitochondrial phenotype in the SEPT9 knockout cells can be rescued by treating cells with RhoA Activator. Together, our results indicate that septins, and particularly SEPT9, regulate mitochondrial fission by local activation of RhoA and ROCK, likely to activate myosin to thereby facilitate the constriction of mitochondria necessary for complete fission.

Mutational analysis of Mitofusin1 and Mitofusin2 reveal distinctive functional properties required for mitochondrial outer membrane fusion.
E.A. Engelhart¹, S.C. Hoppins¹;
¹Biochemistry, University of Washington, Seattle, WA

A dynamic mitochondrial network is essential for both mitochondrial function and a variety of critical cellular pathways including response to stress and apoptotic cell death. In vertebrates, mitochondrial outer membrane fusion is mediated by Mitofusin1 and Mitofusin2 (Mfn), large GTPases of the dynamin related protein family. To gain insight into the poorly understood mechanism of Mitofusin-mediated membrane fusion, we have characterized the activity of Mitofusin mutations etiologically linked to the neurodegenerative disease Charcot-Marie-Tooth (CMT) Syndrome. Here we have characterized the mutation of a highly conserved residue in the GTPase domain that is found in both Mitofusin1 & Mitofusin2 and in the Drosophila homolog, MARF. Despite this level of conservation, the effect of the mutation on mitochondrial fusion activity is highly dependent on context. Cells lacking Mfn1, Mfn2, or both, have a highly fragmented network compared to wild type controls. To determine the effect of the mutation on mitochondrial fusion, we stably express the mutant in null fibroblast cells at levels similar to wild type and score mitochondrial morphology in multiple isolates. When expressed in wild type cells, mutant Mfn1 causes a striking mitochondrial hyperfusion phenotype. In contrast, when expressed alone or with wild type Mfn1, there is no observable change in mitochondrial structure, consistent with no fusion activity. We also observe mitochondrial hyperfusion when the mutant Mfn1 is expressed with wild type Mfn2. These data indicate that the functional differences between Mfn1 and Mfn2 are important to support increased fusion activity. Surprisingly, our analysis of the equivalent mutation in Mfn2 indicate that the mutant does not support hyperfusion, but restores mitochondrial morphology in null cells in a manner that is indistinguishable from wild type. In the mitochondrial outer membrane, Mitofusins form dimers and higher order structures visualized as foci in light microscopy. Although this Mfn1 mutant is also a dimer as determined by sucrose gradient centrifugation, we observe an increased number of foci compared to wild type Mfn1. This is more dramatic when the mutant is expressed in the absence of either wild type Mfn1 or Mfn2. Together, these data indicate that the highly conserved
Mitofusin GTPase domain confers distinct activities on Mfn1 and Mfn2, which can significantly affect the overall rate of fusion in cells.

Mitophagy is a cellular process that selectively removes damaged, old or dysfunctional mitochondria. Defective mitophagy is thought to contribute to normal aging and to various neurodegenerative and cardiovascular diseases. Previous methods used to detect mitophagy in vivo were cumbersome, insensitive and difficult to quantify. We created a transgenic mouse model that expresses the pH-dependent fluorescent protein mt-Keima in order to more readily assess mitophagy. Keima is a pH-sensitive, dual-excitation ratiometric fluorescent protein that also exhibits resistance to lysosomal proteases. At the physiological pH of the mitochondria (pH 8.0), the shorter-wavelength excitation predominates. Within the acidic lysosome (pH 4.5) after mitophagy, mt-Keima undergoes a gradual shift to longer-wavelength excitation. We describe how to apply mt-Keima with stimulated emission depletion (STED) microscopy to visualize mitophagy in various living tissues including skeletal muscle, heart, liver, adipose tissue, and kidney, obtained from mt-Keima transgenic mice. Thus, we can assess this process at nanoscale resolution (50nm) in normal living tissues but also how tissues mitophagy is altered following changes under genetic perturbations, or aging. In addition, we show how to monitor mitophagic flux in living cells exploring mitophagy relationships with other cellular compartments by Hyvolution microscopy via high resolution confocal microscopy combined with deconvolution to achieve resolution of ~120nm of multiple cellular compartments. In conclusion, this approach enable to explore mitochondrial dynamics and mitophagy interconnections in health and disease conditions.

A novel role for RalA during PINK1-Parkin mitophagy.

S.R. Pollock\(^1\), D.F. Kashatus\(^1\);
\(^1\)Department of Microbiology, Immunology and Cancer Biology, The University of Virginia School of Medicine, Charlottesville, VA

Mitochondria have numerous functions that are vital for cellular health, ranging from regulating intracellular calcium levels to generating ATP. Over time, mitochondria become damaged, so they lose their metabolic function and can release pro-apoptotic proteins. Thus, maintaining a healthy pool of mitochondria is critical for overall cellular health. One mechanism of mitochondrial quality control is mitophagy** - the selective removal of damaged mitochondria from the cell. Impaired mitophagy is associated with various pathological conditions, including cancer and neurodegenerative diseases such as Parkinson’s disease. The PINK1-Parkin pathway is one of the best-characterized signaling pathways that regulates mitophagy. Following mitochondrial damage, the kinase, PINK1, accumulates on the outer mitochondrial membrane (OMM). PINK1 accumulation triggers the recruitment of Parkin, an E3 ubiquitin ligase, from the cytosol to the OMM. Parkin recruitment leads to the ubiquitination of outer mitochondrial proteins and recruitment of the autophagy machinery, resulting in mitochondrial clearance. Although PINK1 accumulation is important for Parkin recruitment, it remains unclear how
Parkin relocates to damaged mitochondria. A previous study found that the small GTPase, RalA, recruits Drp1 to facilitate mitochondrial fission during mitosis. Given that RalA recruits Drp1 during mitosis, we hypothesized that RalA functions in a similar manner during mitophagy to mediate Parkin recruitment. We find that RalA relocates to mitochondria following mitochondrial damage and colocalizes with Parkin. To determine if RalA is involved in Parkin recruitment, we examined shRalA HeLa cells and found that they exhibit impaired Parkin recruitment. We also find that clathrin-mediated endocytosis (CME) facilitates RalA and Parkin localization to mitochondria during mitophagy. Collectively, these data support a novel role for RalA during PINK1-Parkin mitophagy.

Nerve Growth Factor Induces Mitochondrial Fission Which is Required for Axon Branching.  
L. Armijo Weingart¹, A. Ketschek¹, R. Sainath¹, A. Pacheco¹, G. Gallo¹;  
¹Shriners Hospitals Pediatric Research Center, Temple University, Philadelphia, PA

Nerve Growth Factor (NGF) induces branching through activation of phosphoinositide 3-kinase (PI3K). Recently, mitochondria have emerged as major determinants of the sites of axon branching. NGF treatment decreased the length and increased the number of axonal mitochondria labeled with mitotracker green after 15 min of acute treatment, indicative of fission. Consistently, live imaging of mitochondria following 5 minutes of NGF treatment revealed mitochondria fission. The effect of NGF in mitochondria length was reversed after 3.5 hour of NGF withdrawal. Direct activation of PI3K using a cell permeable peptide in the absence of NGF copied the effects of NGF. Conversely, inhibition of PI3K using LY294002 blocked the effects of NGF on mitochondria. Pharmacological and peptide-mediated inhibition of dynamin related protein 1 (Drp1), a required component of mitochondria fission, blocked NGF induced axon branching. Live imaging of axons in the presence of NGF revealed that YFP-Drp1 accumulated at sites of mitochondria fission and endogenous Drp1 was detected in axons through immunocytchemistry. NGF promoted phosphorylation of Drp1 at the activating site S616 trough ERK activation independently of the PI3K pathway. Additionally, inhibition of ERK signaling blocked the effect of NGF in mitochondria fission and Drp1 accumulation along the mitochondria. Inhibition of actin polymerization using Latrunculin-A also blocked the effect of NGF in mitochondria fission and Drp1 accumulation. Furthermore, live imaging of axons indicates that actin patches strongly co-localize with sites of mitochondria fission. Expression of DRP1 dominant negative mutant, significantly decreased the number of branches in neurons that were raised in the presence of NGF. Finally, BDNF and NT3 also decrease the length and increase the number of mitochondria. Collectively, these observations indicate: 1) NGF mediates phosphorylation of DRP1 through ERK signaling, and drives mitochondria fission through the activation of both the ERK and PI3K pathways; 2) mitochondria fission is required for NGF-induced branching. As PI3K signaling is not involved in Drp1 phosphorylation, PI3K might contribute to fission through regulation of the actin cytoskeleton independently of changes in Drp1 activity. This work was supported by the NIH NS078030.

Fleming, Athina, Greece, 4NCI, National Institutes of Health, Frederick, MD

Despite increasing interest regarding the role of the TCA cycle and its anaplerosis in cancer pathology and other diseases, valuable information gleaned from live cell imaging and the construction of genetically encoded fluorescent reporters for enzymatic activity related to the TCA cycle is missing from the field. Here we design and implement a set of fluorescently tagged chimeras to study the nanostructural organization of inner mitochondria membrane enzymes by means of fixed and live cell super resolution microscopy along with a new genetically encoded FRET reporter to monitor a-ketoglutarate metabolism upon selective depletion of energy sources. We further complement flow cytometry and live cell imaging data from our FRET reporter with biochemistry and metabolic activity assessment with the use of a Seahorse instrument and fixed and live super resolution imaging of inner mitochondria membrane and matrix enzymes. We present evidence that key enzymes involved in ketoglutarate metabolism alter their nanoarchitectural organization in a reversible and distinct manner in a subpopulation of mitochondria, as a response to selective energy source depletion. We confirm our live and fixed super-resolution data by performing correlative light – electron microscopy (CLEM) to further demonstrate the distinct, local organization of the mitochondrial matrix as a function of energy source challenge.

Mitochondrial-driven assembly of a cortical anchor for mitochondria and dynein. L.M. Kraft\textsuperscript{1}, L.L. Lackner\textsuperscript{1}; 1Molecular Biosciences, Northwestern University, Evanston, IL

Inter-organelle contacts facilitate communication between organelles and impact fundamental cellular functions. Here we examine the assembly of the mitochondria-ER-cortex anchor (MECA), which tethers mitochondria to the ER and plasma membrane. We find the assembly of Num1, the core component of MECA, requires mitochondria. Once assembled, Num1 clusters persistently anchor mitochondria to the cell cortex. Num1 clusters also function to anchor dynein to the plasma membrane, where dynein captures and walks along astral microtubules to help orient the mitotic spindle. We find that dynein is anchored by Num1 clusters that have been assembled by mitochondria. When mitochondrial inheritance is inhibited, Num1 clusters are not assembled in the bud and defects in dynein-mediated spindle positioning are observed. The mitochondrial-dependent assembly of a dual-function cortical anchor provides a mechanism to integrate the positioning and inheritance of two essential organelles and expands the function of organelle contact sites.

Investigating the molecular basis and regulation of the Mmr1-mitochondria association.
W. Chen¹, H.A. Ping¹, L.L. Lackner¹;
¹Molecular Biosciences, Northwestern University, Evanston, IL

During asymmetric cell division, many organelles have to be inherited by daughter cells and retained in mother cells through active transport and retention mechanisms. In order to better understand these mechanisms, we are using Saccharomyces cerevisiae as a model to study mitochondrial transport and retention in polarized, asymmetrically dividing cells. Mmr1 is a bud-enriched protein that functions as a mitochondrial adaptor for Myo2, which drives actin-based transport of mitochondria to the bud. Post-transport, Mmr1 is proposed to anchor mitochondria at the bud tip to ensure proper distribution of mitochondria. Although both functions require an interaction between Mmr1 and mitochondria, the molecular basis of the Mmr1-mitochondria interaction is not well understood. Our in vitro phospholipid binding assays indicate Mmr1 can directly interact with phospholipid membranes enriched in the mitochondrial specific phospholipid, cardiolipin (CL). We find that an unpredicted membrane binding site composed of amino acids 76-195 is both necessary and sufficient to interact with mitochondrial membranes in vivo and CL enriched liposomes in vitro. Furthermore, our work and that of others indicate that Mmr1 is a phosphoprotein. Our data suggest the phosphorylation of amino acids S81 and S83 within the identified membrane-binding domain regulate Mmr1’s interaction with the mitochondrial membrane. All together, our data provide insight into how phosphorylation may be used to spatially and temporarily regulate the Mmr1-mitochondria interaction and, consequently, the function of Mmr1 in mitochondrial inheritance.

Mitochondria-lysosome contacts regulate mitochondrial fission via Rab7 hydrolysis.
Y.C. Wong¹, D. Krainc¹;
¹Neurology, Northwestern University, Chicago, IL

Both mitochondria and lysosomes are critical for maintaining cellular homeostasis, and dysfunction of both organelles has been observed in multiple diseases. Mitochondria are highly dynamic and undergo fission and fusion to maintain a functional mitochondrial network which drives cellular metabolism. Lysosomes similarly undergo constant dynamic regulation by Rab7 GTPase, which cycles from active GTP-bound state into inactive GDP-bound state upon GTP hydrolysis. Here, we investigated the regulation of mitochondria-lysosome membrane contact sites in living cells using high spatial and temporal microscopy. Mitochondria-lysosome contacts dynamically formed in healthy untreated cells and were distinct from damaged mitochondria targeted into lysosomes for degradation. Contact formation was regulated by active GTP-bound lysosomal Rab7, while contact untethering was mediated by Fis1 recruitment of TBC1D15/Rab7-GAP to mitochondria to drive Rab7 GTP hydrolysis to release contacts. Functionally, lysosomal contacts marked sites of mitochondrial fission allowing for lysosomal regulation of mitochondrial network dynamics, while conversely, mitochondrial contacts regulated lysosomal Rab7 hydrolysis via mitochondrial-localized TBC1D15. Mitochondria-lysosome contacts thus allow for bidirectional regulation of mitochondrial and lysosomal dynamics, and may explain the dysfunction observed in both organelles in various human diseases.

Direct Detection of ER-Mitochondrial Contacts with Fully Quantified Fluorescence Microscopy.
C.R. King\textsuperscript{1}; J. Lippincott-Schwartz\textsuperscript{1};
\textsuperscript{1}Janelia Research Campus, Ashburn, VA

Inter-organelle contacts between the endoplasmic reticulum and the mitochondria are tightly regulated in cells. ER-mitochondrial contact sites have been painstakingly characterized through biochemical means, and yet much remains to be understood due to their small physical extent. As a result, even with super-resolution imaging, these inter-organelle contact sites are difficult to study through fluorescence colocalization measurements. Here, we have developed Fully Quantified Fluorescence Microscopy for use with nearly any fluorescence microscope, thereby enabling simple, rapid, and consecutive measurements of donor-quenched FRET efficiencies in biological samples. With this, we are working to characterize the spatial and temporal properties of ER-mitochondrial contact sites in live cells.

Autosomal dominant polycystic kidney disease (ADPKD) is characterized by the development of fluid-filled renal cysts and is caused by mutations in the Pkd1 and Pkd2 genes that encode polycystin-1 (PC1) and polycystin-2 (PC2), respectively. The polycystin proteins form a complex that participates in ciliary mechanosensation and that regulates calcium release from the endoplasmic reticulum (ER). Increasing evidence indicates that loss of PC1 leads to perturbations in energy production, although the mechanisms responsible for this effect are unclear. In an effort to find modulators of PC1 trafficking and function, we performed a Genome Wide siRNA screen and identified the oxygen-sensing Prolyl Hydroxylase Domain-containing protein PHD3 (or EGLN3) as a protein that influences PC1 trafficking. Moreover, we find that oxygen levels regulate the subcellular localization and the channel activity of the polycystin complex through its interaction with EGLN3, which hydroxylates PC1, thus providing a link between polycystin function and oxygen levels. Interestingly, we find that Pkd1\textsuperscript{−/−} cells that lack PC1 expression have a significantly lower oxygen consumption rate as compared to PC1-expressing cells and show less mitochondrial calcium uptake in response to bradykinin-induced ER calcium release. Inhibiting PHD3 function reduces mitochondrial oxygen consumption rate in PC1-expressing cells to the level that is measured in cells that lack PC1 expression. In support of a role for the polycystins in the regulation of mitochondrial calcium dynamics, we find that PC1 and PC2 co-fractionate with Mitochondria-Associated ER Membranes (MAMs). Taken together, our data identify a new regulatory pathway and suggests a novel role for the polycystins in sensing and responding to cellular oxygen levels.

Control of mitochondrial homeostasis by endocytic regulatory proteins.
T.M. Farmer¹, J.B. Reinecke¹, S. Xie¹, K. Bahl¹, N. Naslavsky¹, S. Caplan¹;
¹Biochemistry and Molecular Biology, University of Nebraska Medical Center, Omaha, NE

Mitochondria play essential roles in cellular energy processes, including ATP production, control of reactive oxygen species, and apoptosis. While mitochondrial function is regulated by the dynamics of fusion and fission, mitochondrial homeostasis remains incompletely understood. Recent studies implicate Dynamin-2 and dynamin-related protein-1 (Drp1), as GTPases involved in a step-wise mechanism for mitochondrial fission (Lee et al., Science, 2017). Here we identify the endocytic regulatory ATPase, EHD1, as a novel regulator of mitochondrial fission. Initially, we observed that EHD1-depletion induces a static and elongated network of mitochondria in the cell, suggesting that it either indirectly regulates or participates directly in the process of mitochondrial fission. To test whether EHD1 serves as a mitochondrial fission protein, we used a staurosporine-induced mitochondrial fragmentation assay. It has previously been demonstrated that upon depletion of Dynamin-2 or Drp1, cells are protected from staurosporine-induced fragmentation. However, when we depleted EHD1, we found that cells remained sensitive to staurosporine, suggesting that EHD1 likely functions differently than Dynamin-2 and Drp1, possibly in an indirect manner. Recent studies have demonstrated that VPS35 and the retromer complex influence mitochondrial homeostasis either by Mul1-mediated ubiquitination and degradation of the fusion protein Mitofusin2 (Mfn2), or by removal of inactive Drp1 from the mitochondrial membrane. Given that we have previously demonstrated that both EHD1 and its interaction partner, Rabankyrin-5, interact with the retromer complex, we thus hypothesized that these endocytic proteins might affect mitochondrial homeostasis by influencing retromer function. Indeed, we showed that EHD1-depletion caused a reduction in expression of the retromer subunit Vps35 subunit, while Rabankyrin-5 depletion induced sequestering of Vps35 in the Golgi region. These findings are consistent with a model proposed by Wang et al. (Nat. Med, 2016) in which Vps35 and the retromer is impeded in its ability to translocate to the outer mitochondrial membrane and remove inactive Drp1, thus facilitating localization of active Drp1 on the membrane and promoting fission. Currently we are exploring additional layers of regulation of the retromer by endocytic regulatory proteins and the impact on mitochondrial homeostasis. Overall, our studies provide new information on the previously uncharacterized relationships between endocytic regulatory proteins and mitochondria. Understanding the mechanisms underlying mitochondrial fission and fusion has important ramifications for cancer, cardiovascular diseases, and neurodegenerative disorders including Alzheimer’s disease and Parkinson’s disease.

Modulating mitochondria dynamics is a potential therapeutic strategy for MED13L syndrome.
K. Chang¹, J. Jezek¹, H. Lee², P.M. van Hasselt³, W. Kruger², R. Strich¹;
¹Department of Molecular Biology, RowanSOM, Stratford, NJ, ²Fox Chase Cancer Center, Philadelphia, PA, ³Department of Metabolic and Endocrine Disease, University Medical Center Utrecht, Utrecht, Netherlands

The mediator complex subunit 13-like protein (MED13L), is a component of the Cdk8 module (also containing cyclin C, Cdk8 and Med12) that associates with the RNA polymerase II holoenzyme. Loss of Med13L function results in several developmental defects. For example, MED13L mutation results in...
congenital heart disease including transposition of the great arteries, intellectual disability, muscular hypotonia and behavioral difficulties. One function of MED13 is to anchor cyclin C in the nucleus. Several stressors including oxidative damage interrupts this interaction resulting in cyclin C translocation from nucleus to mitochondria. At the mitochondria, cyclin C promotes mitochondrial fragmentation, an important step in early cell programmed death. In this report, we showed the skin fibroblast from a patient with carboxy-terminal truncated MED13L (HSF MED13L) exhibits released cyclin C and a high frequency of fragmented mitochondria. Our preliminary data suggests that aberrant mitochondrial fragmentation associated cytoplasmic localization causes a decrease in mitochondrial respiration of HSF MED13L. Seahorse analysis suggests that oxygen consumption of MED13L HSF cells is reduced suggesting that mitochondrial function is diminished in these cells. Finally, pharmacological inhibition of cyclin C re-localization partially restores mitochondrial function suggesting that mitochondrial fitness may be part of the pathogenesis associated with MED13 inactivation.

1Natural Science Division, Pepperdine University, Malibu, CA, 2Deptartment of Pharmacology, University of Colorado, Denver, CO

Carbon black (CB) is the primary nanoparticulate component of environmental pollution from fossil fuel combustion. Prior research has demonstrated that CB induces apoptosis, or programmed cell death, upon accumulation of CB via receptor-mediated endocytosis. The cellular consequences of CB incorporation are not well characterized. Human Bronchial Epithelial cells were used for all analyses described here. In evaluating CB incorporation into cells, we found a dose-dependent accumulation of CB that continues over several days. This identified CB as a stress dependent upon accumulation over time though acute affects have been noted in these studies. CB exposure causes an elevation of reactive oxygen species (ROS) within 8 hours of initial exposure. This result, along with observed abnormalities in mitochondrial dynamics in CB exposed cells garnered interest in mitochondria. CB concentrations ranging as low as 25 µg/ml induce a significant decrease in mitochondrial perinuclear localization at 36 and 48-hour time-points. Small/punctate mitochondrial numbers increased significantly with CB dosage over a period of 24-hours which is consistent with mitochondrial stress/dysfunction. Live cell imaging of mitochondrial motility revealed ER stress to disrupt mitochondrial motility, while CB showed no significant affect. Initial analysis of fission events showed that following 24-hours of stress, live cell capture of cellular behavior showed no elevation of fission rates in HBE cells. This suggest changes in mitochondrial numbers may occur at earlier timepoints. Future work with live cell imaging will assess mitochondrial fission events at different time points. This work reveals chronic CB exposure to impact mitochondrial dynamics in human lung epithelial cells.

Inhibition of mitochondrial fission and disruption of swimming behavior following Mdivi-1 treatment of Paramecium tetraurelia.
W.E. Bell, O.A. Emery, J.D. Hatgas
1 Biology, Virginia Military Institute, Lexington, VA

Dynamin-related proteins are components of many cellular processes including mitochondrial fission, vesicle formation and programmed cell death. Previous studies in yeast and mammalian cells have shown that an inhibitor of yeast Dnm-1 protein activity (Mdivi-1) can block fission of mitochondria resulting in elongate mitochondrial networks. Effects on the mammalian homolog Drp-1 show similar effects and also reduce cytochrome C release, a trigger of apoptosis. Contrasting studies find that Mdivi-1 effects are more likely due to inhibition of electron transport chain complexes rather than fission interference. We have examined the effects of Mdivi-1 treatment on Paramecium tetraurelia. Paramecium are large, multinucleate cells covered in cilia that allow them to swim to areas rich in food. When Paramecium are starved, a programmed rearrangement of the macronucleus is triggered, likely by a caspase. The outcome is an easily observed, fragmented nucleus. Treatment with Mdivi-1 delayed entry into macronuclear rearrangement and also resulted in alterations in mitochondrial phenotype. Mitochondria became less punctate and showed denser fluorescence patterns, indicating increased networking. Cells also were significantly larger compared to control after treatment. Interestingly, when we treated cells during stationary phase, we noticed a decrease in swimming speed and increase in turning behavior. This could be due to inhibition of electron transport chain complexes. The effect was only transient, as cells tested 24 hours later showed no differences in swimming behavior. Our experiments indicate that both bodies of work related to mDiva effects on cellular processes related to mitochondria are likely valid.

Translocation of cyclin C during oxidative stress is regulated by interactions with multiple trafficking proteins.
D.G. Smethurst, K.F. Cooper, R. Strich
1 School of Osteopathic Medicine, Rowan University, Stratford, NJ

Eukaryotic cells take cues from their environment and interpret them to enact a response. External stresses can produce a decision between adjusting to behaviors which promote surviving the stress, or enacting a cell death program. The decision to undergo programmed cell death (PCD) is controlled by a complex interaction between nuclear and mitochondrial signals. The mitochondria are highly dynamic organelles that constantly undergo fission and fusion. However, a dramatic shift in mitochondrial morphology toward fission occurs early in the PCD process. We have identified the transcription factor cyclin C as the biochemical trigger for stress-induced mitochondrial hyper-fragmentation in yeast (Cooper et al., 2014 Dev. Cell) and mammalian (Wang et al., 2015, MCB) cells. In response to PCD stimuli such as oxidative stress, cyclin C is released from the nucleus and associates with the mitochondrial fission machinery. Loss of cyclin C prevents mitochondrial fission while its ectopic introduction into the cytoplasm induces complete fragmentation in the absence of stress. Many of the details of the control of cyclin C localization within the cell have not been elucidated.
To initially investigate the regulation of cyclin C translocation events in S. cerevisiae, a two hybrid screen was used. We have identified multiple conserved trafficking proteins which interact with cyclin C. These
include Gea1/2 and multiple components of the TRAPPII complex, both of which act as guanosine exchange factors (GEFs) for small GTPase regulators of vesicle traffic (Arf1/2 and Ypt31/32 respectively). Arf1 and its homolog Arf2 also mediate mitochondrial dynamics and contact with the ER. Gea2 interaction with cyclin C was confirmed by co-immunoprecipitation, and fluorescence microscopy data also indicates that the two proteins can colocalise. The use of conditional mutants has revealed that upon loss of functional Gea1/2 or Arf1/2, cyclin C is translocated to the cytosol without stress. Following from this we propose a model in which the protein trafficking machinery acts to keep cyclin C in the nucleus during healthy cell maintenance.

The single mitochondrion of *C. fasciculata* is a dynamic network.
J.C. DiMaio¹, G. Ruthel², J.J. Cannon³, M.F. Malfara¹, M.L. Povelones¹;
¹Science Division, Penn State University Brandywine, Media, PA, ²Department of Pathobiology, University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA, ³Department of Medical Laboratory Sciences and Biotechnology, Thomas Jefferson University, Philadelphia, PA

Mitochondria are dynamic organelles, undergoing fission and fusion in order to maintain their shape and function. Kinetoplastid parasites, including the causative agents of Chagas disease, African sleeping sickness and Leishmaniasis, possess unusual mitochondrial characteristics. For instance, each cell contains only one mitochondrion, which typically assumes the shape of a branched network extending throughout the cell. Also, all of the organism’s mitochondrial DNA is found in a unique structure called the kinetoplast. The cell cycle of these organisms must therefore be carefully orchestrated to coordinate division of the kinetoplast and mitochondrion with nuclear mitosis and cytokinesis. We are using the model kinetoplastid *Crithidia fasciculata* to investigate the timing of mitochondrial biogenesis and division within the parasite cell cycle. We have created a cell line expressing mitochondrial-targeted GFP and examined the fluorescence pattern in partially synchronized cultures. By measuring different parameters of the mitochondrial network during various cell cycle stages, we have determined that mitochondrial biogenesis occurs mainly in G1 and is correlated with cell growth. During mitosis, mitochondrial size remains constant before being divided symmetrically in a process coincident with cytokinesis. We also sought to observe mitochondrial growth and division in live cells. This analysis revealed that the mitochondrial network is surprisingly dynamic. Tubules branch, fuse and slide at a frequency of approximately one event every 5 minutes regardless of cell cycle stage. The role of such rapid mitochondrial remodeling in an organism with a single organelle is not yet clear, nor do we know the proteins that mediate these reactions. Interestingly, kinetoplastids lack homologs for most of the proteins involved in mitochondrial dynamics in yeast and mammals, suggesting that certain components of the machinery for fusion and fission may be novel. In exploring mitochondrial dynamics in an early-diverging eukaryote such as *C. fasciculata*, we hope to gain insight into the ancestral functions of these processes. In addition, our screen for molecules involved in maintenance of mitochondrial shape may reveal new proteins that also function in higher eukaryotes.

CoQ biosynthetic components form a supracomplex localized to ER-mitochondria contact sites.
1MCB, University of California, Davis, Davis, CA

In eukaryotes, the conserved coenzyme Q biosynthetic pathway is housed within mitochondria and functions to enzymatically produce coenzyme Q (CoQ) - an essential electron transporting component of the respiratory chain. The pathway is comprised of at least 13 proteins, which build CoQ from 4-hydroxybenzoate and farnesyl-PP, derived from tyrosine and the extramitochondrial mevalonate pathway, respectively. Previously published biochemical and proteomic analysis indicate that a subset of CoQ pathway components interact together to form a dynamic, multi-subunit complex associated with the matrix side of the mitochondrial inner membrane. We examined the spatial organization and dynamics of the CoQ biosynthetic complex in vivo in budding yeast using endogenously expressed functional fluorescently-tagged Coq proteins. Our data indicate that components of the biosynthetic complex uniquely localized to multiple resolvable focal structures within mitochondria in cells. The relatively low cellular copy number of the Coq-labeled foci suggests that these structures represent supramolecular assemblies of the CoQ complex. Consistent with the high evolutionary conservation of this pathway, we also observed discrete Coq focal structures within mitochondria in human cells. In yeast, Coq foci formation was dependent on pathway components that are essential for the production of CoQ, suggesting that Coq substrates are required for supracomplex formation. To test a role for substrate in Coq supracomplex assembly, we utilized cells expressing an enzymatically inactive allele of Coq6 that can be bypassed by the addition of exogenous vanillic acid, a bihydroxybenzoic acid derivative. In these cells, Coq foci formation was strictly dependent on the presence of vanillic acid, indicating that supramolecular complex formation depends on substrate and/or substrate flux through the pathway. To gain insight into the function of the CoQ supracomplex, we examined its spatial localization in cells relative to other cellular structures. Our analysis indicates that Coq foci were highly enriched at ER-mitochondria contact sites. Thus, our data suggest a model where CoQ intermediates drive the formation of a supramolecular CoQ biosynthetic machine at ER-mitochondria contact sites to facilitate substrate influx and utilization as well as product distribution.

A HIGH-CONTENT LIVE IMAGING MITOPHAGY ASSAY TO EVALUATE SMALL MOLECULE MITOPHAGY ENHANCERS.
1Neuroscience, Amgen, Cambridge, MA, 2Clinical Biomarkers, Amgen, Cambridge, MA, 3Therapeutic Discovery, Amgen, Cambridge, MA, 4Medicinal Chemistry, Amgen, Cambridge, MA

Human genetic evidence has implicated mitochondrial dysfunction in the etiology of Parkinson’s disease, a neurodegenerative disorder characterized by motor dysfunction. Loss of function mutations in the PARK2 (encoding parkin) and PINK1 genes cause early-onset recessive Parkinson’s disease. PINK1, a protein kinase, and parkin, a ubiquitin ligase, act together to remove damaged mitochondria from the cell by mitophagy, a crucial process to maintain healthy mitochondria. These findings suggest that enhancing mitophagy may be a therapeutic strategy for Parkinson’s disease. To evaluate the effects of
small molecules on mitophagy, we developed a stable PARK2 overexpressing U2OS cell line with a tandem RFP+GFP reporter that is tagged to mitochondria by a MTS signal. RFP is acid-stable, whereas GFP is quenched in acid environments, such as the lysosome. Mitochondria tagged with this reporter appear orange (RFP+GFP) in the cytoplasm. Once they undergo mitophagy and end up in the lysosomes, the GFP fluorescence is quenched and only the red RFP fluorescence remains visible. High content live imaging of this cell line shows that administration of the protonophore carbonyl cyanide 3-chlorophenylhydrazone (CCCP) causes a dose-and time-dependent increase in mitophagy. These effects are mediated by parkin as confirmed by the absence of CCCP-induced mitophagy in control cells. Transient overexpression of USP30 decreases mitophagy as previously demonstrated by others. HBX 41,108, a non-selective USP30 inhibitor, dose-dependently enhances CCCP-induced mitophagy, whereas Nilotinib, a BCR-Abl inhibitor, shows little effect. Neither inhibitor has an effect in the absence of CCCP in this assay. A Tank-binding kinase 1 inhibitor BX795 inhibited CCCP-induced mitophagy. These data suggest that high content live imaging with the PARK2 and tandem RFP+GFP reporter overexpressing U2OS cell line is a suitable assay for evaluating small molecule enhancers of parkin-mediated mitophagy.

\(^1\)Department of Chemical and Systems Biology, Stanford University School of Medicine, Stanford, CA, \(^2\)Department of Neurosurgery, Stanford University School of Medicine, Stanford, CA

Within a single mammalian cell, thousands of mitochondria form a dynamic network. The morphological state of this network is tightly linked to its function. Cellular viability depends on maintaining a balance between fission and fusion of mitochondria within this network. An imbalance between these two processes is a hallmark of numerous pathologies. Excessive fission is found in cancers, cardiovascular disorders, and neurodegeneration. While mitochondrial fission poses as an attractive therapeutic target for these disorders, better tools are needed to differentiate physiological fission from excessive pathological fission or fragmentation. Four identified adaptor proteins recruit the main mediator of fission, dynamin related protein 1 (Drp1), to the mitochondrial outer membrane, yet the function of each adaptor is unknown. One adaptor Mff is primarily responsible for physiological fission. We hypothesized that a specific Mff-Drp1 protein-protein interaction inhibitor would differentiate physiological from pathological fission. Using a rational design approach, we identified a small peptide P259 that specifically inhibits Drp1’s interaction with Mff, but not with any of the other outer-membrane adaptors. Contrary to a pathological fission inhibitor, treatment with P259 disrupted mitochondrial network morphology and function under basal conditions. In WT mouse brains, P259 limited mitochondrial recruitment of Drp1, resulting in a 30% decrease in ATP production and enlargement of striatal mitochondria. Furthermore, treatment with P259 reduced the lifespan of R6/2 Huntington’s disease model mice and caused behavioral abnormalities in WT mice. Cumulatively, these results suggest that Mff orchestrates basal recruitment of Drp1 to the mitochondrial membrane thereby by facilitating physiological fission and maintaining mitochondrial network homeostasis. Results from this study suggest that adaptor specific recruitment of Drp1 mediates pathological versus physiological fission.

The size of the fission complex based on the FCS calibrated imaging of GFP-Drp1 protein in the HeLa cell line.
B. Michalska1, J. Szymanski1, J. Duszynski1;
1Biochemistry, Nencki Institute of Experimental Biology Polish Academy of Sciences, Warsaw, Poland

One of the main players in the process of mitochondrial fission is the protein Drp1 which assembles into helical ring-like structures on the outer mitochondrial membrane. Using fluorescence microscopy we performed a quantitative analysis of the diffusion and distribution of the GFP-Drp1 protein expressed in the gene edited HeLa cell lines. The obtained distribution shows that around half of the endogenous GFP-Drp1 pool remains in the cytoplasm, predominantly as the tetramer. The mitochondrial pool of GFP-Drp1 forms many different oligomeric states with average size of the complex equal to 56 GFP-Drp1 monomers. We identified individual fission events on the recorded time lapse movies and estimated the average number of Drp1 molecules forming the functional fission complex to be around 100.

An optical method for detecting associations between the endoplasmic reticulum and mitochondria, and their relevance to motor neuron disease.
M. Harmon1, M. Jackson1, P. Skehel1;
1Centre for Integrative Physiology, The University of Edinburgh, Edinburgh, United Kingdom

Physical membrane interactions between the ER and mitochondria play a key role in a number of cellular processes including calcium homeostasis, lipid trafficking and cell death signalling. These organelles are tethered by the formation of protein complexes at specialised regions of ER membrane termed mitochondrial associated membranes or MAMs. Dynamic changes in these contact sites are observed in response to certain physiological stresses, and perturbations to the MAMs have been identified in both familial and sporadic forms of neurodegenerative diseases including Alzheimer’s disease, Parkinson’s disease and amyotrophic lateral sclerosis (ALS). It has been suggested that dysfunction to ER-mitochondria contacts may be a common pathogenic mechanism underlying neuronal cell death. The integral ER membrane protein VAPB is enriched at the MAMs and binds to the outer mitochondrial membrane (OMM) protein PTPIP51 to regulate membrane associations. A missense point mutation vapB<sup>S565</sup> is associated with a familial form of ALS termed ALS type 8. Here, we have developed a bi-fluorescence complementation (BiFC) system for the visualisation of ER-mitochondria contacts in both fixed and living cells using complementary split Venus YFP fragments fused to the ER targeting domain of VAPB or the OMM targeting sequence of the mitochondrial protein TOMM20 respectively. Co-expression of these fusion proteins yields discrete fluorescent puncta at regions of close apposition between the ER and mitochondria (<10nm distance), consistent with a MAM localisation. We have validated the use of this approach by detecting an increase in ER-mitochondria contacts in response to tunicamycin-induced ER stress and serum deprivation as previously observed. By using this technique, we have detected a significant increase in the number of fluorescent puncta in NSC34 cells expressing the ALS-linked VAPB<sup>S565</sup> but not from overexpression of wild-type VAPB. Further work will allow us to directly correlate features of the MAMs with mitochondrial abnormalities and dysregulated calcium homeostasis as is observed in neurodegeneration.

A STANDARDIZED METHOD TO QUANTIFY ER-MITOCHONDRIAL INTERFACES IN ELECTRON MICROGRAPHS.

D. Weaver	extsuperscript{1}, A. Bartok	extsuperscript{1}, G. Csordas	extsuperscript{1}, G. Hajnoczky	extsuperscript{1};

	extsuperscript{1}MitoCare Center, Dept. of Pathology, Anatomy and Cell Biology, Thomas Jefferson University, Philadelphia, PA

The interaction sites between endoplasmic reticulum (ER) and mitochondria are signaling hubs in the cell implicated in calcium transfer, lipid metabolism, autophagy, and cell death among other functions. Transmission electron microscopy (TEM) is commonly used to visualize the geometry of these interfaces, but metrics used to describe and compare between conditions, as well as the techniques of measurement are not standardized. Here we describe a pair of scripts for ImageJ that allow for rapid, reproducible and flexible quantification of interface geometries. One script is focused on measuring the physical apposition of the membranes while the other considers the potential exposure of the outer mitochondrial membrane (OMM) to calcium released from the ER. In both cases, the user simply traces the OMM and nearby ER membranes; the script bins the interface distances and returns the length of the OMM that participates in an interface of a given gap width, as well as the total OMM and ER lengths. A ‘score’ based on the inverse-square of the distance is also generated as an attempt to make a single value representing ‘interface-ness’. The additive nature of these measures allows cell-wise totals or averages to be calculated for a given TEM section. While this approach standardizes the measurement technique for a number of parameters of ER-mitochondrial interfaces, it remains to be seen which parameters best correspond with physiological changes in different models.

Mechanistic insights into the regulation of mitochondrial fission by cyclin C.

V. Ganesan	extsuperscript{1}, K.F. Cooper	extsuperscript{1}, R. Strich	extsuperscript{1};

	extsuperscript{1}Molecular Biology, Rowan University, Stratford, NJ

Cyclin C is a component of the mediator complex of RNA polymerase II that localizes to the nucleus under normal conditions. In response to stress, cyclin C translocates to the cytosol and mitochondria and mediates stress-induced mitochondrial fission and apoptosis. The molecular mechanisms by which cyclin C induces mitochondrial fission are unknown. Using in vitro experimental approaches, we sought to investigate the mechanistic basis of cyclin C mediated mitochondrial fission. We found that recombinant cyclin C and Drp1, the dynamic-like GTPase that produces mitochondrial scission, directly interact with each other without the requirement of any accessory proteins. This interaction requires the C-terminal 120 amino acids of cyclin C independent of the cyclin Box motif that directs Cdk binding. Upon heterologous expression, the GFP tagged carboxyl terminal domain localized to mitochondria and induced mitochondrial fission in cyclin C null MEF cells even in the absence of stress. On the contrary, the N-terminal 250 amino acid cyclin box domain is responsible for the nuclear retention of cyclin C under normal conditions and cannot induce stress-induced mitochondrial fission. The GTPase domain of Drp1 is an important site of interaction between Drp1 and cyclin C. Using size-exclusion chromatography and native-PAGE, we found that cyclin C reduces the oligomerization of Drp1 in solution. This is accompanied by a concomitant decrease in Drp1 GTPase activity in the presence of lipids. The ability of cyclin C to depolymerize Drp1 is enhanced by GTP and GTP analogs. We hypothesize that cyclin C
depolymerizes inactive multimeric Drp1 in solution enabling the interaction of Drp1 with the mitochondrial fission machinery to facilitate mitochondrial fission.

The Role of Golgi Apparatus in Phagocytosis: Ca2+-Dependent Focal Exocytosis of Golgi-derived Vesicles Helps Uptake in Macrophages.
N. Vashi, S. Andrabi, S. Ghanwat, M. Suar, D. Kumar;
1Cellular Immunology Group, International Centre for Genetic Engineering and Biotechnology, , New Delhi, India, 2School of Biotechnology, KIIT University, Bhubaneshwar, India

During phagocytic uptake by macrophages, role of Golgi apparatus was previously ruled out. Notably all such reports were limited to Fcy-receptor mediated phagocytosis. Here we unravel a highly devolved mechanism for recruitment of Golgi-derived secretory vesicles during phagosome biogenesis, which was important for uptake of most cargos except IgG-coated ones. We report recruitment of Mannosidase-II positive Golgi-derived vesicles during uptake of diverse targets including latex beads, E. coli, Salmonella Typhimurium and Mycobacterium tuberculosis in human and mouse macrophages. The recruitment of Mannosidase-II vesicles was an early event mediated by focal exocytosis and coincided with the recruitment of transferrin receptor, VAMP3 and dynamin-2. Brefeldin A treatment inhibited Mannosidase-II recruitment and phagocytic uptake of serum coated or uncoated latex beads and E. coli. However consistent with previous studies, Brefeldin A treatment did not affect uptake of IgG-coated latex beads. Mechanistically recruitment of Mannosidase-II vesicles during phagocytic uptake required Ca2+ from both extra- and intra-cellular sources apart from PI3Kinase, microtubules and dynamin-2. Extracellular Ca2+ via voltage-gated Ca2+ channels establish a Ca2+-dependent local PIP3 gradient, which guides the focal movement of Golgi-derived vesicles to the site of uptake. We confirmed Golgi-derived vesicles recruited during phagocytosis were secretory vesicles as their recruitment was sensitive to depletion of VAMP2 or NCS1 whereas recruitment of recycling endosome marker VAMP3 was unaffected. Both VAMP2 and NCS1 depletion individually resulted in the reduced uptake by macrophages. Together the study provides a previously unprecedented role of Golgi-derived secretory vesicles in phagocytic uptake, the key innate defense function.

TRPM7 Ion Channel Regulates Magnesium Reabsorption in the Renal Proximal Tubule.
L. Lou, L.W. Runnels;
1Graduate School of Biomedical Sciences, Rutgers Biomedical and Health Sciences, Piscataway, NJ, 2Department of Pharmacology, Rutgers-Robert Wood Johnson Medical School, Piscataway, NJ

Mg2+ deficiency can be identified in up to 60% of critically ill patients and contributes to many human diseases and conditions, including hypertension and diabetes. One cause of hypomagnesemia stems from phosphate depletion and hyperparathyroidism, but the mechanisms by which hypomagnesemia develops remains undetermined. Phosphate reabsorption in renal proximal tubule segment is mediated by sodium-phosphate cotransporters, which are bound to and regulated by NHERF1 and NHERF3 scaffolding proteins. The TRPM7 ion channel, which is associated with hypomagnesemia with secondary hypocalcemia (HSH) disease, is also expressed in the proximal tubule, but its functions in this nephron
segment remain unknown. To determine the impact of TRPM7 channel on Mg\(^{2+}\) reabsorption in the proximal tubule, we generated mice lacking the channel specifically in proximal tubule by crossing TRPM7\(^{−/−}\) mice with PEPCK-Cre transgenic mice. TRPM7\(^{−/−}\) (PEPCK-Cre) mice excrete more Mg\(^{2+}\) in urine than control TRPM7\(^{+/+}\) mice but have a lower serum Mg\(^{2+}\) level. This data indicates that TRPM7 is involved in controlling the renal Mg\(^{2+}\) reabsorption in the proximal tubule. We conducted a yeast two-hybrid screen using a mouse kidney library and identified NHERF3 as a potential TRPM7-interacting protein. Biochemical approaches were employed to confirm the interaction, and we found that the COOH-terminal six amino acids of TRPM7 constitute a PDZ binding motif, which is required for the channel binding to the 2nd PDZ domain of NHERF3. NHERF3 is co-localized with TRPM7 in proximal tubule epithelial cells, where it appears to regulate the concentration of the channel on the apical membrane. We previously showed that the TRPM7 channel is regulated by G protein coupled receptors signaling through the phospholipase C (PLC) and protein kinase C (PKC) pathway. Our experiments in the proximal tubule cell line have shown that PKC regulates internalization of the channel. We conclude that TRPM7 regulates Mg\(^{2+}\) reabsorption in the renal proximal tubule and that NHERF3 plays a critical role in TRPM7 channel regulation.

**STIM1-Induced Conformational Transition of Orai1 Leads to Channel Activation.**

Z. Haydari\(^{1}\), H. Shams\(^{1}\), M. Mofrad\(^{1}\);

\(^{1}\)BioEngineering, University of California, Berkeley, CA

The immune response mechanisms at the cellular level are mostly triggered by a decrease in the concentration of Ca\(^{2+}\) within the endoplasmic reticulum (ER), followed by the opening of the calcium release-activated calcium (CRAC) channels that leads to an increase in the concentration of intracellular Ca\(^{2+}\). The stromal interaction molecule1 (STIM1) detects the decline of ER Ca\(^{2+}\) concentration and activates the channel via protein-protein interaction with Orai1 protein (the pore unit of CRAC channel). Mutations in Orai1 that impair its function cause severe immunodeficiency in humans. Although there are some experimental studies on the activation mechanism of Orai1 channel using STIM1, the molecular details of STIM1 interaction with Orai1 that results in channel opening are not yet understood. For example, there are two distinct STIM1 binding sites on Orai1, one in the N-terminus and one in the C-terminus. Yet, it is not known whether the C-terminus binding can cause Orai1 conformational changes and trigger channel gating by itself or requires N-terminus binding as well. To understand the molecular details of this signal transduction pathway, we developed all-atom molecular models of the STIM1/Orai1 complex and studied the binding of STIM1 to C-terminus of Orai1 followed by conformational changes in Orai1 that leads to channel activation. In this study, we compared Orai1 conformation after STIM1 binding with that in the control simulation, where STIM 1 was excluded. Our results showed an important conformational change in the Orai1 channel upon STIM1 binding in which M1 helices in the pore of Orai1 are bent. Furthermore, we observed an increase in the volume of the pore that most likely facilitates the gating process, while the hydrophobic part and glutamate ring remained fairly fixed. Thereby, our results indicated the mechanism by which STIM1 binding to the Orai1 C-terminal induces activation and suggests that such binding is most likely both necessary and sufficient for channel gating.

Lysosomal calcium signaling through channel TRPML1 is impaired by lipofuscin accumulation in RPE cells.
C. Mitchell1, N.M. Gomez1;
1Anatomy and Cell Biology, University of Pennsylvania, Philadelphia, PA

The TRPML1 channel is a conduit for lysosomal calcium efflux, and channel activity may be affected by lysosomal contents. The lysosomes of retinal pigmented epithelial (RPE) cells are particularly susceptible to lysosomal accumulations as they must degrade the outer segments phagocytosed daily from adjacent photoreceptors, and incomplete degradation can lead to storage of waste material and lipofuscin in the cells. This study asks whether stimulation of TRPML1 can release lysosomal calcium in RPE cells and whether such release is affected by lysosomal accumulations. The TRPML agonist ML-SA1 raised cytoplasmic calcium levels in mouse RPE cells and ARPE-19 cells; this rise was rapid, robust, reversible, and reproducible. The rise was not altered by extracellular calcium removal or by thapsigargin, but was eliminated by lysosomal rupture with glycyl-L-phenylalanine-beta-naphthylamide (GPN). Treatment with desipramine to inhibit lysosomal acid sphingomyelinase or YM201636 to inhibit PIKfyve reduced the cytoplasmic calcium rise triggered by ML-SA1. Co-treatment with chloroquine and U18666A induced formation of neutral, autofluorescent lipid in RPE lysosomes and decreased lysosomal calcium release. Lysosomal calcium release was also impaired in RPE cells from the ABCA4/- mouse model of Stargardt’s retinal dystrophy. Neither TRPML1 mRNA nor total lysosomal calcium levels were altered in these models, suggesting a more direct effect on the channel. In conclusion, stimulation of TRPML1 elevates cytoplasmic calcium levels in RPE cells, but this response is reduced by lysosomal accumulations.

High Throughput Functional Characterization of the SLC-Transporters PEPT1 and OCT2 in Real Time.
M. Barthmes1, A. Bazzone1, C.T. Bot2, R. Haedo2, N. Fertig1, M. George1, A. Brüggemann1;
1Nanion Technologies GmbH, Munich, Germany, 2Nanion Technologies Inc., Livingston, NJ

PepT1 and OCT2 are members of the SLC transporters family. Recently, they are of high interest in the development process of new pharmacological agents, due to their involvement in drug uptake and secretion. PepT1 is involved in absorption of oligopeptides in the small intestines, working as a proton/peptide symport into the cell, while OCT2 is involved in renal secretion of organic cations. Due to this growing interest in membrane transporters, there is an increasing demand for reliable high throughput systems, enabling the measurement of membrane transporter activity. Electrophysiological methods generate detailed and high quality data. However, conventional electrophysiology is in most cases not applicable or inefficient for the investigation of membrane transporters, due to their usually low turnover rates compared to ion channels.

Here we present dose responses based on single point or cumulative additions post repeated activations of both transport types under different pharmaceutical targets. Electrophysiological data of the SLC transporters PepT1 and Oct2 was generated with a fully automated high throughput platform, applying solid-supported membrane (SSM) based electrophysiology. This method, proven by about 100 peer-reviewed publications, allows the recording of a large number of individual transport proteins in parallel, ensuring a better signal to noise ratio compared to patch clamp.
Using this system, we were able to compare the kinetics (Km, vmax) of three different OCT2 substrates in a highly parallelized manner. By a competitive inhibitor assay we determined the IC50 of a PepT1 inhibitor. Furthermore, we performed several case studies of various targets, such as NaK-ATPase, mitochondrial transporters, channel rhodopsin, sugar transporters, and others.

Identifying Proteins that Interact with the Yeast Multidrug Transporter Pdr5 Through Genetic Suppression.
H. Rahman1, S.P. Joly1, J. Carneglia1, M. Robertello1, J. Golin1;
1Biology, The Catholic University of America, Washington, DC

Critical to an understanding of how ABC transporters function is the identification of interacting proteins and their biochemical function. We analyzed a mutation (E1013A) in the C-loop of the deviant ATP-binding site of Pdr5, a highly promiscuous multidrug transporter. This mutation causes a modest reduction in ATP hydrolysis and increased sensitivity to xenobiotic compounds. To identify proteins that interact with Pdr5, we transformed this mutant with a yeast genomic clone bank that overexpresses yeast genes and selected colonies with restored resistance to clotrimazole, a potent Pdr5 transport substrate. Of particular interest was a plasmid encoding the Sks1, serine/threonine kinase, which phosphorylates Ser-837 located in the linker between transmembrane helix 6 and nucleotide-binding domain 2. Overexpression of Sks1 increases drug resistance without increasing the level of Pdr5 in plasma membrane vesicles or restoring ATPase activity. It also further increases resistance in wild-type strains. The Sks1 kinase is known to be induced during glucose and nitrogen starvation. Our research demonstrates, however, that although Pdr5-mediated resistance is diminished under these conditions, it is not rescued by overexpressing Sks1.

Heparan Sulfate restricts BMP signaling and BMPR dynamics and interactions, mechanisms possibly altered in Hereditary Multiple Exostoses.
C. Mundy1, P.C. Billings1, H. Takano2, M. Pacifici2;
1Orthopaedics, Children’s Hospital of Philadelphia, Philadelphia, PA; 2Neurology, Children’s Hospital of Philadelphia, Philadelphia, PA

The bone morphogenetic protein (BMP) signaling pathway has critical roles in many processes including skeletal development and growth, and its perturbations can lead to diverse pathologies. A case in point is Hereditary Multiple Exostoses (HME), a pediatric musculoskeletal disorder caused by loss-of-function mutations in the heparan sulfate (HS)-synthesizing enzymes EXT1 and EXT2. HME is characterized by benign cartilaginous tumors (exostoses) that form next to the growth plates of various skeletal elements, causing multiple health problems. The HS chains, and the proteoglycans of which they are part, regulate signaling by key HS-binding proteins including hedgehogs and FGFs, but their roles in BMP signaling remain unclear. Previously we showed that interference with HS function by genetic or pharmacological means rapidly increases canonical BMP signaling, suggesting that HS normally limits BMP signaling by restricting ligand availability, BMP receptor (BMPR) dynamics and/or BMPR-ligand interactions. To analyze such possibilities, we transfected cell lines with constructs encoding Snap-BMPRII and/or Snap-BMPRIa fusion proteins. Co-transfected cells rapidly responded to BMP-2 treatment with major increases in pSMAD1/5/8 and interestingly, the same was seen after treatment
with HS antagonist Surfen. To assess BMPR dynamics, we carried out fluorescence recovery after photobleaching assays and found that receptor mobility decreased significantly after treatment with BMP-2 or Surfen, suggesting that the receptors had transitioned to lipid rafts and/or had undergone oligomerization. To demonstrate that BMPRII population transitioned to lipid rafts, we carried out sucrose gradient ultracentrifugation to separate lipid raft and non-lipid raft cell surface domains. Indeed, treatment with Surfen recruited an abundant amount of BMPRII to the lipid raft domains compared to control-treated cells. Lastly, to show that BMPRIA and BMPRII undergo oligomerization during treatment with Surfen, we performed in situ proximity ligation assays. As indicated by increased number of cell surface fluorescent sites, treatment with Surfen did promote receptor-receptor interactions compared to the control-treated cells. Together, the data indicate that cell surface HS chains are important regulators of both BMP signaling and BMPR dynamics. The HS deficiency in HME may alter these important basic physiologic mechanisms, causing increases in local BMP signaling and promoting formation of exostoses.

Genetic improvement of iron content in Arabidopsis seeds through double Overexpression of IRP1 (Iron Responsive Protein 1) and VTL (Vacuolar Iron Transporter-Like) genes.
Z. Ghalamkari\(^1\), T.J. Buckhout\(^1\);
\(^1\)Applied Botany, Biology Institute, Humboldt Universität Berlin, Berlin, Germany

Iron is an essential element that participates in numerous oxidation-reduction reactions in all organisms. Iron exist in two reversible oxidation states, Fe\(^{2+}\) and Fe\(^{3+}\), and chemical properties of these redox states determine the unique functions of Fe in electron transport chains in respiration and photosynthesis. Fe is also important in metabolic processes like DNA, lipid synthesis, removing ROS and nitrate assimilation. Recent evidence shows that in monocotyledon plants the re-mobilization of iron to the apoplast is a controlling factor in H2O2 production associated with the activation of defenses in plants. According to the WHO, 2002, about two billion people suffer from iron anemia. The strategies that the increase iron content in plants by biotechnological methods may be useful to decrease iron anemia in the world. In my research I am testing a new strategy for increasing the Fe content in the plant Arabidopsis. Our lab is focusing on the small family of vacuolar Fe transport proteins (5 VTL proteins) that we have recently shown to be involved vacuolar Fe homeostasis. Furthermore I am working on IRP1 gene that is involved in iron acquisition and homeostasis by an unknown mechanism. The results show that double over-expressing plants VTL1×IRP1 (4.3 nmol/mg), VTL2×IRP1 (3.7 nmol/mg), VTL3×IRP1 (4.8 nmol/mg), VTL5×IRP1 (4.0 nmol/mg) have higher amounts of iron compare with the wild type (2.7 nmol/mg). Localization of Fe in Arabidopsis seedlings was visualized using Perls’ staining with DAB intensification. For this study, six-day-old seedlings, which had been grown on ES solid medium with 40 μM iron, were stained. In all VTL-IRP1 OE lines the localization of Fe was stronger than the wild type, with some unique localization in the VTL4 and 5-IRP OE lines. These points may show accumulation of iron in the nucleus and/or vacuoles. Morphological analyzes support an increased iron content of the plant, Over-expressed lines were grown on agarose media containing different iron concentrations (40 μM and 0 μM Fe) and the length of primary roots was analyzed after 7 days. Results show that inVTL2- IRP1 and VTL5 - IRP1 plants in 0 μM Fe, the root length was the same as the root length in 40 μM iron and confirm that these plants do not suffer from iron deficiency, likely as a result of their genetic background. All these results establish a proof that gene manipulating of VTL and IRP1 is novel strategy to increase in bio-available seed Fe.

POST-STIM1 interactions differentially regulate PMCA4 splice variant function during T cell activation.

C.K. Go\textsuperscript{1,2}, R. Hooper\textsuperscript{1,2}, T. Cangoz\textsuperscript{1}, M. Madesh\textsuperscript{2}, J. Soboloff\textsuperscript{1,2};

\textsuperscript{1}Fels Institute for Cancer Research and Molecular Biology, Temple University, Philadelphia, PA, \textsuperscript{2}Medical Genetics and Molecular Biochemistry, Temple University, Philadelphia, PA

T cells are dependent upon prolonged elevations in cytosolic Ca\textsuperscript{2+} to initiate NF-kB/NFAT gene expression signatures in response to antigen presentation. STIM1-dependent inhibition of Ca\textsuperscript{2+} extrusion through PMCA4 contributes to this Ca\textsuperscript{2+} signal. Recent investigations revealed the ER membrane protein Partner of STIM1 (POST) as a STIM1-binding protein proposed to negatively regulate PMCA4 function, although this was not studied in the context of T cell activation, the focus of the current study. Interestingly, while we confirmed that POST negatively regulates PMCA4 activity in resting T cells, this role changes in response to T cell activation, with POST opposing STIM1-mediated attenuation of PMCA4 activity. To further define this phenomenon, we co-expressed POST and/or STIM1 with either PMCA4a or PMCA4b splice variants in Jurkat T cells. Inhibition of PMCA4b-mediated Ca\textsuperscript{2+} clearance by STIM1 was independent of T cell activation or POST whereas PMCA4a exhibited a STIM1-induced activation-dependent delay in Ca\textsuperscript{2+} clearance that was enhanced by POST KD. Analysis of molecular interactions by colocalization and FRET studies revealed complex activation-dependent interactions between all 3 proteins, with STIM1 and POST stably associating but POST dissociating from PMCA4a upon activation. Finally, to understand the implication of POST-mediated control of Ca\textsuperscript{2+} clearance on T cell function, we examined control of Ca\textsuperscript{2+} oscillations and NFAT activation. Interestingly, significant Ca\textsuperscript{2+} oscillations were observed in both resting and stimulated T cells, with POST expression inversely related to oscillation frequency. These results reveal differential regulation of PMCA4a and PMCA4b by STIM1 and POST during T cell activation, with profound implications for the generation of Ca\textsuperscript{2+} oscillations and, perhaps, downstream activation of NFAT.

Super resolution localization and live-tracking analyzed by pair correlation and a novel powerspectral method reveal short-term cAMP regulation of the water channel aquaporin-3.

E.C. Arnspang\textsuperscript{1,2,3}, P. Sengupta\textsuperscript{1,4}, H.H. Jensen\textsuperscript{5}, U. Hahn\textsuperscript{6}, E.B. Jensen\textsuperscript{6}, C.K. Mortensen\textsuperscript{7}, J. Lippincott-Schwartz\textsuperscript{1,4}, L.N. Nejsum\textsuperscript{7};

\textsuperscript{1}The Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, NIH, Bethesda, MD, \textsuperscript{2}Department of Clinical Medicine and Interdisciplinary Nanoscience Center (iNANO), Aarhus University, Aarhus, Denmark, \textsuperscript{3}Department of Chemical Engineering, Biotechnology and Environmental Technology, University of Southern Denmark, Odense, Denmark, \textsuperscript{4}Janelia Research Campus, Ashburn, VA, \textsuperscript{5}Department of Molecular Biology and Genetics and Interdisciplinary Nanoscience Center (iNANO), Aarhus University, Aarhus, Denmark, \textsuperscript{6}Department of Mathematics, Aarhus University, Aarhus, Denmark, \textsuperscript{7}Department of Micro- and Nanotechnology, Technical University of Denmark, Lyngby, Denmark

Single particle localization and live tracking in cells are essential to reveal nanoscale regulation of proteins. The water channel aquaporin-3 (AQP3) is important for the renal ability to concentrate urine but little is known regarding plasma membrane regulation of AQP3 in response to short-term hormone
mediated urine concentration facilitated by increased levels of cAMP. Super resolution Photoactivatable Localization Microscopy (PALM) with quantitative Pair Correlation analysis (PC-PALM) revealed cAMP mediated nanoscale clustering of AQP3 in the plasma membrane upon cAMP stimulation. Novel power spectral analysis of live-PALM image sequences of tracks lasting 5 frames revealed that while the measured diffusion coefficients of AQP3 were identical between control and cAMP stimulated cells, the confinement radius increased significantly, in qualitative agreement with the results from PC-PALM analysis. Thus fixed and live PALM measurements revealed a change in AQP3 plasma membrane nano-organization upon cAMP stimulation, indicating short-term hormone regulation of AQP3 at the nanoscale level. This regulation of nano-organization may play an important physiological function in regulation of urine concentration and body water homeostasis.

Characterization of the membrane progesterone receptor beta (mPRβ) using the Xenopus laevis oocyte model.

N. Nader1, M. Dib1, R. Hodeify1, K. Machaca1;

1Research, Weill Cornell Medicine-Qatar, Doha, Qatar, 2Research, American University of Ras Al Khaimah, Dubai, United Arab Emirates

Membrane progesterone receptors (mPRs) are distinct from the classical nuclear progesterone receptors and have 7 membrane spanning domains and belong to the progestin and AdipoQ receptor (PAQR) family. Unlike the classical nuclear receptor which mediates its effects via genomic mechanisms, mPRs are cell surface receptors which rapidly alter cell signaling via non-genomic modulation of intracellular signaling cascades. Emerging physiological roles for mPRs have been documented in different tissues, including oocytes, testis, uterus, placenta, breast, brain and immune cells. This raises the profile of mPRs as potential therapeutic targets for different diseases linked to neurological disorders, cancer, fertility-related issues and type II diabetes. However, the structure of mPRs and their immediate downstream intracellular signaling pathways remains ill defined. Here we use progesterone (P4)-dependent release of meiotic arrest in the Xenopus laevis oocyte to characterize mPR structure and function. We show that mPR topology is opposite to that of GPCRs with an extracellular C-terminus and a cytosolic N-terminus. We further show through deletions of the N- or C-terminus that the N-terminal domain is essential for mPR signaling, whereas the C-terminus is crucial for XmPR trafficking and plasma membrane residence. Since mPR shares sequence similarity with alkaline ceramidase, we have initiated studies to test whether mPR in the oocytes has ceramidase activity. We used metabolomics and pharmacological approaches and showed that the ceramidase inhibitor, ceranib1, negatively regulates P4-induced oocyte maturation, whereas preliminary metabolomics data revealed changes in free fatty acids in response to P4 treatment. Collectively, our data provide new insights into the structure-function relationship of membrane progesterone receptors with physiological implications in different tissues.

¹Instituto de Bioquimica y Microbiologia, Universidad Austral de Chile, Valdivia, Chile

GLUT transporters are a family of transmembrane proteins that facilitate the translocation of various sugars across membranes. Because these carriers are involved in metabolic diseases and cancer, understanding the molecular details of sugar transport is critical for the rational design of drugs targeting these diseases. The recent publication of crystal structures of some members of this family provides a starting point for assembling the mechanism of sugar transport, but further biochemical and physicochemical characterization is needed. Here, we generate and functionally characterize constructs of GLUT1 and GLUT2 devoid of their six cysteine residues (C-less) as platforms for biochemical and physicochemical studies, i.e. cysteine scanning mutagenesis and site-specific labeling. To test the functional expression of the C-less proteins, we used a combination of overexpression in cells (HEK 293T and CHO-K1 cells, and Xenopus oocytes) followed by kinetic assays of radiolabeled 2-deoxyglucose (DOG) uptake. Our results indicate that both constructs retain native-like functionality, as judged by the minor changes in kinetic parameters when compared to the wild-type carriers. Similarly, both proteins preserve their sensitivity to the GLUT inhibitors cytochalasin B and quercetin, which confirms kinetic properties similar to those of the wild-type transporters. As proof of concept, we introduced cysteine residues in GLUT2 C-less and test accessibility of MTSET, an alkylating thiol-reactive agent, by following changes in DOG uptake. While MTSET did not affect DOG import into Xenopus oocytes expressing the C-less protein, it blocked the activity of GLUT2 wild-type and that of mutants carrying single cysteine residues at selected positions. Together, our results suggest that replacement of the cysteines residues of GLUT1 and GLUT2 causes minimal structural and functional alterations. We propose that these constructs are suitable platforms for biochemical and physicochemical studies aimed at understanding the interactions of the transporter with its substrate and immediate environment. A novel inactivation mechanism of STIM1 involving the interplay of multiple cytosolic domains in a resting state.
S. Lee¹, S. Jeong¹, K. Kim¹, Y. Kweon¹, A. Lee¹, Y. Lee¹, C. Park¹;
¹Department of Biological Sciences, UNIST, Ulsan, Korea, South

Store-operated Ca2+ entry (SOCE) is the main supervisor of calcium signaling pathways in various cellular processes like the gene expression, differentiation. Two key components of the store-operated calcium channel (SOC) or calcium released activated Ca2+ channel (CRAC) complex are stromal interaction molecule 1 (STIM1), an ER Ca2+-sensor, and Orai1, a pore-forming channel protein in the plasma membrane. When ER store is depleted, STIM1 undergoes conformational changes that unveil CAD (CRAC channel-activating domain). CAD binds and activates Orai1. STIM1 is known to have its inhibitory domain within a cytosolic domain called IDstim right after CAD region. However, the molecular mechanism by which the inhibitory domain induces rearrangement of functional domains of STIM1 by shielding CAD in the closed state before store depletion remains largely unclear. Here we identified a linker between CAD and the inhibitory domain (IDstim) of STIM1 is another functional
determinant and essential for stabilizing the closed state of STIM1, which might arrange the interactions between IDStim and CAD associated domains. Surprisingly, structural distortion of the linker of CAD and IDStim activates the CRAC channel without store depletion by altering the segments by the mutation and insertion of a different length of ELP linker. Also, STIM1 deleted IDStim is capable of constitutively activating Orai1, verifying an inhibition effect of IDStim. Furthermore, we found the deletion of CC1 causes loss of IDstim inhibition effect. Especially, leucines (L251 or L258) in CC1 which is critical in CC1-CC3 interaction, are important for IDstim-related inhibition of CAD activity. These studies propose, establishes a detail STIM1 resting/inactivation mechanism by which IDstim rearranges CAD by stabilizing the interaction of CC1-CC3 domain in the closed state.

Cell migration is a fundamental process involved in physiological and pathological events such as wound healing, embryonic development and cancer metastasis. Cell migration regulation depends on a variety of mechanisms such as cytoskeleton rearrangements, focal adhesions turnover and local Ca²⁺ oscillations. TRPM4 is a Ca²⁺-activated non-selective cationic channel that conducts monovalent but not divalent ions. We previously demonstrated that TRPM4 channels regulate cell migration, contractility and is required for focal adhesion disassembly. Moreover, increased TRPM4 expression has been related to pathologies in which cytoskeletal rearrangement and cell migration are altered, such as fibrosis and cancer. Thus, the elucidation of the mechanisms that regulate TRPM4 activity might contribute important information for therapeutic strategies. We used a mass spectrometry-based proteomics approach to identify TRPM4-associated proteins. These studies revealed K⁺ Channel Tetramerization Domain 5 (KCTD5), a putative adaptor of cullin-3 E3 ubiquitin ligase, as a novel TRPM4-interacting protein. Therefore, we hypothesized that KCTD5 is a novel regulatory protein of TRPM4, modulating focal adhesion dynamics and cell migration. Here, we demonstrate that KCTD5 interacts with TRPM4 and regulates its activity. Moreover, we show that KCTD5 induces the ubiquitination of the channel and that KCTD5 silencing diminishes maximal TRPM4 currents. Moreover, we demonstrate that KCTD5 regulates the number of focal adhesions, cell spreading, migration and contractility. Together, these data suggest that KCTD5 interacts with TRPM4, promotes its ubiquitination, and regulates its activity, probably leading to an increase in cellular migration.

Tunneling of Ca\(^{2+}\) downstream of SOCE specifically signals to downstream effectors and subcellular domains.

K. Machaca\(^1\), R. Courjaret\(^2\);
\(^1\)Physiology and Biophysics, Weill Cornell Medicine Qatar, Doha, Qatar

The function of Store-Operated Calcium Entry (SOCE) extends beyond the replenishment of Endoplasmic Reticulum (ER) Ca\(^{2+}\) stores following agonist stimulation, to controlling directly and indirectly the activity of multiple intracellular Ca\(^{2+}\) effectors and as such cellular processes. The point source Ca\(^{2+}\) entry through SOCE channels is restricted to a small sub-plasmalemal (PM) microdomain due to biochemical and physical barriers. However, some Ca\(^{2+}\)-dependent effectors downstream of SOCE do not localize to the SOCE microdomain. Ca\(^{2+}\) tunneling has been well characterized in pancreatic acinar cells and frog oocytes and shown to extend the spatial spread of SOCE Ca\(^{2+}\) signals while maintaining specificity, by using ER tunnels to activate distant effectors. Ca\(^{2+}\) in the SOCE microdomain is taken up into the ER and released at distal sites to activate effectors such as the Ca\(^{2+}\)-activated Cl channel Ano1. Herein, we show that Ca\(^{2+}\) tunneling is functional in non-excitatory cells and that it encodes significant specificity in the SOCE signal. By dissecting the sensitivity and dependence of multiple SOCE downstream effectors and subcellular domains, including the mitochondria, Ca\(^{2+}\)-activate K channel, bulk cytosol, sub-PM domain, and NFAT, we show that Ca\(^{2+}\) tunneling defines spatio-temporal Ca\(^{2+}\) coding downstream of SOCE. While mitochondria readily perceive Ca\(^{2+}\) release when stores are full, SOCE shows little effect in raising mitochondrial Ca\(^{2+}\), while Ca\(^{2+}\)-tunneling is completely inefficient. In contrast, Ca\(^{2+}\)-activated potassium channels display a similar sensitivity to Ca\(^{2+}\) release and Ca\(^{2+}\) tunneling, while the activation of NFAT1 is exquisitely sensitive to SOCE and not to Ca\(^{2+}\) release. Those results establish Ca\(^{2+}\) tunneling as a mechanism for encoding specificity in the cellular responses downstream of SOCE. They further show that Ca\(^{2+}\) tunneling is most efficient in specifically activating activators in the sub-PM domain thus expanding the spatial scope of the limited SOCE microdomain.

The yeast H\(^{+}\)-ATPase Pma1 promotes Rag/Gtr-dependent TORC1 activation in response to H\(^{+}\)-coupled nutrient uptake.

E. Saliba\(^1\), F. Corillon\(^1\), I. Georis\(^1\), B. Andre\(^1\);
\(^1\)Molecular Physiology of the Cell, Free University of Brussels (ULB), Gosselies, Belgium

The yeast Target of Rapamycin Complex 1 (TORC1) plays a central role in controlling growth. How amino acids and other nutrients stimulate its activity via the Rag/Gtr GTPases remains poorly understood. We now report that the signal triggering Rag/Gtr-dependent TORC1 activation upon amino-acid uptake is the coupled H\(^{+}\) influx catalyzed by amino-acid/H\(^{+}\) symporters. H\(^{+}\)-dependent cytosine uptake, ionophore-mediated H\(^{+}\) diffusion, and inhibition of the vacuolar V-ATPase also activate TORC1. As the increase in cytosolic H\(^{+}\) elicited by these processes stimulates the compensating H\(^{+}\)-export activity of the plasma membrane H\(^{+}\)-ATPase (Pma1), we have examined whether this major ATP-consuming enzyme might be involved in TORC1 control. We found that when the endogenous Pma1 is replaced with an H\(^{+}\)-ATPase from tobacco plant, H\(^{+}\) influx or increase fails to activate TORC1. Our results show that H\(^{+}\) influx coupled to nutrient uptake stimulates TORC1 activity and that Pma1 is a key actor in this mechanism.

The inhibitory effects of haptoglobin on osteoclast differentiation through TLR4 signaling.
J. Kim\textsuperscript{1}, Z.H. Lee\textsuperscript{2};
\textsuperscript{1}Pediatric Dentistry, Seoul National University School of Dentistry, Seoul, Korea, South, \textsuperscript{2}Cell and Developmental Biology, Seoul National University School of Dentistry, Seoul, Korea, South

Haptoglobin (Hp), a member of the acute phase proteins, is known to be a major hemoglobin (Hb)-binding protein that plays a protective role against Hb-induced cytotoxicity in various organs. However, the involvement of Hp in bone-related cells has not been fully understood. In this study, we investigated the effects of Hp on osteoclastogenesis. Histomorphometric analyses with Hp gene-deficient mice showed significant bone loss due to increased osteoclast formation. Administration of exogenous Hp in these mice recovered bone volume. Consistent with the in vivo results, Hp inhibited osteoclastogenesis by suppressing expressions of major transcription factors such as c-Fos and NFATc1. Hp-induced suppression of c-Fos expression was mediated by an increase in interferon beta (IFN\textbeta) levels, a well-known c-Fos inhibitor. Hp-induced inhibition of osteoclastogenesis was recovered by treatment with IFN\textbeta-specific neutralizing antibody. Taken together, these results demonstrate that inflammation-induced Hp secretion from osteoblast plays a protective role against excessive osteoclastogenesis via IFN\textbeta augmentation.

Huguenin-Dezot\textsuperscript{3}, M.J. Dyer\textsuperscript{4}, J.W. Chin\textsuperscript{3}, A. Zhuravleva\textsuperscript{1}, A.M. Fry\textsuperscript{2}, R. Bayliss\textsuperscript{1};
\textsuperscript{1}School of Molecular and Cellular Biology, University of Leeds, Leeds, United Kingdom, \textsuperscript{2}Department of Molecular and Cell Biology, University of Leicester, Leicester, United Kingdom, \textsuperscript{3}MRC Laboratory of Molecular Biology, Cambridge, United Kingdom, \textsuperscript{4}Ernest and Helen Scott Haematological Research Institute, University of Leicester, Leicester, United Kingdom

The function of protein phosphorylation in cell regulation is perhaps best understood in terms of regulating protein-protein interactions with reader modules that directly recognize the phosphorylated side chain. Another major role for phosphorylation is in the regulation of protein kinases, through stabilization of the activation loop to stabilize a catalytically-competent state. We have discovered a new role for phosphorylation in the regulation of a molecular chaperone, Hsp72, a member of the 70kDa Heat shock family of molecular chaperones (Hsp70s). These proteins comprise a nucleotide binding domain (NBD) and substrate-binding domain (SBD) connected by a linker that couples exchange of ADP for ATP with release of protein substrate. Mitotic phosphorylation of Hsp72 by Nek6 at Thr66 located in the NBD targets Hsp72 to the mitotic spindle. We determined the crystal structure of Hsp72 NBD containing a genetically encoded phosphoserine at position 66. Mutations in the residues that link phosphorylation to subdomain interactions restore the connection between ATP binding and substrate release. Thus, phosphorylation of Thr66 is a reversible mechanism that decouples the allosteric connection between nucleotide binding and substrate release, providing a new paradigm in our understanding of regulation in the Hsp70 family. Cancer cells frequently possess extra amplified...
centrosomes and the Nek6-Hsp72 is critical for the clustering of excess centrosomes into two poles. Inhibition of Hsp72 in acute lymphoblastic leukaemia cells resulted in increased multipolar spindle frequency that correlated with centrosome amplification, while loss of Hsp72 or Nek6 function in non-cancer derived cells disturb neither spindle formation nor mitotic progression. Hence, the Nek6-Hsp72 module represents a novel actionable pathway for selective targeting of cancer cells with amplified centrosomes.

Cell size-dependent regulation of Wee1 localization bursts by Cdr2 cortical nodes.
C.A. Allard¹, H.E. Opalko¹, K. Liu¹, U. Medoh¹, J.B. Moseley¹;
¹Biochemistry and Cell Biology, The Geisel School of Medicine at Dartmouth College, Hanover, NH

Cell size control requires mechanisms that link cell growth with the cell cycle machinery. In eukaryotes, the key driver of the cell cycle is the cyclin-dependent kinase Cdk1. How information about cell size and geometry is relayed to Cdk1 is poorly understood. In many eukaryotes, complex cell geometry and non-cell autonomous signaling complicate studies of cell size signal transduction. The fission yeast Schizosaccharomyces pombe is an excellent model organism for size control research because of their simple rod-shaped geometry, stereotyped growth pattern, and conserved cell cycle machinery. Fission yeast cells enter mitosis at a defined size due in part to mysterious multiprotein punctate structures termed “nodes.” These nodes form a belt around the medial cell cortex, and their components include the Cdk1 inhibitor Wee1, along with two Wee1-inhibitory kinases Cdr1 and Cdr2. The number of nodes scales with cell size, but how nodes are organized to facilitate cell-size signal transduction is unclear. Here, we addressed node organization and function by combining TIRF microscopy, photobleaching, super-resolution molecule counting, and biochemical fractionation. We show that Cdr2 forms the stable core of megadalton-sized nodes, and nodes are enriched for catalytically active Cdr2, which increases in level during interphase growth. While Cdr2 and Cdr1 remain constant at nodes over time, Wee1 localizes to nodes in short bursts with lifetimes of several seconds. Recruitment of Wee1 to nodes requires Cdr2 kinase activity and a short domain within the N-terminus of Wee1. These localization bursts are required for progressive phosphorylation of Wee1 as cells grow, and burst frequency increases over 10-fold as cells approach division size. Cell size-dependent burst frequency is altered in cells lacking the protein kinase Pom1, which couples Cdr2 kinase activity to cell size. Our results indicate that stable Cdr2 nodes become progressively active as cells grow during interphase. Increasing node activity leads to more frequent bursts of Wee1 localization to nodes, where the combined activities of Cdr1 and Cdr2 kinases lead to inhibitory phosphorylation of Wee1. Our work suggests a mechanistic model for how Cdr2 nodes integrate cell size signals for dynamic regulation of Wee1 during cell growth.

Ubiquitin- dependent maturation of the PP1 phosphatase that opposes yeast Aurora B during mitosis.
R. Ravindran¹, L.C. Robinson¹, K. Tatchell¹;
¹Biochemistry Molecular Biology, Louisiana State University Heath Sciences Center, Shreveport, LA

Ubiquitylation of proteins regulates the fidelity of mitotic chromosome segregation through both proteolytic and non-proteolytic mechanisms. In this study, we report a novel mechanism by which ubiquitylation affects chromosome segregation. The Aurora B - Protein Phosphatase 1 pair (Ipl1 and Glc7...
in S. cerevisiae) maintains the fidelity of chromosome segregation by ensuring correct bipolar attachment of spindle microtubules prior to anaphase. We show that the Glc7/Ipl1 balance is affected by a single point mutation in the gene encoding the E1 ubiquitin activating enzyme, Uba1 (uba1-W928R). This mutation increases Histone H3-S10 phosphorylation in a temperature-sensitive ipl1-2 strain, indicating that uba1-W928R acts by increasing Ipl1 activity and/or reducing phosphatase activity. Consistent with this, Ipl1 protein levels are higher in the uba1 mutant, indicating that uba1-W928R acts in part by increasing Ipl1 protein levels. However, Glc7 phosphatase activity is reduced in uba1-W928R mutant even though Glc7 protein levels remain constant. Two GLC7 mutations that suppress the temperature-sensitivity of ipl1-2 (glc7-127 and glc7-S99L) cause lethality in the uba1-W928R mutant background. Furthermore, uba1-W928R alters the localization of Glc7- most cells possess a Glc7 spot close to the nucleolus. It is known that Glc7 maturation requires the activity of the two highly conserved PP1 regulators Sds22 and Ypi1, as well as the AAA ATPase Cdc48 and its adaptor Shp1. Loss of any one of these proteins results in the aggregation of Glc7. We show that uba1-W928R does not prevent the sds22-6-induced aggregation of Glc7, but it blocks the formation of cytoplasmic Glc7 aggregates in a YPI1 mutant. Similarly, while mutations in sds22 exacerbate growth defects of the uba1-W928R mutant, a mutation in YPI1 does not cause additive growth defects in the presence of uba1. Thus, the uba1-W928R mutation is epistatic to mutations in YPI1 but not SDS22. Together, our work indicates that one or more steps in the folding or maturation of Glc7 is dependent upon ubiquitylation. Furthermore, although Sds22 and Ypi1 can form a ternary complex with Glc7, they appear to have separate roles in Glc7 maturation that are differentially influenced by a defect in ubiquitylation. Cdc48 (also known as VCP or p97) is a hexameric AAA ATPase that acts as a segregase to extract (segregate) ubiquitylated proteins from macromolecular complexes. Glc7, known to be ubiquitylated in vivo, or another regulator, such as Sds22 or Ypi1, could be the Cdc48 client(s) necessary for Glc7 maturation.

Cell-type-specific isolation of 14-3-3 associated phosphoprotein from complex brain tissues.
M. Yoshikawa1, K. Kuroda1, T. Nagai2, K. Kaibuchi3;
1Department of Cell Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan,
2Department of Clinical Pharmacology, Nagoya University Graduate School of Medicine, Nagoya, Japan

Understanding the general properties of signal transduction processes in the nervous system make it possible to clarify how these processes work to mediate specific functions in the brain. The major molecular mechanism underlying signal transduction is protein phosphorylation. Previously, phosphoproteomics on striatal slices treated with forskolin are performed and more than 200 phosphorylated proteins are obtained. However, this method is still limited by the fact that brain tissues are composed of multiple cell types that are each unique in their patterns of signal transduction. In order to pursue protein phosphorylation at the specific cell type that is excited in a particular stimulation, in vivo phosphoproteomic analysis is needed. Here we developed Cre-dependent AAV vector expressing 14-3-3 proteins. When this AAV vector is injected to a cell-type-specific Cre recombinase expressing mouse, Cre recombinase activates the expression of 14-3-3 proteins to enrich phosphorylated proteins. When crossed to a variety of Cre recombinase expressing mouse lines, this methodology is generalizable and useful for the identification of molecular changes in any cell type in response to specific stimulus.

To ascertains whether the inhibitory activity of MMP-9 induced by the low molecular-weight gel fraction of Aloe vera (lgfAv) affects ethanol-induced gastric lesions, we investigated the gastroprotective effects of oral (p.o.) administration of lgfAv (molecular weight cut-off < 50.0 KDa, 150.0 mg/kg body weight) in an ethanol-induced gastritis using mice for 1 h exposure. By measuring ulcer index, we compared the anti-ulcerative activity of the fraction by mRNA Expression and immunohistochemical analysis. As a result, the lgfAv-treated mice exhibited drastically fewer ulcer lesions than the untreated control mice did. It featured that lgfAv lessened the ulcer lesions than their relevant controls. Moreover, the transcriptional level of MMP-9 was completely alleviated by lgfAv treatment. The transcriptional level of MMP-9 was significantly alleviated by lgfAv treatment of the model. However, RT-PCR and immunohistochemistry experiments revealed that lgfAv treatment in mucosal tissues had the potential to inhibit the mRNA and protein expression levels of MMP-9, respectively. The protein expression of MMP-9 was closely associated with lgfAv-induced gastroprotection against ethanol-induced gastric lesions. Overall, the present results suggest that lgfAv has the potential to alleviating ethanol-induced acute gastric lesions, which is mediated partly by the suppression of the mRNA expression of MMP-9.

The with no lysine [K] kinase pathway regulates the localization of inward rectifier potassium channels.
S. Gallolu Kankanamalage\textsuperscript{1}, C.A. Taylor\textsuperscript{1}, S. An\textsuperscript{2}, S. Stippec\textsuperscript{1}, S. Earnest\textsuperscript{1}, C. Huang\textsuperscript{2}, M.H. Cobb\textsuperscript{1};
\textsuperscript{1}Pharmacology, The University of Texas Southwestern Medical Center, Dallas, TX, \textsuperscript{2}Internal Medicine, University of Iowa Carver College of Medicine, Iowa City, IA

The with no lysine [K] (WNK) pathway regulates ion transport across cell membranes and regulates cellular processes such as blood pressure control, sodium reabsorption in kidney and neuronal function. It consists of protein kinase WNK (WNK1-4 in mammals), its downstream target kinases oxidative-stress responsive 1 (OSR1) and Ste20-related proline-alanine-rich kinase (SPAK), and downstream cation chloride cotransporters. The deregulation of these components results in human diseases such as hypertension \cite{1}. The objective of our study was to identify novel interactions of the WNK pathway components and subsequently elucidate novel functions of the pathway. Using a bioinformatics approach to identify potential OSR1/SPAK binding proteins, we discovered several proteins of the inward rectifier potassium channel (Kir) family to contain the OSR1/SPAK recognition motif. Our electrophysiological studies showed that constitutively active OSR1 increased the activities of Kir2.1 and Kir2.3 which contain the OSR1/SPAK binding motif. However, it did not alter the activity of Kir4.1 which does not contain that motif. The co-expression of WNK1 with wild-type OSR1 also activated Kir2.1, suggesting that WNK pathway is involved in controlling the Kir channels. Then we explored possible mechanisms of how the Kir channels are regulated by the WNK pathway. We depleted OSR1 in cells by siRNA-mediated gene knockdown and expressed epitope-tagged Kir2.3, followed by the treatment of cells with or without sodium chloride (NaCl) that induces WNK pathway activation. We discovered that Kir2.3 is localized primarily in the perinuclear region of the cells. Treatment of cells with NaCl decreased
the perinuclear Kir2.3 localized cells and increased cell membrane-associated Kir2.3 containing cells and cells in which Kir2.3 is dispersed throughout the cytoplasm. In addition, it also drove OSR1 towards the cell membrane. Interestingly, the depletion of OSR1 prevented the sodium chloride-induced localization changes of Kir2.3, indicating that OSR1/SPAK regulates its localization. The expression of Kir2.3 was not affected by the depletion of OSR1. The inhibition of WNK kinase activity by a small molecule WNK inhibitor (WNK463) also decreased the sodium chloride-induced cellular localization changes of Kir2.3, indicating that OSR1 activation by WNK is necessary for the regulation of Kir channel localization. In addition, it also prevented the localization change of OSR1occured with NaCl treatment. Therefore, these data indicate that WNK pathway regulates the Kir channel cellular localization via the activation of OSR1. 1. Dbouk, H.A., C.L. Huang, and M.H. Cobb, Hypertension: the missing WNKs. Am J Physiol Renal Physiol, 2016. 311(1): p. F16-27.

The Role of Glycolytic ATP Generation for the Maintenance and Restoration of Vascular Endothelial Barrier Function.
P. Gajwani1, L. Wang1, P. Chaturvedi1, W. Sinclair2, S. Krantz1, D.E. Leckband2, A.B. Malik1, A.V. Karginov1, J. Rehman1;
1Department of Molecular and Cellular Pharmacology, University of Illinois at Chicago, Chicago, IL,
2Department of Chemical Engineering, University of Illinois at Urbana Champaign, Urbana, IL

Acute Lung Injury (ALI) is a disease which causes pulmonary edema leading to severe morbidity and mortality in critically ill patients, usually occurring as a consequence of severe pneumonia or sepsis. ALI is characterized by endothelial barrier dysfunction of the lung vasculature, leading to disassembly of endothelial adherens junctions, increased vascular permeability and fluid accumulation in the lungs. While the mechanisms of assembly and disassembly of endothelial adherens junctions have been extensively studied, little is known about the bioenergetics of the barrier repair process, or barrier maintenance.

Endothelial ATP generation primarily relies on glycolysis, and PFKFB3 has recently been shown to act as a key glycolysis regulatory enzyme in endothelial cells, but little is known about its role in regulating the endothelial barrier.

To quantitatively determine the role of PFKFB3 in endothelial barrier permeability, we performed a transendothelial electrical resistance (TER) assay. Human lung microvascular endothelial cells (HLMVECs) were stimulated with the inflammatory mediator thrombin to induce barrier leak. During the recovery phase, endothelial cells were subsequently treated with PFK15, a specific inhibitor of PFKFB3. PFK15 significantly attenuated barrier restoration after thrombin treatment (p<0.05). Using live cell confocal microscopy of endothelial cells expressing the ATP biosensor Perceval HR, we assessed intracellular ATP levels following thrombin stimulation and found an initial decrease followed by rapid recovery, indicative of enhanced glycolytic ATP generation. Interestingly, pharmacological inhibition of PFKFB3 even in the absence of thrombin stimulation resulted in a drastic increase in barrier permeability.

These data suggest that glycolytic ATP generation as regulated by PFKFB3 is important for restoring the endothelial barrier after injury and for homeostatic maintenance of barrier function. A better understanding of the endothelial barrier bioenergetics could allow for the development of novel therapeutic approaches which enhance barrier function in severe diseases such as acute lung injury.

Regulatory roles of weak encounters between proteins.
S. Kale1, M. Strickland2, A. Peterkofsky3, N. Tjandra3, J. Liu1;
1Theoretical Cellular Physics, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD, 2Laboratory of Molecular Biophysics, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD, 3Cell Biology and Physiology Center, National Heart, Lung and Blood Institute, National Institutes of Health, Bethesda, MD

Weak encounters between proteins are conventionally attributed to the transition state intermediates. This view shares the spirit of the similar, but better understood, exchange between proteins and DNA where the low-affinity interactions are instrumental in accelerating the search for a promoter site. The Gram-negative bacterium Escherichia coli (E. coli) is a unique survivalist equipped to handle a myriad of external stress conditions. Recent structural work has shown the presence of weak protein-protein interactions between two paralogous, albeit functionally distinct pathways in E. coli: one that regulates sugar uptake and carbon metabolism, and the other one involved in nitrogen metabolism and a diverse array of other cellular processes. We built a stochastic, theoretical model of these weak, transient encounters between three proteins from these pathways. We find that the futile encounters by the third protein can have non-trivial outcomes for the formation of a specific complex between the two cognates. We argue that the bacteria could exploit such interactions for signaling purposes to complement conventional gene regulation, particularly under complex starvation conditions. The emerging picture hints toward an elegant stress response machinery that reflects a tight balance between competing metabolic demands of the cytosol.

The glycolytic enzyme phosphofructokinase-1 assembles into filaments.
B.A. Webb1,2, A. Dosey2, T. Wittmann1, J.M. Kollman2, D.L. Barber1;
1Cell and Tissue Biology, University of California, San Francisco, San Francisco, CA, 2Biochemistry, West Virginia University School of Medicine, Morgantown, WV, 3Biochemistry, University of Washington, Seattle, WA

Despite abundant knowledge of the enzymology, regulation, and biochemistry of glycolytic enzymes, we have limited understanding of how they are spatially organized in the cell. Emerging evidence indicates that non-glycolytic metabolic enzymes regulating diverse pathways can assemble into polymers. We show here the tetramer- and substrate-dependent filament assembly by phosphofructokinase-1 (PFK1), considered the “gatekeeper” of glycolysis because it catalyzes the step committing glucose to breakdown. The recombinant liver isoform of PFK1 (PFKL) but not the platelet or muscle isoforms (PFKP and PFKM, respectively) assemble into filaments, initiated by the substrate fructose-6-phosphate (F6P). Negative stain electron micrographs reveal that PFKL filaments are apolar and made of stacked tetramers oriented with exposed catalytic sites positioned along the edge of the filament. We confirmed activity-dependent filament assembly with an inactive but tetrameric mutant, PFKL-His199Tyr, that does not form filaments in the presence of F6P, as determined by transmission electron microscopy and 90° light scattering. Electron micrographs and biochemical data with a PFKL/PFKP chimera indicate that the PFKL regulatory domain mediates filament assembly. To assess filament formation by PFK1 in cells, we expressed EGFP-tagged PFKL in MTLn3 rat mammary carcinoma cells and used live-cell imaging to examine PFKL-EGFP localization and dynamics. TIRF microscopy shows that PFKL-EGFP form dynamic
punctae throughout the cytoplasm. A small subset of PFKL-EGFP particles remained stationary at the ventral plasma membrane for several seconds, suggesting temporary docking events. Neither glucose starvation nor incubation of cells with 2-deoxyglucose, a glucose analogue that cannot be metabolized, had a discernable impact on punctae size, dynamics, or membrane docking. However, addition of citrate, an allosteric inhibitor of PFK1, induced the formation of large PFKL-EGFP-positive structures resembling stress granules. Our findings reveal a new behavior of a key glycolytic enzyme with insights on spatial organization and isoform-specific glucose metabolism in cells, including possibly a mechanism for localized ATP production. Moreover, our findings open a clinically relevant new direction for determining whether PFKL filaments regulate metabolic programming in diseases such as cancer.

**Proliferation of Immortalized Schwann Cells and Cyclic AMP Levels in Response to Forskolin.**

A. Williams¹, A.L. Asirvatham²;

¹Biology, Misericordia University, Dallas, PA

Schwann cell growth in vitro is stimulated by heregulin, a neuronal growth factor and mitogens that activate cyclic AMP, the universal cellular second messenger. Schwann cell proliferation versus myelination is orchestrated by optimal concentration of mitogens and promyelinating factors. While the concentration of heregulin and forskolin that stimulates growth has been well characterized in primary cultures, the levels of forskolin that stimulate proliferation in Schwann cell lines are not known. This study was undertaken to determine the concentration of forskolin and corresponding levels of cAMP that promotes optimal Schwann cell proliferation. It was hypothesized that an increase in forskolin dosage will elicit a dose-dependent rise in cell proliferation and cAMP levels. Immortalized Schwann cells were cultured with no growth factors (control media N2), 12.5 ng/ml heregulin, various doses of forskolin at 0.5 µM, 1 µM, 2 µM or 3 µM and heregulin + forskolin for 4, 6, 12 or 24 hours. Using the MTT proliferation assay, preliminary studies show that a time-dependent cell growth was observed in cultures incubated with 0.5 µM forskolin or heregulin + forskolin. Cells incubated with 1 µM forskolin exhibited a decrease in proliferation after 12 hours while cells treated with heregulin and forskolin continued to grow for 24 hours. A similar pattern was observed for cells treated with 2 µM forskolin and heregulin + forskolin. At concentrations of 3 µM forskolin, a significant decrease in proliferation was observed after 12 hours. Levels of cAMP were increased in cultures incubated for 12 hours with 1 µM forskolin (184+/−10.51 pmol/300,000 cells) compared to N2 (14.34+/−5.3 pmol/300,000 cells) and heregulin (14.31+/−3.67 pmol/300,000 cells); while cells incubated with heregulin+2 µM forskolin showed a considerable increase (225+/−4.88 pmol/300,000 cells). Secretion of cAMP decreased in cultures incubated with 3 µM forskolin (107.52+/−43.72 pmol/300,000 cells) or forskolin + heregulin (135.67+/−39.32 pmol/300,000 cells). These preliminary findings indicate that increasing concentration of forskolin along with incubation time promotes Schwann cell growth. However, increasing forskolin dosage beyond 2 µM limits Schwann cell proliferation and concentrations of cAMP.

¹Department of Biomedical Sciences and CNR Neuroscience Institute, University of Padova, Padova, Italy, ²Department of Biomedical Sciences, University of Padova, Padova, Italy

CK2 is an extremely conserved tetrameric protein kinase implicated in a plethora of cellular processes due to its terrific pleiotropy and constitutive activity. Despite the growing knowledge about its functions, little is known about its involvement in muscle differentiation. In this study, we dissect the CK2 role in myogenic differentiation using in vitro C2C12 myoblast cell line and primary muscle derived stem cells (MDSCs) as well as two different in vivo systems. Our data show that the CK2 subunits are differently regulated during the differentiation process, namely the protein-level of the regulatory β-subunit significantly increases, while the amount of the catalytic α and α’ subunits is unchanged. Moreover, the inhibition of CK2 activity by the specific compound CX-5011 dramatically inhibits myotube formation in both C2C12 and MDSC cells. In particular, CX-5011 does not affect the initiation of the myogenic program, as revealed by the expression of the early myogenic markers, while it dramatically dampens the expression of late contractile (troponins) and fusion (caveolin-3 and myomaker) differentiation markers. Finally, we demonstrate that CK2 plays an essential role also in vivo, since its kinase activity is required for efficient muscle differentiation in both mouse and zebrafish animal models. Concluding, our findings clearly reveal a crucial role of CK2 in the progression of in vitro and in vivo myogenic program.

Protein tyrosine phosphatase alpha positively regulates invadopodia-mediated cancer cell motility.
L.R. Decotret¹,², C.J. Palen¹,²,³;
¹Pathology and Laboratory Medicine, University of British Columbia, Vancouver, BC, ²BC Children’s Hospital Research Institute, Vancouver, BC, ³Pediatrics, University of British Columbia, Vancouver, BC

Cell migration plays a critical role in many physiological processes including wound healing. Aberrant cell migration is implicated in cancer metastasis, the leading cause of cancer-related mortality. In normal cells, migration is a dynamic process characterized by cycles of cell adhesion to and release from the extracellular matrix (ECM), and this involves cellular structures known as focal adhesions. Tumour cells often gain the ability to migrate through tissues, and this invasive migration involves cellular structures called invadopodia. Invadopodia are dynamic actin-based protrusions of the plasma membrane that mediate ECM degradation, and they are related to but distinct from focal adhesions. Protein tyrosine phosphatase alpha (PTPα), a widely expressed transmembrane protein, acts in normal cells to promote focal adhesion formation and migration. However, little is known about the role of PTPα in cancer cell motility. We hypothesize that PTPα regulates invadopodia formation and function to promote the invasive motility of malignant cells.

MDA-MB-231 breast cancer cells are a classic model for invadopodia research, and express PTPα. Small interfering-RNA (siRNA) was used to deplete PTPα in MDA-MB-231 cells, and PTPα can be reintroduced into the depleted cells using a siRNA-resistant PTPα-expressing plasmid. Transwell migration and invasion assays were used to investigate the role of PTPα in tumour cell motility. An invadopodia-mediated ECM-degradation assay was then used to determine the degradation ability of control vs.
PTPα-depleted cells. Lastly, MDA-MB-231 cells were transfected with GFP-PTPα, immunostained for invadopodial markers and imaged to determine if PTPα localizes to invadopodia. We found that PTPα-depleted cells had reduced abilities to migrate and invade. Matrix degradation assays revealed that PTPα-depleted cells are impaired in their ability to degrade ECM and this defect was rescued by restoring PTPα expression. Interestingly, PTPα-depleted cells and control cells formed equivalent numbers of invadopodia, and PTPα co-localized with cortactin, actin, and MT1-MMP to punctate invadopodia-like structures. Together, these findings indicate that PTPα, present within mature invadopodia, positively regulates invadopodia-mediated ECM degradation while not affecting invadopodia formation. Our ongoing research is investigating the molecular basis of PTPα-dependent invadopodia function. An improved understanding of invadopodia assembly, maturation, and function may reveal new mechanistic targets for therapeutic intervention to prevent cancer metastasis and limit mortality.

Regulation of Renal Proximal Tubule Na,K-ATPase by Creb Regulated Transcriptional Coactivators and Salt Inducible Kinase 1.
M.L. Taub1, D. Kim1, S. Krovi1, T. Rajkhowa1, F. Cutuli1;
1Biochemistry, University at Buffalo, Buffalo, NY

The kidney plays a central role in blood pressure regulation, controlling Na+ reabsorption via locally produced natriuretic, and anti-natriuretic factors. Previous studies indicated that natriuretic and anti-natriuretic factors, including dopamine and norepinephrine acutely alter Na+ reabsorption through the phosphorylation of Na,K-ATPase in the renal proximal tubule (RPT). However chronic regulation at the transcriptional level has not been studied. Our investigations indicate that protein Kinase A and calcium-mediated signaling pathways are involved in transcriptional control by dopamine and norepinephrine, as well as at the post-transcription level. Our studies have focused in transcriptional regulation of the gene encoding the Na,K-ATPase beta subunit gene (atp1b1) in primary rabbit kidney proximal tubule (RPT) cell cultures. In this report, evidence is presented that (1) recently discovered cAMP-regulated transcriptional coactivators (CRTC), and Salt-Inducible Kinase 1 (SIK1) contribute to the transcriptional regulation of atp1b1 in RPT cells and (2) renal effectors, including norepinephrine, dopamine, prostaglandins, and Na+, play a role. Evidence for the role of CRTC includes the loss of transcriptional regulation of atp1b1 by a dominant-negative CRTC, and as well as by a CREB mutant with an altered CRTC binding site. In a number of experimental systems, SIK1 phosphorylates CRTC, which are then sequestered in the cytoplasm, preventing their nuclear effects. Consistent with such a role of SIK1 in primary RPT cells, atp1b1 transcription increased in the presence of a dominant-negative SIK1 (which could not phosphorylate CRTC). Regulation by dopamine, norepinephrine, and monensin was also disrupted by a dominant-negative SIK1. These latter observations can be explained if norepinephrine phosphorylates and inactivate SIK1, resulting in CRTC mediated nuclear effects. In contrast, the effects of monensin very likely are mediated by activated SIK1 which phosphorylates class IIa Histone Deacetylases (HDACs), leading to increased transcription by MEF2c transcription factors. Our results support the hypothesis that Na,K-ATPase in the RPT is regulated at the transcriptional level via SIK1 and CRTCs, in addition to the previously reported control of the phosphorylation of basolaterally oriented Na,K-ATPase.

Stat3 Regulates Primary Embryonic Erythroid Cell Maturation and is Activated Independently of Erythropoietin Signaling.
Z.C. Murphy¹, P.D. Kingsley², K.E. McGrath¹, A. Koniski², J. Palis²;
¹Cell Biology of Disease, University of Rochester, Rochester, NY, ²Center for Pediatric Biomedical Research, University of Rochester, Rochester, NY

Stat3, when phosphorylated (pStat3), is a common transcriptional regulator and often a drug target to treat many cancers that use its signaling to modify cellular respiration and evade apoptosis. We have found that pStat3 is present during embryonic (primitive) erythropoiesis and have used this system as a model to better understand the role of Stat3 in primary blood cells. Primitive erythropoiesis arises on embryonic day 7.5 in the murine embryo and is required for embryonic survival. Using imaging flow cytometry to facilitate quantitative protein and morphometric analysis at the single cell level, we find pStat3 in primitive erythroblasts throughout maturation. Importantly, pStat3 is also observed in human stem cell-derived primitive erythroblasts. pStat3 inhibition results in increased apoptosis and decreased proliferation of primitive erythroblasts, and is associated with delayed erythroblast maturation and increased cell size. Stat3 binds and regulates several caspase related genes and caspase inhibition also results in delayed erythroblast maturation. The cell cycle checkpoint regulator, Gadd45g, is bound by Stat3 and its expression is increased following pStat3 inhibition, suggesting that Stat3 repression of Gadd45g may be a mechanism to increased cell division and terminal maturation. Known Stat3-targeted mitochondrial and oxidative phosphorylation genes are highly expressed in primitive erythropoiesis, suggesting that Stat3 may also regulate these general processes. Indeed, chemical inhibition of Stat3 results in rapid depolarization of the mitochondrial membrane. Though pStat3 levels increase in response to erythropoietin (Epo), surprisingly, normal pSTAT3 levels were observed in EpoR-null mice, indicating that other pathways activate Stat3 in primitive erythroblasts. Our preliminary studies suggest that the elevated level of ROS found in primitive erythroid cells may increase pSTAT3. Taken together, our data support a model where by Stat3 acts as a general regulator of the apoptotic machinery required for erythroid maturation, proliferation, and mitochondrial respiration. Additionally, this signaling is likely achieved through an endogenous pathway that is independent of cytokine signaling, a default “on-switch” to allow for rapid establishment of primitive erythropoiesis in the murine embryo. Finally, our data suggest that cancer cells may have co-opted Stat3 roles normally functional in primary embryonic erythroid cells.

The Semaphorin receptors, Neuropilins and Plexins, promote Hedgehog signaling through distinct cytoplasmic mechanisms.
J.M. Pinskey¹, N.E. Franks¹, R.J. Giger¹, B.L. Allen¹;
¹Cell and Developmental Biology, University of Michigan, Ann Arbor, MI

Hedgehog (HH) signaling is essential for embryonic and postnatal development, while perturbation of HH pathway function can lead to a variety of developmental diseases, birth defects, and cancers. Neuropilins, which have well-characterized roles in Semaphorin and VEGF signaling, have recently been implicated in the regulation of HH signaling. Neuropilins contain short, catalytically inactive cytoplasmic
domains, requiring Plexin co-receptors to regulate small intracellular GTPases during Semaphorin signal transduction. However, the mechanism of Neuropilin function in HH signal transduction remains unclear, and a role for Plexin proteins in HH signaling has not been explored. Here we report that Neuropilins and Plexins both promote HH signaling through distinct cytoplasmic mechanisms. Using HH-dependent luciferase reporter assays in NIH/3T3 cells, we show that the Neuropilin-1 cytoplasmic and transmembrane domains are both necessary and sufficient to regulate HH pathway activity, independently of Plexin and Semaphorin binding. We also show that Neuropilin-1 localizes to the primary cilium, a key platform for HH signal transduction, although this localization does not correlate with HH signaling promotion. Instead, our data suggest that Neuropilin-1 selectively regulates GLI activator function through a novel 12-amino acid cytoplasmic motif. Strikingly, we also find that multiple Plexin family members promote HH signaling, independent of their ability to interact with Neuropilins. Instead, point mutations in the GTPase activating domain of Plexins prevent HH pathway promotion, suggesting that GAP function is required for Plexin-dependent HH regulation. Furthermore, deletion of the autoinhibitory Plexin-A1 extracellular domain significantly increases HH pathway activity, providing additional evidence that Plexin GAP activity regulates HH signaling. Together, our data suggest that Neuropilins and Plexins regulate HH signaling downstream of ligand activation through distinct cytoplasmic mechanisms. Therapeutic approaches targeting Semaphorin receptors may be useful to regulate overactive HH signaling in cancer and other diseases.

Novel hypomorphic **Smoothern** allele causes skeletal and craniofacial defects.
E. Gigantes,1 A. Bushey Long1, J. Ben-Ami2, T. Caspary1;
1Human Genetics, Emory University, Atlanta, GA

Sonic hedgehog (Shh) signaling is a critical developmental pathway best known to regulate cell fate specification and proliferation. Shh signals through a tightly regulated signaling cascade that requires the G-protein coupled receptor Smo (Smo) and the primary cilium. Smo acts as the obligate transducer of the Shh signal and is normally enriched in cilia when the pathway is stimulated. Without Smo development ceases at embryonic day (E)9.0 and the embryo dies, signifying the necessity of the pathway during development. While the Shh pathway and Smo are well studied, the biological mechanisms surrounding Smo have yet to be fully characterized. Using an ENU-induced forward genetic screen in mice we identified a novel recessive allele of Smo carrying a missense mutation, called **AW4**. Smo**AW4** mutants display craniofacial defects by E10.5 and subsequent limb anomalies before dying shortly after birth. To test allelism, we generated E9.5 embryos heteroallelic for Smo**AW4** and Smo**bentbody** (known null); these alleles failed to complement indicating Smo**AW4** is an allele of Smo. Moreover, Smo**AW4** only partially restored the Smo null phenotype; the Smo**AW4/bentbody** embryo still appeared developmentally delayed but survived until E10.5. The less severe phenotype indicates Smo**AW4** is a hypomorphic Smo allele. In the developing neural tube Shh signaling is important for the patterning of ventral cell fates. Smo**AW4** embryos display diminished ventral cell fates and decreased Shh activity in the neural tube. Consistent with this, we found transcription of Shh-dependent gene expression was lower in Smo**AW4** mouse embryonic fibroblasts (MEFs) stimulated with Shh conditioned media than in their wild type controls. Additionally, we found Smo**AW4** MEFs were insensitive to Smo agonist (SAG), which binds to the Smo binding pocket to directly activate the protein. Through immunofluorescence we determined Smo fails to properly localize to the primary cilium in Smo**AW4** neural tube and MEFs. Taken together, our data argue Smo**AW4** is a novel Smo allele that perturbs Shh signaling, leading to aberrant craniofacial and limb development. Despite a reduction in Shh signal transduction, the Smo**AW4** embryo
survives longer than the Smo null. It is widely believed that Smo activation occurs in the primary cilium, therefore it is unclear how the Smo\textsuperscript{AWd} mutant signals as well as it does despite a cilia localization defect.

Single-molecule tracking study of β-catenin nucleocytoplasmic translocation and regulation thereof by Custos.
S.J. Schnell\textsuperscript{1}, C. Magura\textsuperscript{1}, W. Luo\textsuperscript{1}, R. Habas\textsuperscript{1}, W. Yang\textsuperscript{1};
\textsuperscript{1}Biology, Temple University, Philadelphia, PA

The purpose of this study is to determine the translocation dynamics of wild-type (wt) β-catenin at the single-molecule level and their changes over a time course of exposure to wnt3a ligand in HeLa cells, and to characterize the interaction with this process of the novel protein Custos. Single-particle tracking (SPT) was conducted via single-point edge-excitation subdiffraction (SPEED) microscopy, measuring translocation efficiency and mapping the route of the molecule through the nuclear pore complex (NPC). Results indicate that β-catenin translocation follows a route similar to that of transport receptors and is regulated via wnt3a such that the import efficiency increases with ligand stimulation to a peak at 4 hours after introduction of the ligand and decreasing thereafter, with export efficiency decreasing in comparison with control to a nadir at 4 hours and rising back to a level approximating control within 8 hours. It is shown via single-molecule FRET (SMF) that Custos interacts with β-catenin on both sides of the nuclear envelope, providing evidence that Custos is involved with the translocation of β-catenin; however, the exact nature of this relationship remains to be elucidated in further study. It is concluded thus far that β-catenin is regulated via wnt3a via translocation efficiency, enters the nuclear envelope via the nuclear pore in the manner similar to that of a transport receptor, and interacts with Custos during the translocation process. Study continues to characterize the interaction between β-catenin and Custos at the NPC and between β-catenin and the phenylalanine-glycine (FG)–repeat regions of NPC central channel nucleoporins curing translocation.

Comparison of YAP translocation in primary and immortalized cells.
J.T. Morgan\textsuperscript{1}, C.J. Murphy\textsuperscript{2,3}, P. Russell\textsuperscript{1};
\textsuperscript{1}Bioengineering, University of California, Riverside, Riverside, CA, \textsuperscript{2}Department of Ophthalmology Vision Science, University of California, Davis, School of Medicine, Davis, CA, \textsuperscript{3}Surgical and Radiological Sciences, University of California, Davis, School of Veterinary Medicine, Davis, CA

Objective: Yes-associated protein (YAP) is a transcriptional co-activator that has been implicated in a wide range of cell functions: proliferation, survival, fibrosis, differentiation, apoptosis, and senescence. As indicated by such diverse functional outputs, YAP’s activity and function is regulated by a host of scaffolding, transcriptional, and structural proteins which are likely cell, tissue, and disease dependent. Our previous work has demonstrated the expression and active function of YAP in primary human trabecular meshwork (HTM) cells. In this study, we wished to test whether immortalized HTM cells (TM1) were an appropriate model for studying the regulation of YAP. To this end, we used two YAP
stimuli that have been well characterized in other model systems, cell density and oxidative stress, and assayed the nuclear localization of YAP.

**Methods:** Primary (isolated from 7 donors) and immortalized HTM cells were routinely cultured in DMEM/F12 supplemented with 10% fetal bovine serum and antibiotics. To test the effect of cell density, cells were plated at low or high density on glass coverslips and serum starved for 3 days to remove the effects of serum. To test the effect of oxidative stress, cells were handled similarly and exposed to 250 μM hydrogen peroxide in media for 1 h. In all cases, cells were fixed and standard immunofluorescent techniques were used to assay the intensity of YAP within the cell nucleus. All values are expressed as percentage of control and shown as mean ± SEM.

**Results:** In all cases, YAP demonstrated a mixed expression pattern, with signal in both the cytoplasm and the nucleus. Increased cell density reduced the average nuclear intensity of YAP in primary (79.6% ± 2.8%; p<0.05; n=3) HTM while increasing it in immortalized cells (113.6% ± 2.0%; p<0.05; n=2). Further, the decrease observed in primary HTM cells is modest compared to reports in other cell types. After oxidative stress, primary cells exhibited a subtle drop in nuclear intensity (84.8% ± 5.4%; p<0.05; n=4), however, this was not observed with immortalized cells (102.0 ± 1.6%; p=0.33; n=2).

*Osthole and nitric oxide attenuate advanced glycation end products-induced NF-kB and MAPK activation in renal tubular cells.*

J. Huang1;  
1Biomedicine and Healthcare, Chung Hwa University of Medical Technology, Tainan, Taiwan

Osthole, 7-methoxy-8-(3-methyl-2-butenyl) coumarin, a natural coumarin derivative extracted from Chinese herbs, reportedly possesses various therapeutic properties and applications. To explore whether osthole was linked to altered advanced glycation end products (AGE)-mediated diabetic nephropathy, the molecular mechanisms of osthole responsible for inhibition of AGE-reduced nitric oxide (NO) bioactivity in renal proximal tubular cells were examined. We found that raising the ambient AGE concentration causes a dose-dependent decrease in NO generation. Osthole significantly reverses AGE-inhibited NO generation and induces high levels of cGMP synthesis and PKG activation. Treatments with osthole, the NO donor S-nitroso-N-acetylpenicillamine, and the MAPK inhibitor U0126 markedly attenuated AGE-inhibited NOS protein levels and NO generation. Moreover, AGE-induced NF-kB/MAPK activation, RAGE/p27Kip1/collagen IV protein levels, and cellular hypertrophy were reversed by osthole. The ability of osthole to suppress NF-kB activation was also verified by the observation that it significantly decreased IkB protein degradation. These findings indicate for the first time that in the presence of osthole, the suppression of AGE-induced biological responses is probably mediated by blocking NF-kB and MAPK signaling cascades or activating the NO pathway.

DETECTION OF NUCLEAR AND CYTOPLASMIC PROTEIN-PROTEIN INTERACTIONS OF THE CD44-INTRACYTOPLASMIC DOMAIN WITH RUNX2 BY PROXIMITY LIGATION ASSAY.

H. Miller1, K. Miletti-Gonzalez1;  
1Biological Sciences, Delaware State University, Dover, DE

CD44 is a transmembrane receptor involved in signal transduction. CD44 undergoes a proteolytic cleavage by presenilin within the gamma secretase complex, which produces the CD44 intracytoplasmic...
domain or CD44-ICD. This 72 residues peptide can be translocated into the nucleus where it can regulate transcription. The transcriptional regulatory mechanism(s) is not well understood but published EMSA and chromatin immunoprecipitation data have found the CD44-ICD in a complex with Runx2 in the MMP-9 promoter.

We hypothesize that the CD44-ICD directly interacts with Runx2 in the nucleus. To test this hypothesis we carried out Proximity Ligation Assays (PLA) using MCF-7/vector (CD44 negative) and MCF-7/CD44 (CD44 positive) cells grown on chambered slides. An anti-CD44-ICD antibody (Abcam) and an anti-Runx2 antibody (Santa Cruz Biotechnology) were used to generate the PLA data. This assay not only detects protein-protein interactions (PPI) but also the subcellular localization of such interactions. The PLA data collected as confocal microscopy images indicate that the CD44-ICD interacts with Runx2 in the nucleus. This data validates our hypothesis. However, we also detected an unexpected similar interaction in the cytoplasm. This cytoplasmic localization for the CD44-ICD/Runx2 PPI interaction suggests a potential novel CD44-mediated mechanism of gene regulation. Future PLA and co-immunoprecipitation experiments will be carry out to confirm the cytoplasmic CD44-ICD/Runx2 PPI interaction.

Particulate matter and its effect on the aryl hydrocarbon receptor (AhR)/CYP1A1 pathway in adherent THP-1 cells.  
E. Garcia, J. Serrano-Lomelin, A. Osornio-Vargas;  
1Pediatrics, University of Alberta, Edmonton, AB

**INTRODUCTION/OBJECTIVE:** Air pollution and Particulate Matter (PM) have recently been classified as human carcinogens. PM is a mixture of compounds including soil, heavy metals and organics like polycyclic aromatic hydrocarbons (PAH). The objective of this study is to evaluate the molecular mechanisms by which the PAH content in PM10 (PM with mean aerodynamic diameter ≤10 μm) may influence cell responses. Specifically, we are interested in the Aryl hydrocarbon Receptor (AhR)/CYP1A1 pathway in adherent THP-1 cells.

**METHODS:** THP-1 cells were cultured in suspension and transformed to macrophages with phorbol-myristate-acetate. The cells were then treated with eight different PM10 samples of known soil and PAH content collected from an “industrial” (IND) and a “business” (BUS) area in Mexico City. Q-PCR was conducted to measure gene expression levels of AhR and CYP1A1. The intracellular localization of AhR and CYP1A1 was evaluated by immunofluorescence microscopy. We also assessed the production of TNFα and IL-6 by ELISA. All experiments also included the use of the following: 1) Polymyxin A against endotoxins, 2) α-naphthoflavone as an AhR inhibitor, and 3) N-acetyl cysteine as a free radical scavenger. One-way ANOVA was used to determine differences between groups. We assessed correlations between PM10 soil and PAHs content and the cell responses using Pearson’s analysis.

**RESULTS:** After exposure to PM10, THP-1 cells exhibited a significant increase in the expression of CYP1A1 compared to the unexposed cells. A similar effect was not observed in the case of AhR gene expression. In this instance, however, PM10 induced the translocation of the AhR receptor to the nucleus accompanied by the expression of CYP1A1. Only α-naphthoflavone significantly decreased the level of CYP1A1 expression (p<0.01). The PM10 PHA content correlated with an increased trend in the expression of AhR when using the samples with the highest content of PAHs (IND) (r=0.934, p<0.06). PM10 -induced cytokines production correlated with the soil content of the samples (IL-6; r=0.492, p<0.004, TNFα: r=0.669, p=0.000).
CONCLUSIONS: CYP1A1 gene and protein expression are AhR dependent after PM10 exposure. These data demonstrate that PM participates as a xenobiotic in an AhR-mediated signal transduction pathway mediated by the PM10 PAH content.

Diverse patterns of phosphatase activation and localization: unique implications for the control of interferon-gamma signaling in CNS neurons.
L. Jolley¹, A. Broome¹, C. Stotesbury¹, K. Sweeney¹, C. Matullo², G. Rall², W. Rose¹;
¹Department of Biology, Arcadia University, Glenside, PA, ²Blood Cell Development and Function, Fox Chase Cancer Center, Philadelphia, PA

The immune cytokine interferon-gamma (IFN-g) is required for the elimination of numerous central nervous system (CNS) viral infections. Mediated by JAK/STAT signal transduction, the cellular response to IFN-g involves the expression of genes that result in the establishment of the antiviral state, and is controlled by multiple negative feedback mechanisms. Whether these control mechanisms, previously characterized in non-neuronal cells, operate similarly in CNS neurons is not well-understood. We previously demonstrated that the control of the neuronal IFN-g pathway is distinct from that in non-neuronal cells, as the duration of STAT1 phosphorylation and IFN-g responsive gene expression in IFN-g treated neurons was markedly extended as compared to mouse embryonic fibroblasts (MEF). We also showed that compared to MEF, STAT1 dephosphorylation was delayed in IFN-g treated neurons, providing a mechanism for the extended kinetics of neuronal STAT1 phosphorylation. The current study investigated the expression and subcellular localization of two STAT1 phosphatases, TC45 and SHP-2, to address the hypothesis that mislocalization of these phosphatases could result in the observed delay in neuronal STAT1 dephosphorylation. Although no differences in overall expression levels of TC45 were observed between neurons and MEF, neurons demonstrated an approximately 3-fold lower level of SHP-2 activation as compared to MEF, regardless of IFN-g exposure. To examine the subcellular localization of these phosphatases, neurons and MEF were exposed to IFN-g, and subcellular fractions were purified at 1, 24, and 48h post-IFN-g treatment. Our results showed that while SHP-2 was found strictly in the cytoplasmic fraction of both cell types, TC45 was found primarily in the cytoplasmic fraction of the neurons, whereas it was equally distributed between nuclear and cytoplasmic fractions in MEF. These results indicate that as compared to non-neuronal cells, neurons lack TC45 in the nucleus, and demonstrate a lower level of SHP-2 activation, which provides a likely explanation for the observation that neuronal STAT1 is not dephosphorylated as rapidly as it is in MEF. Understanding the control of the IFN-g response in CNS neurons will ultimately aid in the characterization of antiviral immune mechanisms of the CNS.

Changes in corticotrope gene expression upon increased expression of peptidylglycine alpha-amidating monooxygenase, an evolutionarily conserved secretory pathway enzyme.
R.E. Mains1, C.E. Blaby-Haas2, T.P. La Rese1, B.A. Rheaume1, B.A. Eipper1,3; 1Neuroscience, University of Connecticut Health Center, Farmington, CT, 2Biology, Brookhaven National Laboratory, Upton, NY, 3Molecular Biology Biophysics, University of Connecticut Health Center, Farmington, CT.

A key enzyme in the biosynthesis of biologically active peptides is peptidylglycine alpha-amidating monooxygenase (PAM: E.C. 1.14.17.3). This Type I integral membrane enzyme uses a 2-step reaction to convert peptidylglycine intermediates, which are negatively charged at physiological pH, into bioactive peptides with an uncharged alpha-amide. Identification in Chlamydomonas reinhardtii of a gene encoding CrPAM, whose properties closely resemble those of vertebrate PAM, suggests that this enzyme was present in the last eukaryotic common ancestor. In all species, PAM requires Cu, Zn, O2 and ascorbate, functioning best at low pH, making it dependent upon systems that regulate luminal pH and metal levels. In C. reinhardtii and rodent, PAM cycles through the secretory pathway and is found on ciliary membranes. Analysis of PAMKO zebrafish and mouse cell lines over-expressing PAM revealed its effects on cytoskeletal organization and secretion. The gamma-secretase mediated cleavage of PAM releases a soluble cytosolic fragment which localizes to the nucleus, raising the possibility of gene regulation by this fragment of PAM. We examined corticotrope tumor cells in which PAM expression could be induced following exposure to doxycycline to levels seen in the pituitary and atrial myocytes (Ciccotosto et al, 1999, J. Cell. Biol. 144:459). RNaseq analysis was used to identify transcripts altered upon induction of PAM. Differential gene expression analysis was performed on biological triplicates using Cuffdiff, Limma and DESeq2. A set of ~60 transcripts was identified by all 3 analytical methods, and another 200+ transcripts were identified by 2 of the 3 methods. Quantitative polymerase chain reaction (qPCR) was used to validate the differentially expressed transcripts; of the 45 transcripts tested, 23/45 (29) were validated by qPCR. To eliminate transcripts associated only with the doxycycline-inducible system, these transcripts were assessed in wildtype AtT-20 cells vs. two independent, stably transfected AtT-20 lines expressing similarly elevated levels of PAM, trimming the list further. The set of genes whose expression was consistently increased as a consequence of increased PAM expression included a peptidyl-prolyl isomerase (Fkbp4), 4-hydroxyphenylpyruvate dioxygenase (Hpd), and myotilin, an actin cross-linking protein. Genes consistently decreased as a consequence of increased PAM expression included peptide precursors (adrenomedullin, cholecystokinin) and a peptidase inhibitor (Serpine1). Additional studies are in progress to determine whether these proteins contribute to the effects of PAM on cytoskeletal organization and regulated secretion. Support: DK032949 (NIH).

WNT5A Isoforms A and B are differentially regulated during osteogenesis and early mouse development.
D. Bhandari1, K.S. Katula1;
1Biology, The University of North Carolina at Greensboro, Greensboro, NC

WNT5A is a secreted ligand that activates primarily non canonical Wnt signaling pathways. It has important roles in morphogenesis (i.e., anterior-posterior axis elongation and limb formation) and differentiation (i.e., bone and cartilage). WNT5A functions in proliferation, adhesion, migration, and cell...
polarity. Altered WNT5A expression is associated with various human diseases, particularly cancer, but has been linked with the inflammatory response. Our lab is interested in the functional distinctions between the WNT5A isoforms that we term A and B. These isoforms are derived from distinct promoters and the processed proteins differ by 19 AA on their N-terminus. One possibility is that the isoforms display distinct patterns of expression in particular cells, during differentiation and in development, as a consequence of their unique promoters. To begin addressing this hypothesis we analyzed the expression of the WNT5A isoforms during differentiation of osteoblast cells using the cell line hFOB1.19. The cells were plated and grown to confluence at 33.4°C at which point the cultures were transferred to 39°C and treated with differentiation medium. At Days 0, 3, 7, and 10 RNA was isolated from the cells and converted to cDNA. qPCR was conducted using primers for actin, WNT5A isoform A, WNT5A isoform B, RUNX, and OSTERIX and relative-fold change for each target determined. Isoform A and isoform B transcript numbers were also quantified using qPCR generated standard curves. Both isoform A and isoform B transcripts increase by Day 3 of differentiation. At Day 0 there were approximately 1.8X more isoform A than B transcripts. By Day 10 isoform B transcripts levels were slightly higher than isoform A. Isoform B transcripts show a greater fold-change relative to Day 0, increasing by 16-fold, whereas isoform A was found to have a 6-fold increase. RUNX and OSTERIX transcripts both increased and their patterns of expression confirmed that the hFOB1.19 osteoblasts were differentiating. We also examined the expression of WNT5A isoforms A and B during early mouse embryogenesis. Analysis of mouse embryo RNA at stages 10, 11, 12 13, and 14 dpc revealed that promoter A and B transcripts levels are equal at dpc 10 but that promoter A transcripts increase during the period of limb formation and remain higher than promoter B at the other stages. Together, these results suggest that the WNT5A isoform A and B promoters are differentially regulated.

WNT5A isoforms A and B display differential protein function and promoter activity.
A. Elshaarrawi1, K.S. Katula1; 1Biology, The University of North Carolina at Greensbor, Greensboro, NC

WNT5A is a secreted ligand that activates primarily non-canonical Wnt signaling pathways. It has important roles in morphogenesis (i.e., anterior-posterior axis elongation and limb formation) and differentiation (i.e., bone and cartilage). WNT5A functions in proliferation, adhesion, migration, and cell polarity. Altered WNT5A expression is associated with various human diseases, particularly cancer, but has been linked with the inflammatory response. Our lab is interested in the functional distinctions between the WNT5A isoforms that we term A and B. These isoforms are derived from distinct promoters and the processed proteins differ by 19 AA on their N-terminus. One possibility is that the isoforms have differential affinity for non-canonical receptors, selectively affecting particular signaling pathways. Another possibility is that the isoform promoters are differentially regulated. The genomic sequences likely corresponding to the promoter and gene regulatory regions of each isoform were individually cloned into a luciferase reporter vector. Our experimental models are hFOB1.19, normal human osteoblasts that can be induced to differentiate, and HCT-116, a colorectal carcinoma cell line that doesn’t express either isoform A or B proteins. Isoform A and B luciferase promoter constructs were transfected into HCT-116 and hFOB1.19 cells. The patterns of expression in the two cell types were similar for Promoter A but differed more for Promoter B. The cell lines were co-transfected with isoforms A and B expression vectors and luciferase reporters for the transcription factors AP-1 and NFAT, targets of the Wnt Ca2+ and PCP/CE non-canonical signaling pathways. Results show that in HCT-116 the AP-1 reporter is up-regulated when isoform A is transfected but down-regulated when isoform B is transfected. In hFOB1.19 cells both isoforms A and B down-regulate the AP-1 reporter. NFAT
reporter expression was down-regulated in HCT-116, whereas there was no effect in hFOB1.19 cells. Next, AP-1 and NFAT transfected HCT-116 cells were treated with purified isoform B protein for 24 hrs. Our results suggest that the purified isoform B protein up-regulates AP-1 and down-regulates NFAT. Overall, these results suggest that WNTSA isoform proteins have differential effects on the non-canonical signaling pathways in different cell types and that the isoform promoters are differentially regulated.

Size-Dependent Protein Segregation Triggers Macrophage Activation and Phagocytosis.
A.M. Joffe1, M.H. Bakalar2, E.M. Schmid1, M. Podolski1, D.A. Fletcher1;
1Bioengineering, UC Berkeley, Berkeley, CA

Macrophages clear their host of pathogens, cellular debris, and compromised cells through a process of engulfment and digestion known as phagocytosis. One pathway leading to phagocytosis is initiated by macrophage Fc receptor (FcR) recognition of the Fc region of antibodies immobilized on a target. Phosphorylation of an immunoreceptor tyrosine-based activation motif (ITAM)-containing protein associated with the FcR is known to precede phagocytosis, but the mechanism by which FcR binding leads to ITAM phosphorylation remains unclear. The kinetic segregation model of immune signaling proposes that segregation of a phosphatase can lead to sustained ITAM phosphorylation. We tested whether this model holds for antibody-dependent cell phagocytosis by making a set of size-variant synthetic antigens to modulate the distance between a macrophage and a model membrane. We attached these antigens to lipid bilayer-coated beads to act as minimal target cells, and we observed a significant decrease in phagocytosis of targets with large intermembrane distances compared to those with smaller distances. Using TIRF imaging of a live-cell ITAM phosphorylation sensor, we confirmed that ITAM phosphorylation in macrophages decreases with increasing interface distance. By isolating plasma membrane vesicles from macrophages, we were able to show that the tall CD45 phosphatase is segregated from interfaces with short intermembrane distances but present in interfaces with taller intermembrane distances. Taken together, our findings show that shortening the intermembrane distance of a macrophage/target interface to exclude CD45 will lead to increased macrophage activation. This result indicates that the kinetic segregation model applies to antibody-dependent cell phagocytosis and may aid in the design of future antibody therapies.

Heparin-induced BMP6 expression and localization changes in vascular smooth muscle cells.
R. Mathiesen1, M. Garland1, J. Restauro1, E. Jacobson1, L.J. Lowe-Krentz2, J.B. Slee1;
1Department of Natural Science, DeSales University, Center Valley, PA, 2Department of Biological Sciences, Lehigh University, Bethlehem, PA

Bone morphogenetic protein 6 (BMP6) has been shown to bind heparin and influence the activity of bone morphogenetic proteins, which are members of the transforming growth factor-β (TGF-β) superfamily of proteins that regulate proliferation, differentiation, pattern formation, and apoptosis. It can be predicted that BMP6 upregulation might play a role in the anticoagulant functions of heparin; however, the anti-inflammatory mechanisms of heparin are not well characterized, and the role of BMP6 is under investigation. There is an established link between BMP6 and smooth muscle cell physiology, but it is unclear how BMP6 affects this physiology. Microarray data collected from serum-
deprived vascular smooth muscle cells treated with heparin for 24 hours indicated a 1.899-fold increase in BMP6 compared to untreated control cells. Fluorescent microscopy using antibodies specific for BMP6 shows that short-term heparin treatment (less than 40 minutes) resulted in decreased cytoplasmic BMP6 staining, suggesting that heparin could induce BMP6 release from proliferating vascular smooth muscle cells. Current research looks to validate these findings by observing localization and expression changes of BMP6 in response to heparin treatment in vascular smooth muscle cells cultured in serum-containing media and serum-free media.

Signal-Regulated Nuclear Transport and Accumulation of Smad Proteins studied by High-Speed Single-Molecule Microscopy.
Y. Li1, W. Luo1, W. Yang1;
1Department of Biology, Temple university, Philadelphia, PA

Nuclear translocation of active Smad protein complexes is a critical step in signal transduction of transforming growth factor β (TGF-β) from transmembrane receptors into the nucleus. Specifically, normal nuclear accumulation of Smad2/Smad4 protein complexes induced by TGF-β1 plays critical roles in preventing cancers. However, the relationship between nuclear accumulation and the nucleocytoplasmic transport kinetics of Smad proteins in the presence of TGF- β1 remains obscure. By combining a high-speed single-molecule tracking microscopy and Förster resonance energy transfer (FRET) techniques, we tracked the entire TGF-β1-induced process of Smad2/Smad4 complexes formation as well as their transport through nuclear pore complexes (NPCs) in live cells with a high spatiotemporal resolution of 2 ms and < 20 nm. Our single-molecule FRET data have revealed that in TGF- β1 treated cells Smad2/Smad4 complexes formed in cytoplasm, imported through the NPCs as entireties, and finally dissociated into monomers in the nucleus. Moreover, we found that monomeric Smad2 or Smad4 cannot accumulate in the nucleus without the presence of TGF-β1, mainly because both of them have an approximately two-fold higher nuclear export efficiency compared to their nuclear import. Remarkably and reversely, complexes of Smad2/Smad4 induced by TGF-β1 can rapidly concentrate in the nucleus due to its almost four-fold higher nuclear import rate in comparison with its nuclear export. Thus, we believe that the determined TGF- β1 depended transport configurations and efficiencies for monomers or complexes of Smad2 and Smad4 elucidate the basic molecular mechanism to understand their nuclear transport and accumulation.

Differential activation of ERK, JNK, and p38 mitogen-activated protein kinases (MAPKs) is central to cellular decisions ranging from cell cycle progression to apoptosis. In this study, we use an optogenetic and live-cell imaging approach to selectively and acutely activate individual kinases and dissect cross-regulation of MAPKs and its determination of cell responses. Focusing on the MAPK kinase, MKK6, photo-uncaging constitutively active MKK6 activates isoforms of the stress-activated MAPK p38.
subfamily but not JNKs, consistent with prior literature. Uncaging MKK6 strongly inhibits basal and growth factor-stimulated ERK activity, but surprisingly this negative crosstalk is not affected by pharmacological inhibition of p38 nor shRNA depletion of p38alpha, both of which ablate MKK6-mediated p38 kinase activity in our cells. We also show that photo-activation of MKK6 is sufficient to induce caspase-3 activity and release of cytochrome C from mitochondria, hallmarks of apoptosis. The course of MKK6-induced apoptosis is accelerated when type IA phosphoinositide 3-kinases are inhibited; notably, MKK6-induced apoptosis still occurs when p38 kinase activity is inhibited, but in a smaller fraction of cells.

Post-Translational Modifications in Signaling

Board Number: B608
Integration of Post-Translational Modification Spaces in Lung Cancer Signaling Pathways.
M.L. Grimes1, B. Hall2, K. Rikova2, E. Smirnova3, N. Clark4, P. Hornbeck5, A. Ma’ayan6, M.J. Comb5; 1Division of Biological Sciences, University of Montana, Missoula, MT, 2Cell Signaling Technology, Danvers, MA, 3Department of Mathematical Sciences, University of Montana, Missoula, MT, 4Systems Biology Center, Icahn School of Medicine at Mount Sinai, New York, NY

To elucidate patterns in post-translational protein modifications (PTMs) that may point to characteristic disease signatures and etiology in lung cancer, we coupled immunoprecipitation using modification-specific antibodies with Tandem Mass Tag (TMT) mass spectrometry to compare 45 lung cancer cell lines to normal lung tissue, and cell lines treated with anti-cancer drugs. These data reveal more than 4000 proteins modified by phosphorylation, methylation, and acetylation, and represent the first large-scale integrative analysis of these PTMs together. A cluster-filtered network approach was used to interrogate the data. We posit that clustering of protein modifications under different conditions reveals patterns specific to the system, and that PTM clusters that contain proteins known to interact with one another are likely to represent functional signaling pathways. We optimized clustering methods based on a machine learning algorithm (t-SNE) using a combination of statistical relationships. PTM clusters were used to filter protein-protein interaction (PPI) relationships to retain only interactions between proteins whose modifications co-clustered. The resulting cluster-filtered network (CFN) removed bias in protein interaction databases, and outlined signaling pathways specific to lung cancer cell lines. We found that a number of proteins modified by more than one type of PTM had negative correlations between different PTMs, suggesting that molecular “OR” switches govern a surprising number of signal transduction events. We also showed that the acetyltransferase EP300 appears to be a hub in the network of pathways involving phosphorylation, acetylation, and methylation. In addition, the data shed light on the mechanism of action for geldanamycin, the HSP90 inhibitor, and indicate that acetylation and methylation, together with phosphorylation, are involved in regulation of the cytoskeleton, endocytosis, and control of gene expression through RNA binding proteins.
In contrast to non-transformed cells, cancer cells are able to survive and proliferate in stressful conditions often characterized by hypoxia, lack of nutrients, and exposure to chemotherapeutic drugs. Cancer cells accomplish this, in part, by rewiring or activating specific signal transduction cascades. A primary signaling pathway induced by a variety of stresses in cancer cells is the p38 MAP kinase (MAPK) pathway. Upon activation, p38 phosphorylates multiple downstream substrates including the serine/threonine kinase MAPKAP kinase 2 (MK2). However, the precise roles that MK2 plays in breast cancer progression are poorly understood. Here we demonstrate that p38-MK2 signaling pathway is constitutively active in both breast cancer cell lines and in primary human tumor samples. Moreover, we show that shRNA-mediated knockdown of MK2 in SUM149 breast cancer cells reduces cell proliferation. To gain additional insight into the biological functions of this kinase in breast cancer, we performed a proteomics-based screen to identify novel substrates of MK2. Using this approach, we identified and subsequently validated the DNA helicase RECQ1 as a novel substrate of MK2. As a member of the RecQ family of helicases, RECQ1 plays an important role in relieving replicative stress and has recently been implicated as a susceptibility gene in familial forms of breast cancer. We show that MK2 phosphorylates RECQ1 solely at S392, a residues located within the helicase domain of the enzyme, and that MK2-mediated phosphorylation of RECQ1 enhances its catalytic activity as determined by a branch migration assay. We further demonstrate that overexpression of a non-phosphorylatable RECQ1 mutant in triple-negative breast cancer cells sensitizes these cells to DNA damage-induced apoptosis, while expression of a phosphomimetic mutant promotes cell proliferation and enhances resistance to cell death in response to treatment with adriamycin and hydroxyurea. Collectively, these results implicate RECQ1 as a critical substrate of MK2 in breast cancer cells and suggest that MK2-mediated phosphorylation of RECQ1 may foster the development of genomic instability and resistance to chemotherapy.

Constitutively activating mutations in Gaq and Gα11 (Gαq/11) have been reported in up to 93% of uveal melanomas. Although constitutively active Gaq/11 promote uveal melanoma tumorigenesis through activation of multiple downstream pathways, no therapies inhibit constitutively active Gaq/11. Studies suggest that upon activation of some Ga subunits increased palmitate turnover and increased cytoplasmic localization occur. The purpose of our studies is to understand the role of palmitoylation in trafficking and signaling of constitutively active Gaq/11 in uveal melanoma. Using live cell imaging and cellular fractionation of HEK 293 cells and uveal melanoma cells, constitutively active GaαG209L and GaαQ209P show decreased localization at membranes compared to wild type Gaα, suggesting increased turnover of attached palmitate in constitutively active mutants. Moreover, immunofluorescence
microscopy revealed that a palmitoylation-deficient constitutively active mutant displays a complete loss of plasma membrane localization and an inability to signal as measured by Rho- and Rac-dependent YAP translocation into the nucleus, TEAD-dependent luciferase activity, and ERK phosphorylation. These studies demonstrate that palmitoylation of mutationally activated Gαq/11 is required for its signaling functions. Although live cell imaging and cellular fractionation experiments reveal decreased membrane localization of constitutively active Gαq compared to wild-typeGαq, our studies suggest that complete loss of membrane localization abolishes constitutively active Gαq-dependent signaling. Disruption of constitutively active Gαq/11 palmitoylation and localization may be an effective strategy for inhibiting constitutively active Gαq/11 oncogenic signaling in uveal melanoma.

O-GlcNAc Transferase Regulates Glioblastoma Acetate Metabolism via Regulation of CDK5-dependent ACSS2 phosphorylation.
Z. Bacigalupa1, M.D. Smith1, C.M. Ferrer1, L. D’Agostino2, S. Trefely3,4, N. Snyder3, C.D. Katsetos2, M.J. Reginato1;
1Biochemistry, Drexel University, Philadelphia, PA, 2Pathology, Drexel University, Philadelphia, PA, 3A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, 4Cancer Biology, University of Pennsylvania, Philadelphia, PA

Cancer cells preferentially utilize glycolysis to supply the necessary precursors for macromolecular biogenesis. A subset of the glucose taken up is shunted into the hexosamine biosynthetic pathway where it is used to synthesize UDP-GlcNAc, a substrate of O-GlcNAc transferase (OGT), which serves to modify cytoplasmic and nuclear proteins with O-linked sugar moieties. The post-translational addition of an O-GlcNAc moiety to serine or threonine residues can modulate the activity of nuclear and cytoplasmic proteins. Here, we show that both OGT and O-GlcNAcylation are elevated in glioblastoma cell lines compared to normal human astrocytes. Moreover, immunohistological analyses of human glioblastoma show increased OGT staining correlated with disease progression. Interestingly, when OGT expression is reduced in glioblastoma cells, we detect a significant reduction in anchorage-independent growth, cellular acetyl-CoA concentrations, and decrease in free fatty acids. Importantly, reducing OGT expression in an orthotopic intracranial mouse model resulted in significant reduction in tumor growth and extension of survival. Conversely, overexpressing OGT was sufficient to increase anchorage-independent growth, acetyl-CoA concentrations, and intracellular lipids. Mechanistically we show that OGT overexpression regulates carbon-flux of acetate to acetyl-CoA, a reaction that requires the enzymatic activity of acetyl-CoA synthetase 2 (ACSS2). ACSS2 is critical for OGT-mediated regulation of glioblastoma cell growth, as overexpression of ACSS2 partially rescue cell growth defects. Proteomics analysis identified Ser267 on ACSS2 as being uniquely phosphorylated when O-GlcNAc levels were elevated. This residue was predicted to be a substrate for Cdk5-dependent phosphorylation, which we confirmed with site-directed mutagenesis, immunoprecipitation, and in vitro kinase assay experiments. Thus, we show that OGT and O-GlcNAcylation are required for glioblastoma growth, via a novel regulatory mechanism of acetate and lipid metabolism via regulation of CDK5/ACSS2, and suggests that OGT and CDK5 may be a novel therapeutic targets for treatment of glioblastomas.

N-terminal protein modifications regulate the activity of Myosin Regulatory Light Chain 9 in colorectal carcinoma cells.
C.D. Nevitt¹, J.G. Tooley², C.E. Schaner Tooley²;
¹Biochemistry and Molecular Genetics, University of Louisville, Louisville, KY, ²Biochemistry, University at Buffalo, Buffalo, NY

Dysregulation of N-terminal post-translational modifications (Nt-PTMs) is found in multiple cancers and developmental disorders. However, the exact roles Nt-PTMs play in regulating protein function remain poorly understood. Our objective is to clarify the role of N-terminal methylation (Nt-Me) and acetylation (Nt-Ac) on the function of Myosin Regulatory Light Chain 9 (MYL9). MYL9 is a key cytoskeletal regulator and transcription factor and is the first protein confirmed to undergo both Nt-Me and Nt-Ac. Nt-PTM restricted mutants of MYL9 were generated by modifying the consensus sequence targeted by Nt-methyltransferases and Nt-acetyltransferases. These mutants were assayed alongside wildtype (WT) protein for effects on MYL9 stability and activity in HCT116 human colorectal carcinoma cells. MYL9 half-life was tracked using the photoswitchable fluorescent protein Dendra2. Dual loss of Nt-Ac and Nt-Me resulted in an increase in MYL9 half-life, while individual loss of either Nt-Ac or Nt-Me produced no change, suggesting that these modifications redundantly promote protein turnover. We also found that Nt-PTMs regulate the transcriptional activity of MYL9. Upon TNFα stimulation, MYL9 promotes transcription of Intracellular Adhesion Molecule 1 (ICAM-1). HCT116 cells were transduced with WT or mutant MYL9, and ICAM-1 transcript levels were measured by qPCR before and after TNFα stimulation. TNFα treatment resulted in an increase in ICAM-1 transcription when WT MYL9 was present, but this effect was significantly greater in cells expressing an Nt-Ac deficient form of MYL9. No change from WT was seen with an Nt-Me deficient MYL9 variant. This suggests that Nt-Ac reduces the ability of MYL9 to promote ICAM-1 transcription, and identifies a role for this modification in diminishing inflammatory signaling. We are currently testing whether Nt-Ac reduces the transcriptional activity of MYL9 by limiting its nuclear translocation or its ability to bind the ICAM-1 promoter. Our preliminary data thus far indicates TNFα treatment induces nuclear translocation equally for all forms of MYL9. Finally, we are investigating the role of MYL9 Nt-PTMs in its ability to promote cell migration. As Nt-acetylation occurs in the cytoplasm and seems to block MYL9 transcriptional activity, we predict it will be a positive regulator of cell motility. Together, these findings begin to delineate the regulatory role of Nt-PTMs on MYL9 function, which has important implications for multiple disease states, including cancer metastasis and inflammation.

BCAR3, a cell migration-associated protein, is regulated by the E3 ligase Cullin 5-SOCS6.
E.M. Steenkiste¹,², C. Pilling¹,², J.A. Cooper¹,²;
¹Division of Basic Sciences, Fred Hutchinson Cancer Research Center, Seattle, WA, ²Molecular and Cellular Biology Program, University of Washington, Seattle, WA

Cell migration is important for embryogenesis, tissue repair, and other important biological processes. Migrating cells form protrusions in the direction of motion and attach to their surroundings through multi-protein structures called focal adhesions (FAs), which are assembled at the leading edge and disassembled behind. Adaptor proteins breast cancer antiestrogen resistance 3 (BCAR3) and p130Cas (Cas) form a complex in FAs. BCAR3 is elevated in more aggressive, metastatic cancers. Additionally,
BCAR3 regulates pathways that contribute to membrane protrusion, cytoskeletal remodeling, migration, and antiestrogen resistance. These pathways, if aberrant, could contribute to a cancer phenotype. However, very little is known about how BCAR3 is regulated. We found that BCAR3 expression is regulated by the E3 ubiquitin ligase, Cullin 5 (Cul5) in breast epithelial MCF10A cells. In the absence of Cul5 (knockdown or CRISPR knockout), BCAR3 protein, but not RNA, is increased. Cul5 substrate specificity is conferred through different adaptors that bring the substrate to the E3. We found that BCAR3 is bound by SOCS6, a member of a family of Cul5 adaptor proteins called suppressors of cytokine signaling (SOCS). Knockdown of SOCS6 increases BCAR3 protein levels, suggesting that SOCS6-Cul5 complexes mediate BCAR3 turnover. SOCS6 contains an SH2 domain, which binds phosphotyrosine. Mutating the SH2 domain inhibits BCAR3 binding, suggesting that phosphorylation is required. Deleting the C-terminus of BCAR3 is sufficient to inhibit binding to SOCS6. This suggests that the phosphorylation of a tyrosine residue in the C-terminus of BCAR3 mediates its association with SOCS6.

BCAR3 is stabilized and bound by Cas, which also binds Cul5-SOCS6, suggesting that Cas may be required for Cul5-SOCS6 interaction with BCAR3. However, a BCAR3 mutant that cannot bind to Cas still associates with SOCS6, suggesting that Cas is not required for BCAR3-SOCS6 association. Additionally, knocking down Cas does not disrupt BCAR3-SOCS6 association. While more experiments are needed to establish mechanism, the results suggest a model in which BCAR3-Cas interaction stabilizes BCAR3 by inhibiting SOCS6 binding. By investigating how BCAR3 turnover is regulated, we hope to identify factors that increase BCAR3 turnover in cancers where it is overexpressed.

Inhibition of deacetylases attenuates lipid accumulation and caspase 3 activation in pancreatic beta cells under the duress of glucolipotoxicity: Potential roles for CD36 activity.

S. Khan¹, A. Kowluru¹;
¹β-Cell Biochemistry Laboratory, John D. Dingell VA Medical Center, and Department of Pharmaceutical Sciences, Wayne State University, Detroit, MI

The cluster of differentiation 36 (CD36), a membrane glycoprotein, facilitates uptake of long-chain fatty acids in various cell types including the pancreatic beta cell. It is widely felt that CD36 promotes lipid accumulation and storage, thus contributing to the pathogenesis of metabolic stress and diabetes. Recent evidence also indicates that CD36 undergoes posttranslational acetylation and deacetylation. However, putative roles of such modifications in the onset of beta cell dysregulation under pathological conditions (glucolipotoxicity; GLT) remain largely unknown. Using pharmacological approaches, we tested the hypothesis that acetylation/deacetylation signaling steps are involved in CD36-mediated lipid accumulation and downstream apoptotic signaling steps in pancreatic beta (INS-1 832/13) cells under GLT conditions.

INS-1 832/13 cells were exposed to GLT conditions (20 mM glucose plus 0.5 mM palmitate) in the absence or presence of known inhibitors of deacetylase, including valproic acid (VAP; 2.5-5.0 mM) or trichostatin A (TSA; 0.25-0.5 μM) or sulfo-n-succinimidy oleate (SSO; 200 μM), an irreversible inhibitor of CD36. Lipid accumulation was determined by oil-red-o staining and quantified by image analyses (Image J software). Western blotting assessed CD36 expression and caspase 3 activation. Exposure of INS-1 832/13 cells to GLT resulted in significant lipid accumulation without affecting the CD36 expression. SSO markedly suppressed GLT-mediated lipid accumulation. Treatment of pancreatic beta cells with TSA or VPA significantly reduced GLT-associated lipid accumulation with no discernable effects.
on CD36 expression. Furthermore, TSA or SSO treatment significantly reduced GLT-induced caspase 3 activation. Based on these findings, we propose that a deacetylation signaling step might regulate CD36-mediated lipid accumulation and caspase 3 activation in pancreatic beta cells exposed to GLT conditions. Identification of specific deacetylases that control CD36 functional activity should provide novel clues for the prevention of islet dysfunction under conditions of metabolic stress such as GLT.

The function of Metabolic Syndrome Complex 1 (MSC1) in myogenesis by modulating YY1 transcriptional activity.
H. Lee¹, Y. Hong¹, M. Kim¹, Q. Tran¹, H. Cho¹, S. Park¹, J. Park¹, J. Park¹;
¹Department of Pharmacology and Medical Science, Research Institute for medical sciences, Chungnam National University, Daejeon, South Korea

The development of skeletal muscle requires the progression of a highly ordered cascade of events comprising myogenic lineage commitment, myoblast proliferation, and terminal differentiation. Metabolic syndrome Complex 1 (MSC1) is a multidomain protein and subunit of a lysine acetyltransferase complex that acetylates histone H4 and p53 but the function of MSC1 is unclear. MSC1 Knockout (KO) mice die shortly after birth and display a wide variety of phenotypes within the skeletal and hematopoietic systems. YY1 binds DNA through four C-terminal zinc finger domains and can function as an activator or repressor of gene expression. In the present study, we found that protein and mRNA expression level of MSC1 is decreased during myoblast differentiation in C2C12 cells and YY1 is also decreased during myogenesis. And MSC1 overexpression results in inhibition of myogenesis. Therefore, overexpression of MSC1 does not result in the formation of myotubes. On the other hand MSC1 knockdown was showed induction of myoblast differentiation. In addition, MSC1 directly regulates YY1 expression level how was bind YY1 promoter. The promoter activity of YY1 decreases with the progress of differentiation but its promoter activity is maintained without decrease when MSC1 is overexpressed. Also MSC1 transgenic mouse had an unequal shape and length of muscle fibers. The muscle development also seemed to have occurred abnormally. However, the leg muscles of the MSC1 TG mouse showed no significant difference in size from the wile type mouse when viewed visually. Taken together, these results demonstrate that MSC1 has a negative effect on muscle differentiation both in vitro and in vivo. Based on these finding, MSC1 may have an important role in myogenesis.

The SMYD methyltransferase Set6 interacts with the GimC/prefoldin complex to regulate cell growth and stress response pathways.
D. Jaiswal¹, J. Lum¹, J. Moresco², J. Yates iii², E.M. Green¹;
¹Biological Sciences, University Of Maryland Baltimore County, Baltimore, MD, ²Department of Chemical Physiology, The Scripps Research Institute, La Jolla, CA

Protein lysine methylation has emerged as a critical regulator of signaling pathways that promote proper growth, development, and differentiation in response to environmental cues. While lysine methylation has been detected on a large fraction of the proteome, we have a limited understanding of its potential roles in signaling and its contribution to cell growth and development. Specifically, the SMYD protein lysine methyltransferases (KMTs) have been identified as key regulators of skeletal and cardiac muscle development, with clear roles in myogenic differentiation and links to cardiac disease. Furthermore, the
aberrant regulation of SMYD proteins is associated with both solid tumor progression and blood cancer. Despite their critical roles in diverse developmental and pathological pathways, our knowledge of SMYD protein substrates and their potential functions in signaling is severely lacking. The *Saccharomyces cerevisiae* protein Set6 is a conserved member of the SMYD family of enzymes, although little is known about its biochemical or biological function. Here, we performed a proteomic screen to identify interacting partners of Set6 and uncovered an interaction with the GimC/prefoldin complex, a chaperone complex for tubulin, actin and other proteins that also plays a role in transcriptional elongation. Consistent with these findings, loss of Set6 confers mild benomyl sensitivity and cell cycle defects on cells and strongly suppresses phenotypes associated with GimC/prefoldin dysfunction, suggesting that Set6 also genetically functions in the same pathway as GimC/prefoldin. The preliminary biochemical analysis also demonstrates that Set6 is likely an active methyltransferase on multiple non-histone proteins, and we will present data investigating the hypothesis that methylation by Set6 promotes proper functioning of the GimC/prefoldin complex. Overall, this work sheds new light on conserved pathways targeted by SMYD family methyltransferases that will be important to understanding their function in development and disease in metazoan systems.

Poldip2 is an oxygen-sensitive mitochondrial protein that controls Oxidative/glycolytic metabolism balance and Proteasome activity.

F.I. Paredes¹, M. Tejos¹, H. Williams¹, G. Benavides², V. Darley-Usmar², A. San Martin¹;

¹Department of Medicine, Division of Cardiology, Emory University, Atlanta, GA, ²Department of Pathology, University of Alabama at Birmingham, Birmingham, AL

The polymerase delta interacting protein 2 (Poldip2) is a nuclear-encoded mitochondrial protein of unknown function. We recently reported that Poldip2 is repressed under hypoxia and that its deficiency results in repressed mitochondrial function and increased glycolytic activity. However, the mechanisms responsible for this metabolic reprogramming and its consequences are unknown. In this study, we show that Poldip2 controls the lipoylation and consequently the activity of the pyruvate and α-ketoglutarate dehydrogenase complexes by a mechanism that involves Clp-protease complex-mediated degradation of Acyl-CoA Synthetase Medium-Chain Family Member 1 (ACSM1), a lipoate-activating enzyme required for the utilization of lipoic acid derived from the salvage pathway. With regards to the increased glycolytic activity, we found that Poldip2 deficiency inhibits PHDs inducing HIF-1-dependent upregulation of Hexokinase 2. As a result, we observed an increase in the flux through the Hexosamine biosynthetic pathway (HBP), a glucose metabolic pathway that produces uridine diphosphate N-acetylglucosamine, the sugar donor for the O-GlcNAc transferase (OGT). The OGT-catalyzed transfer of O-GlcNAc is a post-translational modification implicated in cell signaling. Interestingly we found that Poldip2 deficiency induces the inhibition of the ubiquitin proteasome system (UPS) by OGT-dependent O-GlcNAcylation of the 19S regulatory unit of the 26S proteasome regulatory subunit 4 (PRS4).

Additionally, we demonstrated that Poldip2-mediated inhibition of the UPS is required for the hypoxia-induced expression of connective tissue growth factor (CTGF), a cytokine that participates in multiple pathologies including fibrotic diseases and cancer. In all, we demonstrate that Poldip2 is an oxygen sensitive protein that regulates the activity of key enzymes of the Krebs cycle by coupling proteasome activity to mitochondrial function and fibrotic responses under hypoxia.

Prolyl dihydroxylation of extra-ribosomal Rps23/uS12 regulates hypoxic adaptation in fission yeast.
S.J. Clasen1, W. Shao1, H. Gu1, P.J. Espenshade1;
1Department of Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Low-oxygen adaptation is transcriptionally controlled by the Sterol regulatory element-binding protein Sre1N in fission yeast. Sre1N is inactive in the presence of oxygen through direct binding to the prolyl-3,4-dihydroxylase Ofd1. We show that under hypoxic conditions, Ofd1 is sequestered from Sre1N by the nuclear import adaptor Nro1 and the Ofd1 substrate Rps23/uS12. Ofd1, Nro1, and Rps23 form a complex in the cytosol that traffics to the nucleus to deliver dihydroxylated Rps23 for assembly into the small ribosomal subunit. In cells lacking Nro1, we find that Rps23 is predominantly unmodified or monohydroxylated using SILAC and targeted mass spectrometry. Low oxygen stabilizes the Ofd1-Nro1-Rps23 complex by inhibiting Ofd1-dependent dihydroxylation of Rps23. This sequestration model for Sre1N regulation by Ofd1 is further supported by our discovery of a shared Ofd1-binding sequence in Sre1N, Nro1, and Rps23, and by our ability to control Sre1N activation by reducing or elevating Rps23 levels. Since ribosomal protein expression is tightly correlated to the growth state of the cell, this allows nutrients to control Ofd1 availability and thus Sre1N activity. Ofd1 is one of several hydroxylases that modify ribosomal proteins. Our work provides a paradigm for how ribosomal oxidases use their substrates to regulate extra-ribosomal signaling networks to coordinate pro-growth pathways in the cell.

Antiproliferative Activity of Natural Compounds Isolated from Artemisia species.
V. Godieva1, M.A. Barbieri1, M.L. Veisaga1, S. Soriano1;
1Biological Sciences, Florida International University, Miami, FL

Throughout human history, natural products have been used in traditional medicines. Today, plants continue to retain their historical significance as important sources of natural and novel compounds useful directly as medicinal agents and as sources for generating derived-natural compounds. Artemisia is a large and diverse genus of plants with approximately 400 species. In this study, we examined the effect of plant extracts prepared from two different species of Artemisia (Artemisia douglasiana and Artemisia tridentata tridentata) on survival and melanogenesis of B10F16 murine cell lines.

Several extracts from aerial parts of Artemisia species were prepared with selective organic solvents (e.g., hexane, ethyl acetate). Plant extracts were dried, dissolved in DMSO to a concentration of 100 mg/ml, and then added to media containing B10F16 murine cell lines in a concentration dependent manner. After incubation, the effect of these plant extracts on cell proliferation and melanin production were evaluated by the MTT proliferation assay and by measuring the absorbance of the collected sample at a wavelength of 405 nm, respectively.

Both species of Artemisia inhibited proliferation of B10F16 murine cell lines in concentration depended manner. However, Artemisia tridentata tridentata showed the strongest inhibitory effect on melanogenesis even in the presence of IBMX. Furthermore, GC/MS analysis showed a unique chemical composition for each species of Artemisia.
Therefore, these observations indicate that both species of Artemisia may contain several potential natural compounds, which are able to block cell proliferation as well as melanin production in murine cell lines.

Trim13 E3 ligase regulates stability of orphan nuclear receptor Nur77 via casein kinase 2.  
B. Huang1, H. Pei1, S. . Baek1;  
1Biochemistry Molecular Biology, Yeungnam University, College of Medicine, Daegu, South Korea

Nur77, also known as NGFI-B, NR3, or NR4A1, was the first member of the NR4A family to be identified as a gene induced by NGF. Nur77 is an immediate early response gene and plays a critical role in cellular processes in response to diverse stimuli including cytokines, stress, and apoptotic signals. Nur77 has been implicated in a many pathological processes, including cancer, immune alterations and metabolic or neurological diseases. Here we show that Nur77 protein is degraded by ubiquitin-proteasome mechanism and determined that the ubiquitination by E3 ligase is important for an efficient targeting of Nur77 to degradation. We found that the ubiquitination of Nur77 is mediated by the tripartite motif 13 (Trim13), a RING-type E3 ubiquitin ligase. An interaction between Nur77 and Trim13 was confirmed by co-immunoprecipitation assay. We determined ubiquitination site in Nur77 that is important for Trim13-mediated degradation. Moreover, motif scan analysis provided potential that specific sites are able to be phosphorylated by CK2. Treatment of TBB or CX-4945, CK2 inhibitors, increased Nur77 protein levels. Nur77 levels were significantly decreased in cells overexpression of CK2a, but not in cells expressing inactive mutant K68M form. CK2a increased Nur77 ubiquitination, but had less effect on inactive mutant. We also found the phosphorylation site by CK2 that is important for Nur77 stability. Importantly, the introduction of special serine mutant abrogated Trim13-induced Nur77 degradation and ubiquitination. Taken together, these results suggest that CK2a-mediated Nur77 phosphorylation is target for its degradation by Trim13.

Phosphorylation of the HPV E6 oncoprotein by DNA damage response kinases links the E6 interaction with 14-3-3 proteins and p53.  
J.V. THATTE1, P. Massimi1, L. Banks1;  
1Tumour Virology, International Centre for Genetic Engineering and Biotechnology (ICGEB), TRIESTE, Italy

Human Papillomavirus (HPV) is a major cause of human cancers, with cervical cancer being the most prevalent. The virus encodes two oncoproteins, E6 and E7, together which are responsible for the initiation and maintenance of malignancy. The cancer-causing E6 oncoproteins are characterized by the presence of a PDZ binding motif (PBM) on the C-terminus. This motif confers interaction with a variety of cellular proteins involved in the regulation of cell polarity, and phosphorylation by PKA switches E6 substrate specificity to members of the 14-3-3 protein family. In this study we have been interested in analyzing the conditions under which E6 is subject to phosphorylation within the PBM. Using a variety of approaches, we demonstrate a striking increase in the levels of E6 phosphorylation by a number of DNA damage response kinases, including those that are induced following treatment with chemotherapeutic agents. In order to understand the biological relevance of these phospho-modifications of E6, we have analyzed their effects upon the ability of E6 to inhibit p53 transcriptional activity. We show that
phospho-E6 has increased interaction with 14-3-3 proteins, a direct consequence of which is an inhibition of p53 transcriptional activity. These studies demonstrate that, under conditions that induce the DNA damage response, E6 has acquired an alternative means of disrupting p53 activity, through its PBM phosphorylation and subsequent sequestration of 14-3-3 from p53. This has important implications for how E6 contributes towards the development of malignancy: it provides an alternative means of inhibiting p53 activity, explains why the PBM is specifically conserved in cancer causing E6 oncoproteins, and explains why the residual levels of p53 in cervical cancer are nonetheless subject to inactivation by E6.

Investigating the function and mechanism of Gpa2 phosphorylation.
S. Huang¹, Y. Wang¹, R. Green¹;
¹Biology, Saint Louis University, SAINT LOUIS, MO

G proteins are important molecular switches that are involved in transmitting a variety of signals from outside to the inside of the cells. G proteins are highly conserved, which allows studying their mechanisms of regulation in model organisms such as the budding yeast Saccharomyces cerevisiae. Gpa2 is a yeast G alpha protein that functions in the glucose signaling and pseudohyphal growth pathway. Through the usage of phos-tag SDS-PAGE, we found that in normally growing cells a substantial amount of Gpa2 protein exists as phosphorylated species. Phosphorylation of Gpa2 requires its N-terminal region, a region that is important in mediating the interaction of Gpa2 with GPCR as well as the plasma membrane. We tested possible kinase(s) that could regulate Gpa2 phosphorylation and found that protein kinase A and casein kinases are involved in this process. In the future study, we will identify Gpa2 phosphorylation sites and then investigate the potential role of Gpa2 phosphorylation.

Investigating Gpa2 Phosphorylation in Saccharomyces cerevisiae.
R. Green¹, S. Huang¹, Y. Wang¹;
¹Department of Biology, Saint Louis University, Saint Louis, MO

Gpa2 is a G alpha protein in a nutrient signaling pathway in yeast. Recently, we found that Gpa2 undergoes elevated levels of phosphorylation as well as accumulation in the mitochondria in response to the treatment of nitrogen starvation. We hypothesize that phosphorylation of Gpa2 could regulate its localization. Typically, the N-terminal region of G alpha proteins functions to interact with the cell membrane. If phosphorylation does control the observed localization of Gpa2 inside of the cell, it is very likely the modification occurs at the N-terminal region of the protein. To test this, we constructed a truncated mutant of Gpa2 and demonstrated that the N-terminal region of the protein is indeed required for this phosphorylation. Simultaneous mutating the 10 serine residues within the N-terminal region of Gpa2 to alanine also blocked Gpa2 phosphorylation. This further supported phosphorylation sites are located on the N-terminal region of Gpa2. In future studies, we will work to identify the kinase(s) responsible for phosphorylating Gpa2, which is a critical step in understanding the signaling roles of this modification; furthermore, we will investigate the precise role of phosphorylated Gpa2.

Visualizing Direct Interactions in the Mechanobiome.
P. Kothari², V. Srivastava³, V. Aggarwal³, I. Tchernyshyov³, J. Van Eyk⁴, T. Ha³, D.N. Robinson¹; ¹Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD, ²Pharmaceutical Chemistry, University of California San Francisco, San Francisco, CA, ³Biomedical Engineering, Johns Hopkins School of Medicine, Baltimore, MD, ⁴Cedars-Sinai Medical Center, Los Angeles, CA

Every biological process, ranging from cell migration to embryogenesis, relies on a cell’s ability to adapt to changing mechanical environments. By studying the model shape change process cytokinesis in Dictyostelium, we find that the cell is a finely tuned control system, with proteins that modulate their behavior in response to mechanical and biochemical signals. We have uncovered the integrated control system that endows the cell with the ability to drive contractility and furrow ingress in the presence of various mechanical and environmental stresses. Although we know many of the players involved in this control system, their biochemical interactions that allow force propagation through the cortical network are still poorly defined. To identify the direct interactions that govern a cell’s mechanical response, we performed immunoprecipitation followed by mass spectrometry on two key nodes of the control system, the scaffolding protein IQGAP2 and the actin crosslinker cortexillin I. This approach led to the discovery of potential binding partners of these nodes. Using fluorescence cross-correlation spectroscopy (FCCS), we have confirmed many of these interactions in live cells, and by measuring concentrations and apparent binding coefficients, we are elucidating the network of biochemical interactions.

From the mass spec analysis, myosin II was identified as a biochemical interactor of both cortexillin I and IQGAP2. By FCCS, myosin II has a measured apparent in vivo KD of 0.6 μM with cortexillin I, and 1.5 μM with IQGAP2. Interestingly, the myosin II-IQGAP2 and cortexillin I-IQGAP2 interaction in vivo KD’s decrease by approximately 5-fold in an iqgap1 null. This, in combination with stoichiometry information from Single Molecule Pulldown, suggests a potential mechanism for the role of IQGAP1 as a negative regulator on the myosin II-cortexitillin I mechanoresponsiveness. In addition, we identified a few unusual interactors by mass spec analysis, such as RNP1, discoidins, and methylmalonyl semialdehyde dehydrogenase (mmsdh), which we previously identified in genetic suppressor screens, providing greater evidence for their function in the network. Using the cytokinesis control system as a model, we are identifying a quantitative interaction map, complete with new interactions, that is uncovering new biochemistry associated with the mechanobiome.

Truncating mutations in the sarcomere protein titin cause dilated cardiomyopathy due to sarcomere insufficiency. However, it remains mechanistically unclear how these mutations decrease sarcomere content in cardiomyocytes. Using human induced pluripotent stem cell derived cardiomyocytes and live microscopy, we characterized the fundamental mechanisms of cardiac sarcomere formation. We identify that titin truncating mutations lead to an impairment of sarcomerogenesis and subsequent myofibrillar assembly. We observe that sarcomerogenesis initiates at focal adhesions, where nucleation and radial assembly of α-actinin-2 containing fibers provide a template for z-body fusion and subsequent striation. Using CRISPR/Cas9-mediated engineering, we mechanistically identify that titin provides an essential mechanical connection that propagates diastolic traction stresses from β-cardiac myosin, but not nonmuscle myosin II, to focal adhesions during sarcomerogenesis. Ablating focal adhesions or decoupling titin binding from focal adhesions abolishes sarcomere assembly. The β-cardiac myosin-titin-focal adhesion mechanical connection transmits the forces required to direct α-actinin-2 radial fiber assembly and sarcomere formation. Together these results identify the mechanical and molecular components critical for human cardiac sarcomerogenesis and provide insights into the molecular and environmental origins of cardiomyopathies.

Development and implementation of a Förster Resonance Energy Transfer based biosensor for measuring intracellular tension and force.
R.G. Hart1, D. Kota2, L. Brunmaier2, J. Liu3, I. Chandrasekar1;
1Sanford Children’s Health Research Center, Sanford Research, Sioux Falls, SD, 2Department of Nanoscience and Nanoeengineering, South Dakota School of Mines and Technology, Rapid City, SD

During cellular processes such as cell adhesion, migration and cell division, the actin cytoskeleton exhibits varying changes in tension to generate mechanical force. Nonmuscle myosin 2 (NM2) is an actin binding motor protein that generates the contractile force to facilitate these cellular processes. We have developed a Förster Resonance Energy Transfer (FRET) based biosensor probe of Nonmuscle Myosin 2 (NM2); this probe enabled us to measure the dynamic changes in intracellular tension during various cellular processes. We utilized the recently published tension sensor module (TSMod) in which a 40 amino acid long elastic domain from a spider silk protein was inserted between fluorophores mTFP1 (Donor probe) and venusA206K (acceptor probe) that undergoes low or high FRET depending on the state of the protein (tensed or relaxed) attached to it. We strategically designed and cloned the tension sensor module into the coiled-coil domain of NM2A and NM2B cDNA. The biosensor was then introduced into osteosarcoma (U2OS) and kidney epithelial cell lines (HEK293 and MDCK) by stable and transient transfections. Live cell fluorescence lifetime imaging microscopy (FLIM) was used to quantify
the molecular forces by measuring the FRET efficiency, and cells expressing NM2A-TSMod or NM2B-TSMod tension sensors indicated higher and varying FRET efficiency (11.3±4.5%) compared to the donor only control probe (mTFP1-NM2A or mTFP1-NM2B) (2.79±1.4%). Our NM2 biosensor has identified dynamic changes in tension and force within the cell during various activities. First, molecular forces in the range of 3-8 pN were identified in different regions of the cell, as well as along the individual actin filaments in both adherent and migrating cells. The mechanotransduction on a single actin filament was characterized by the fluorescence correlation spectroscopy (FCS), and indicates a fast force transmission (~500 ms) on a single actin filament in U2OS cells. In addition, we measured the mechanical force map of the MDCK cells during cellular migration, molecular forces of actin on the focal adhesion sites exhibit an alternative pattern varying from 2.5 pN to 7.2 pN within 7.2±3 mins. Our NM2 TSMod biosensors can be applied to visualize and measure dynamic tension changes in cells during various physiological processes.

Improved and tunable molecular tension sensors reveal extension-based control of vinculin loading.
A.S. LaCroix1, A.D. Lynch1, M.E. Berginski1, B.D. Hoffman1;
1Biomedical Engineering, Duke University, Durham, NC

Despite the importance of applied forces and stiffness of the cellular microenvironment in many developmental, physiological, and pathophysiological processes, the molecular mechanisms enabling cells to sense and respond to mechanical stimuli are poorly understood. Forster resonance energy transfer (FRET)-based molecular tension sensors, which enable the visualization of the forces experienced by specific proteins in living cells, are uniquely suited to study these mechanisms. However, the limited dynamic range in existing sensors has hindered their widespread use. The most common design of these sensors involves two fluorescent proteins (FPs) linked by an unstructured, extensible domain. In response to applied load, the domain extends, reducing FRET, and producing a readily detectable optical signal. To enable the rational design of novel tension sensors with improved force sensitivities, we developed a first principles model based on standard descriptions of polymer mechanics to describe the behavior of these sensors under load. Guided by this model, we altered aspects of the tension sensors, such as the optical properties of the FPs as well as the length and composition of the extensible domain, to improve sensor sensitivity and create a collection of sensors for use in living cells. By utilizing a sensor optimized for studying vinculin mechanobiology, we readily observe that loads supported by vinculin are not uniformly distributed within individual adhesion structures. Also, comparison of multiple sensors with distinct mechanical properties reveals the existence of an extension-based, instead of the traditionally assumed force-based, mechanism regulating vinculin loading. Simple simulations of the mechanical characteristics of FAs suggest that the extension-based control is most likely due to extension-controlled mechanical inputs, such as the step size of a molecular motor or the discrete increases in length associated with a growing actin filament, regulating the loading of vinculin. The model also can predict the behavior of readily achievable FRET-based tension sensor designs. Based on the optical properties of commonly used FPs, the length of springs typically used in FRET-based tension sensors, and estimates of the persistence length of unstructured polypeptides, we also calculate the mechanical behavior of an additional 1020 possible designs. The various sensors are predicted to have sensitivities covering the range of 1-25 pN (1-14 nm) with different sensors exhibiting wide varieties of characteristics, including extremely sharp transitions or broad responsiveness. These
rationally-designed sensors should uniquely enable a wide variety of novel studies and be very useful in elucidating key mechanisms of mechanotransduction

Detecting Vinculin Load-Dependent Protein Recruitment to Focal Adhesions.
A.S. LaCroix¹, K. Xu¹, S.S. Neibart¹, B.D. Hoffman¹, K.E. Rothenberg¹;
¹Biomedical Engineering, Duke University, Durham, NC

Cells are sensitive to alterations in the mechanical nature of the extracellular microenvironment. In order to interact with the extracellular matrix (ECM), cells assemble integrin-mediated adhesion structures termed focal adhesions (FAs). To detect the mechanical nature of the ECM, cells apply forces generated by the actomyosin cytoskeleton to FAs, altering the activities of key proteins to enable complex cell functions such as cell migration and differentiation. However, the fundamental mechanisms underlying FA-based mechanosensitive signaling are unclear. To study these processes, we use a FRET-based molecular tension sensor that reports the loads across the key mechanical linker protein vinculin. Specifically, we seek to investigate the relationships between these loads, actomyosin structures, and the signaling state (composition) of FAs. Initial experiments combining FRET imaging with phalloidin labeling of actin structures showed high loads across vinculin in the cell periphery where FAs are associated with either stress fibers or lamellar protrusions. Strikingly, the distribution of the loads supported by vinculin within individual FAs associated with these two distinct actin structures are different. Within FAs loaded by stress fibers, we observed a spatial gradient in the loading of vinculin with the highest tension at the edge of the FA proximal to the cell membrane, while loading of vinculin associated with lamellar protrusions appears uniform. Consistent with these observations, FAs exhibit uniformly distributed loads during the early stages of cell spreading, when protrusion is enhanced, and the observation of gradients in vinculin loading coincides with the formation of stress fibers during the later stages of spreading. Also, the expression of constitutively active forms of Rac1 and RhoA lead to enhancements of FAs exhibiting uniform or gradient loading of vinculin, respectively. Furthermore, the mechanical state of vinculin within an individual FA is a strong predictor of the signaling state (composition) of that FA. By combining FRET-imaging with immunofluorescent staining, we screened 22 proteins for vinculin tension sensitivity and associated actomyosin structure preference and observed evidence of distinct mechanosensitive signaling nodes within specific actomyosin structures. For example, VASP, a direct binding partner of vinculin preferentially localizes to loaded FAs associated with stress fibers and not similarly loaded FAs associated with protrusions. In total, this work shows that both the magnitude and the molecular basis of vinculin loading impacts mechanosensitive signaling, and suggests that these distinct relationships may mediate the diverse mechanosensitive aspects of FAs.

Tissue geometry directs patterns of bioelectricity and growth.
B.B. Silver¹, C.M. Nelson¹²;
¹Molecular Biology, Princeton University, Princeton, NJ, ²Chemical Biological Engineering, Princeton University, Princeton, NJ

Epithelial cells form intact tissues wherein cells communicate with their neighbors by juxtacrine signaling, diffusible morphogens, and mechanical stresses. Mechanical stress gradients can transmit information about the geometry of the tissue to its constituent cells and lead to the emergence of
patterns of proliferation within the population, with highest proliferation at sites of maximum stress. Here, we found that tissue geometry also controls the pattern of cellular membrane voltage (Vm), defined as the electric potential difference between the cytoplasm and external medium. Manipulation of Vm has been demonstrated to impact cellular behaviors including proliferation and apoptosis. Using our microfabricated epithelial tissues in combination with the voltage-reporter dye DiBac4(3), we observed Vm depolarization in cells located along the convex edges of epithelial tissues. These are the same high-stress regions where cells show high proliferation. Surprisingly, we also observed an increase in apoptotic markers in cells within these regions. These observations suggest a relationship between Vm, proliferation, and apoptosis during the cellular response to tissue-generated mechanical stress, and a combined role of these factors during the orchestration of global patterning events.

Traction force microscopy using embedded marker arrays with an implied zero-displacement state.
O.A. Banda1, J.H. Slater1;
1Biomedical Engineering, University of Delaware, Newark, DE

Cytoskeletal tension generated by cells directly governs initiation of intracellular signaling cascades that mediate cell fate in a tension-dependent manner. A better understanding of how tension-dependent signaling cascades are initiated and maintained may provide new strategies for preempting the onset of pathological processes but this is difficult to achieve with existing approaches. One major limitation in current approaches to measure cell-generated traction forces, a direct indicator of cytoskeletal tension, is the need to chemically relax or completely remove the cells being investigated to obtain a material zero displacement state for force calculations. This limitation inhibits molecular analysis of signaling processes in contractile cells. To address this limitation, we developed a new traction force microscopy platform which utilizes patterned arrays of fluorescent fiducial markers within a PEGDA hydrogel to measure material deformation induced by contractile cells. Using an image-guided, pulsed (140fs; 740nm) laser, the marker arrays are composed of Gaussian-like features with full-width, half-maximum dimensions of 0.86μm in XY and 3.45μm in Z, with center-to-center spacing of 2.18μm in XY and 3.5μm in Z. Precise vertical alignment of the fiducial markers allows for facile measurement of shear displacement, within 66±40nm, through comparisons of displaced markers near the cells with non-displaced markers sufficiently below the surface. Normal displacements at the surface are measured from a surface approximated by local regression of non-deformed regions to provide simultaneous measures of shear and normal forces. We demonstrate the utility of this platform in measuring cellular tractions without interrupting cellular function using human umbilical vein endothelial cells (HUVECs) imaged at timepoints ranging from 4hrs to 72hrs post-seeding. Time-lapse cellular traction measures confirm the elasticity of the substrate, even in cases where markers were displaced greater than 4μm from their original locations and subsequently released. Consistent with previous findings, the total output of individual HUVECs, measured as the sum of surface shear displacements, increased with cell spread area. Additionally, HUVECs sharing a border with another cell generate less traction per unit area compared to isolated cells during early spreading (p=0.0136). During migration, HUVECs utilizing blebbing generate larger normal forces compared to those utilizing filipodia and/or lamellipodia (p=0.0006). We are currently optimizing this platform to couple it with standard immunofluorescence labeling to investigate the role of tension on activation of adhesion site signaling proteins (FAK and paxillin) and present preliminary findings towards this goal.
Many cell types polarize and migrate directionally in response to spatially organized ECM cues and other organized cues from the extracellular matrix (ECM) in the form of contact guidance. Collagen and other ECM components in vivo are often organized into wavy, sinusoidal bundles rather than linear fibers. For example, in tumors bearing ovarian stroma, sinusoidal collagen bundles are observed with a lateral curvature radii that can vary between 2 and ~30 microns, and are predictive of tumor grade. To investigate how cells respond to curved ECM, we used nanofabrication to create solid ridges with the approximate cross-section of large collagen bundles (300-600 nm), with lateral curvatures of varying wavelength or amplitude, which were then coated with ECM as a proxy for curved ECM bundles. On either linear or short wavelength curvature substrates, cell shape was polarized such that they were elongated and aligned with the pattern propagation, and their Golgi were likewise oriented in front of the nucleus with respect to this axis. However, as the wavelength of curvature approaches the average diameter of the cell spread area, cells are depolarized with respect to the axis of ridge wave propagation. Focal adhesions, Arp2/3, free barbed ends, and PIP3 accumulate at sites of substrate curvature, mimicking leading edge machinery, even within the cell center. Integrin engagement, PI3K activity and myosin II (myo2) activity are all required for the polarization response. On cell-scale curvatures, myo2 assembles and flows centripetal to the curvature, like arcs observed in two-dimensional lamella. On shorter wavelength curvatures, while actin polymerization sites still occur along curved portions, myo2 flow is altered such that myosin and actin assemble onto long linear bundles spanning the curvature, enforcing an elongated cell shape. When contractility is inhibited, this no longer occurs, and cells flow along the ridge pattern and lose polarization. Conversely, highly contractile cells such as fibroblasts continue to polarization along the long axis of the ridges even at cell-diameter curvatures, extending stress fibers across the waveforms. We propose a model in which cells “detect” curvature of ECM by actomyosin arc and bundle formation which are constrained by adhesion sites. When curvature is low enough for actomyosin bundle deformation, compliance with the curvature occurs thus depolarizing cells, while on shorter wavelength, higher curvature substrates, contractile bundles prevent cell compliance to the curvature, allowing for robust polarization of cells along ECM bundles despite local curvatures. This model would predict that tumor cells may overcome curved bundle induced depolarization by increasing their contractility to migrate along curved bundles found in vivo.
Mechanotransduction properties of the PECAM-1 cytoplasmic tail.

E. McBeath*,1, J. Snyder*2, T. Thomas1, Y. Chiu3, R. Clark4, K. Fujiwara1;  
1Cardiology, University of Texas MD Anderson Cancer Center, Houston, TX, 2Biomedical Engineering, University of Rochester, Rochester, NY, 3Research and Development, Chris Cam Mirror, Yungkang, Taiwan, 4Mechanical Engineering, University of Rochester, Rochester, NY

Vascular endothelial cells (ECs) are a well-known cell system used in the study of mechanobiology. We previously showed that platelet EC adhesion molecule 1 (PECAM-1, CD31), a cell adhesion protein which localizes to regions of EC-EC contact, was rapidly tyrosine phosphorylated in cultured ECs exposed to flow or cyclic stretch. Src-homology 2 domain-containing protein tyrosine phosphatase 2 (SHP2) was found to then bind phosphorylated PECAM-1 and activate the extracellular signal-regulated kinase1/2 (ERK1/2) signaling cascade, a known flow-activated signaling pathway. Although PECAM-1 tyrosine phosphorylation is well characterized in ECs exposed to fluid shear stress, it is less so in cyclically stretched cells. Here, using a two-dimensional cell stretch apparatus, we show that the stretch-induced change in EC shape is a dynamic and reversible response. We also show that the EC-EC contact site is a major region for stretch-induced mechanosignaling. We hypothesized that external forces applied to a monolayer of ECs are directly transmitted to PECAM-1, causing the molecule to be stretched and in turn, allowing phosphorylation sites in its cytoplasmic domain to be exposed and phosphorylated. This hypothesis requires the presence of a stretchable structure within the PECAM-1 cytoplasmic domain.

Force spectroscopy measurements were performed with a construct containing cytoplasmic PECAM-1 domains inserted between I27 motifs, a recombinant string of the structural elements from titin. This strategy allowed us to identify the events in which a single molecule is being pulled and to detect the unravelling of the cytoplasmic domain of PECAM-1 by force. The response by PECAM-1 to mechanical loading was heterogeneous but with magnitudes as high as or higher than the naturally force bearing I27 domains. In conclusion, the PECAM-1 cytoplasmic domain has a structure that can be unfolded by externally applied force and this unfolding of PECAM-1 may be necessary for its phosphorylation, the first step in the PECAM-1 mechanosignaling cascade. *E.M. and J.L.S. contributed equally to this work.
under in vivo conditions. Vascular smooth muscle cells (VSMCs) are constantly subjected to mechanical stimulation in physiological and pathological conditions. Phenotype and functional changes of VSMCs, including production of reactive oxygen species, proliferation and migration are often associated with mechanical stimulation. Since mechanical forces are known to induce rearrangement of cytoskeleton that also participates in endocytosis process, we asked whether cyclic mechanical strain may reduce MNP uptake by VSMCs. Primary culture of VSMCs were obtained from spontaneously hypertensive rats with an explant technique and used between passages 3 to 8. VSMCs were cultured in Flexcell plate to near confluence prior to be subjected to cyclic strain (1 Hz, 10% elongation) for 2 to 8 hrs, followed by exposure to polyacrylic acid-coated magnetic nanoparticles (MNPs; 200 nm, 25 μg/cm²) for additional 4 hrs. VSMC-associated MNPs (MNPcell) was analyzed with a KSCN method, which revealed high capacity of MNP internalization by VSMC in a concentration-dependent manner. Application of cyclic strain for 4-12 hrs significantly reduced MNPcell by up to 65% (P <0.05). Confocal microscopy demonstrated that both cyclic strain and fibronectin coating of the culture plate reduced VSMC uptake of MNPs by 71% and 40%, respectively. Incubation of MNPs with VSMCs for 4 hrs induced microvilli formation associated with MNP internalization observed with transmission electron microscopy; whereas cyclic strain stimulated formation of jigsaw-like protrusion from cell surface in the presence of MNP. However, pretreatment of N-acetylcysteine (0.1 mM), an antioxidant, did not alter the effects of cyclic strain on MNPcell. In conclusion, cyclic strain reduced MNP internalization by VSMCs, which may be due to cytoskeleton rearrangement; such effects of cyclic strain may preserve nanocomposites to the extravascular target.

The SMuSh pathway is essential for survival during growth-induced compressive mechanical stress.
M. Delarue1,2,3, G. Poterewicz4, J. Kayser2, O. Hallatschek2, L.J. Holt5;
1Institute for Systems Genetics, New York University School of Medicine, New York, NY, 2Department of Physics and Integrative Biology, University of California Berkeley, Berkeley, CA, 3Mile Team, Laboratoire d'analyse et d'architecture des systèmes, Toulouse, France

Cells that proliferate in a confined environment eventually build up mechanical compressive stress. For example, mechanical pressure can emerge from the growth of cancer cells or microbes in their natural settings. However, while the biological effects of tensile stress have been extensively studied, little is known about how cells sense and respond to mechanical compression. By combining genetic analysis with microfluidic approaches, we discovered that compressive stress is sensed through a module consisting of the mucin Msb2 and Sho1, which is one of the two osmosensing pathways in budding yeast. This signal is transmitted via the MAP kinase Ste11 to the cell wall integrity pathway. We term this mechanosensitive pathway the SMuSh pathway, for Ste11 through Mucin / Sho1 pathway. The SMuSh pathway is necessary for G1 arrest and cell survival in response to growth-induced pressure. Our study demonstrates the ability of budding yeast to specifically respond to mechanical compressive stress raising the question of whether homologous pathways confer mechano-sensitivity in higher eukaryotes.

A novel role for the small heat shock protein, HspB1, in the response of cells to mechanical stress.

L.M. Hoffman¹, C.C. Jensen¹; M.C. Beckerle²;

¹Huntsman Cancer Institute, University of Utah, Salt Lake City, UT

The mechanical environment exerts a tremendous influence on cells, but the molecular mechanisms involved in mechanical stimulation, sensing and response are not entirely clear. We hypothesized that the activation of MAPK pathways in mechanically stimulated fibroblasts may directly impact the resulting actin reorganization through post-translational modifications, subcellular redistributions, and actin polymerization and reinforcement. Mechanical stimulation (via uniaxial cyclic stretch) activates p38 MAPK and MK2 kinase which increases phosphorylation of the downstream target HspB1 (Hsp25/27), a small heat shock protein implicated in actin regulation. We eliminated HspB1 expression using a CRISPR/Cas9-nuclease targeting strategy and determined that the normal stretch-stimulated actin thickening was disrupted without HspB1. Using fluorescence microscopy we found that the phosphorylated HspB1 protein localizes to the ends of actin stress fibers in stretch-stimulated cells. These cytoskeletal structures extending from focal adhesions towards the cell center are known as “comet tails” and include retrograde actin flux away from focal adhesions. Actin comet tails and cell migration are inversely correlated, so we next examined the effect of HspB1 on migration using time lapse microscopy. Compared to parental wild-type (WT) cells, cells lacking HspB1 protein exhibited increased migration. The HspB1-null cell migration returned to WT levels with expression of an HspB1-rescue construct. These HspB1-null phenotypes (decreased actin stress fiber reinforcement and increased cell migration) were reminiscent of those previously described for cells lacking the mechanosensitive cytoskeletal regulator and comet tail constituent zyxin. To determine if HspB1 and zyxin might function cooperatively or in parallel pathways of actin remodeling, we used the CRISPR/Cas9-nuclease targeting strategy to generate double-mutant HspB1/zyxin-null cells and compared them to single-null cells. The HspB1/zyxin double-null cells displayed an enhanced failure of the actin reinforcement response to mechanical stress, suggesting that HspB1 and zyxin may act through parallel pathways. This work identifies HspB1 as a new player in the field of mechanotransduction.

Effects of Mechanical Stress on Remodeling of Periodontal Ligament.

A. Fujita¹, M. Morimatsu¹, M. Nishiyama², S. Takahiba³, K. Naruse⁴;

¹Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama University, Okayama City, Japan, ²Graduate School of Medicine, Kyoto University, Kyoto City, Japan

Periodontal ligament (PDL), which connects the teeth to the alveolar bone, is always exposed to mechanical stress such as occlusal force. The response of PDL cells to mechanical stress has been studied by many dentists and researchers. However, it was difficult to obtain the quantitative data related to mechanical stress effect on PDL in vivo. Here we study the effects of stretch and pressure on PDL fibroblasts. First, we cultured PDL fibroblasts under uniaxial cyclic stretch for 16 hours. After 4 hours, PDL cells and actin stress fibers were aligned in the vertical direction to the stretch axis. These results suggest that mechanical stress regulate the orientation of PDL cells to support the teeth. Second, we used high hydrostatic pressure microscope to observe PDL fibroblasts under high pressure in real time. Our systems control the level of hydrostatic pressure and stimulate cells equally. They also apply...
various patterns of occlusion to cells by controlling the hydrostatic pressure. Furthermore, high hydrostatic pressure microscope observes cells and molecules under high pressure in real time. As a result, high hydrostatic pressure (> 20 MPa) contracts PDL fibroblasts and actin stress fibers. After the release of pressure, contracted cells restart spreading on the surface after high pressure releasing process. Our data suggest excessive occlusal force induces the collapse of PDL and occlusal force at biological range affects homeostasis of PDL. Our systems directly show mechanical stress effect on PDL and give us new clinical knowledge about the treatment of periodontal diseases.

Activities of daily living such as walking and sitting pressurize articular cartilage. Chondrocytes, which constitute articular cartilage, synthesize collagen and aggrecan to maintain the function of articular cartilage. Aggrecan is a type of proteoglycan, and collagen type II is the main articular cartilage. However, the effect of pressurization on chondrocytes at a molecular level is poorly understood due to the lack of methods that directly observe cells under high pressure condition. Here we used hydrostatic pressure to apply higher pressure to chondrocytes in vitro and investigated cell morphology, molecules, and gene expression levels under high pressure condition. We observed higher pressure (dozens of MPa) decreased the size of chondrocytes and collapsed actin actin stress fibers. We also used high pressure microscope to directly observe chondrocytes under high pressure. The chondrocytes adhesion area was decreased to ~80% at 20 MPa for 1 h. However, after pressure releasing process, cells restarted to spread on the surface. We also found that gene expression levels of collagen and aggrecan were increased during the incubation after pressurizing process. Our results suggest that pressurization to chondrocytes is related to maintenance of articular cartilage function.

Water Pumping performance of human polycystic kidney disease epithelial cells.  
M. Choudhury¹, S.X. Sun¹;  
¹Mechanical Engineering, Johns Hopkins University, Baltimore, MD

Autosomal dominant polycystic kidney disease (ADPKD) is a common hereditary disorder caused by mutations in the genes PKD1 and PKD2, which encode for the proteins polycystin 1 (PC 1) and polycystin 2 (PC 2). A major characteristic of the disease is formation and progressive growth of numerous fluid-filled cysts in the renal tubules. Previous studies have shown that cysts are formed due to rapid cell proliferation and are sustained by hydrostatic pressure generated by the mural epithelial cells by pumping ions and water into the lumen. However, previously no work has been done to quantify the water pumping performance of normal and diseased cells. Also the influence of external cues like fluid shear stress, osmolarity and hormonal perturbation on the pump performance of renal epithelial cells in a physiologically relevant setup is not yet studied.

We have developed a Kidney-an-a-Chip microfluidic set-up, that can measure the water flux across renal epithelium with a volumetric resolution ~0.785 uL. The device is capable of applying a range of mechanical, chemical and osmotic perturbations, both on the apical and basal domains of the
epithelium. By seeding the device with primary ADPKD cells derived from human renal cysts, the water flux as a function of the hydrostatic pressure difference between the apical and basal domain for different values of shear stresses was measured. The apical to basal water flux increased from 3.33 to 6.67 μL/min/cm² with change in shear stress from 0.125 to 0.25 dyn/cm², but it decreased to 3.33 μL/min/cm² with further increase in shear stress to 0.5 dyn/cm². The water flux was also found to change as a function the hydrostatic pressure on the apical side. Our observations reveal that renal epithelial cells can be modelled as mechano-biological pumps whose performance can be mapped under both normal and diseased conditions.

Forces and dynamics in three-dimensional epithelia of controlled size and shape.
E. Latorre¹,², L. Casares³, S. Kale⁴, M. Gomez-Gonzalez¹, M. Uroz¹, L. Valon¹, M. Arroyo¹,², X. Trepát¹,³,⁴,⁵, ¹Institute for Bioengineering of Catalonia, Barcelona, Spain, ²Universitat Politècnica de Catalunya-BarcelonaTech, Barcelona, Spain, ³University of Barcelona, Barcelona, Spain, ⁴Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain, ⁵Centro de Investigación Biomédica en Red en Bioingeniería, Biomat. y Nanomed., Madrid, Spain

Mechanobiology of epithelial tissues plays a central role in morphogenesis, tissue compartmentalization, protection against pathogens, wound healing, and tumor progression. Current understanding of epithelial mechanobiology relies on measurements of forces and deformations obtained in flat epithelial layers. However, most epithelia in vivo exhibit a curved three-dimensional shape that encloses a pressurized lumen. Here we provide direct measurements of epithelial mechanics in three-dimensional cell sheets. Using soft micropatterned substrates we produce massive parallel arrays of epithelial domes with controlled size and basal shape. By measuring 3D deformations of the substrate we obtain a direct measurement of epithelial tractions and luminal pressure. The local tension in the freestanding epithelium is then mapped by combining measured luminal pressure and local curvature. We show that tension and dome curvature remain isotropic and uniform during perturbations of the contractile machinery, osmotic shocks, and spontaneous fluctuations of dome volume. By examining dome tension over time-scales of hours and for nominal strains reaching 300%, we establish that epithelial sheets exhibit superelastic behavior. Despite the fact that the dome is subjected to uniform tension, the areal strain of each individual cell can differ by more than one order of magnitude. This remarkable heterogeneity is suggestive of a mechanical instability caused by limited availability of structural components of the actin cortex. We develop a 3D vertex model that captures both the global tension/strain relationship in the dome and the strain heterogeneity. Our study provides the first direct measurement of pressure, tension and strain in three-dimensional epithelia and shows that epithelial cells can sustain extreme deformations under constant tension.

Ca2+-calmodulin dependent kinase kinase II regulates mechanosensitive actin stress fiber assembly.
S. Tojkander1, K. Ciuba2, P. Lappalainen2;
1Section of Pathology, Department of Veterinary Biosciences, University of Helsinki, Helsinki, Finland,
2Institute of Biotechnology, University of Helsinki, Helsinki, Finland

Ventral stress fibers are contractile actomysin bundles, which guide adhesion, migration, and morphogenesis of non-muscle cells. Their assembly and alignment are under precise mechanosensitive control, and thus stress fiber networks undergo rapid alterations upon changes in the biophysical properties of cell’s surroundings. In migrating cells, stress fiber maturation requires mechanosensitive activation of the 5’AMP-activated protein kinase (AMPK), which subsequently inhibits actin filament assembly at focal adhesions through phosphorylation of vasodilator-stimulated phosphoprotein (VASP). Here we identify Ca2+-calmodulin-dependent kinase kinase II (CaMKK2) as a critical upstream factor controlling mechanosensitive activation of AMPK during stress fiber maturation. CaMKK2 accumulated to focal adhesions located at the ends of ventral stress fibers, and its inhibition, or depletion of Ca2+, led to defects in mechanosensitive regulation of AMPK and VASP. Consequently, inactivation of CaMKK2 resulted in the loss of mature contractile stress fibers, accompanied by diminished cell-exerted forces. Collectively, these data provide evidence that Ca2+, CaMKK2, and AMPK form a locally-activated, mechanosensitive signaling cascade in focal adhesions that is critical for maturation of contractile stress fibers in migrating cells.

Spatiotemporally varying wall shear stress modulates lymphatic endothelial cell alignment and transcriptional regulation.
E. Michalaki1, V.N. Surya1, G.G. Fuller1, A.R. Dunn1;
1Chemical Engineering, Stanford University, Stanford, CA

The lymphatic system is an essential though sometimes overlooked part of the cardiovascular system. One-way valves within lymphatic vessels, which are formed from lymphatic endothelial cells during embryonic development, are required to maintain unidirectional fluid flow. At present relatively little is known about how these valves form during lymphatic development, and how they regenerate in the adult. Fluid flow is proposed to be a key cue in determining the location and timing of valve formation. We built a novel in vitro cell culture device that reproduces key aspects of the flow environment at sites of valve formation. Using this device, we observed that human lymphatic microvascular endothelial cells (HLMVECs) reoriented perpendicular to the flow direction at the region of maximum wall shear stress (WSS), i.e. at the site of maximum constriction, and exhibited enhanced nuclear localization of FOXC2, a transcription factor required for valve formation. In addition, we found that HLMVECs exposed to oscillating flow, such as occurs in vivo, showed a marked increase in their responsiveness to WSS. Further experiments revealed that the cell surface protein E-selectin was required for HLMVECs to orient perpendicular to the flow at sites of flow constriction. Our observations support the hypothesis that spatial and temporal variations in WSS provide synergistic physical cues that may help to define the timing and location of valve formation, and implicate E-selectin as a possible component of a mechanosensory mechanism for sensing localized gradients in WSS.

\(^1\)Chemical Engineering, Stanford University, Stanford, CA

Spatial variations in fluid flow are thought to help trigger the formation of valves within the lymphatic circulatory system during embryonic development. However, how the physical stimulus provided by fluid flow may direct the changes in gene expression required for valve formation is not well understood. Previous studies in developing mouse embryos have shown that lymphatic valves preferentially form near sites of vessel constriction and branching, where the lymphatic endothelial cells (LECs) which form the valve are exposed to gradients in wall shear stress (WSS). Previous work also identified the Ca\(^{2+}\) and Calcineurin-dependent nuclear localization of the transcription factor NFATc1 as a critical cue in driving valve formation. However, how the physical stimulus provided by fluid flow may influence Ca\(^{2+}\) signaling in LECs remains poorly understood. We have subjected LECs treated with the calcium indicator Fluo4 to spatially varying WSS such as occurs at sites of valve formation in vivo. We found that LECs displayed oscillatory pulses of cytoplasmic Ca\(^{2+}\) release in response to spatial gradients in WSS, and that Ca\(^{2+}\) pulses were more frequent in the areas of highest WSS. However, the Ca\(^{2+}\) duty cycle showed the opposite trend, with shorter individual pulses in the regions of highest WSS. Ongoing work aims to identify the molecular mechanisms that couple the physical cue provided by fluid flow to the activation of Ca\(^{2+}\) pulses. In summary, our data indicate that Ca\(^{2+}\) dynamics in LECs are exquisitely sensitive to local variations in WSS. These data support the hypothesis that the dynamics of stored Ca\(^{2+}\) release may play a key role in coupling the physical cue provided by fluid flow to the changes in transcriptional regulation required for valve formation.

Functional analysis of larval chordotonal organ mechanics in *Drosophila*.
C. Guan\(^3\), M.C. Goeppert\(^3\), C.F. Schmidt\(^3\);
\(^3\)Third Institute of Physics–Biophysics, University of Goettingen, Goettingen, Germany, \(^4\)Department of Cellular Neurobiology, Schwann-Schleiden-Centre for Molecular Cell Biology, University of Goettingen, Goettingen, Germany

In *Drosophila* larvae and adults, chordotonal organs (ChOs) are ubiquitous mechanoreceptors, converting a diverse range of physical forces such as sound, vibration and stretch into biological responses. The mechanoelectrical transduction, operated by an active, force-generating process, has been linked to adaptation motors. The underlying force generator, however, is poorly known, and the functional dissection of ChO mechanics *in vivo* has been challenging. We combine electrophysiological analyses with mechanical stimulation, and correlate mechanical properties and active manipulation with neuronal activity. We find that myosin II motors power contraction of the cap cells of ChO and regulate mechanosensation. Our *in vivo* model reveals larval ChOs as complex, but accessible organs to study the molecular machinery involved in the regulation and encoding of mechanical forces by primary mechanoreceptor neurons.

Understanding how the transcription factor signal transducer and activator of transcription 3 (STAT3) controls glial scar formation may have important clinical implications. We show that astrocytic STAT3 is associated with higher amounts of secreted MMP2, a crucial protease in scar formation. Moreover, we report that STAT3 inhibits the small GTPase RhoA, and thereby controls acto-myosin tonus, adhesion turnover, and migration of reactive astrocytes, as well as corralling of leukocytes in vitro. The inhibition of RhoA by STAT3 involves ezrin, the phosphorylation of which is reduced in STAT3-CKO astrocytes. Reduction of PTEN levels in STAT3-CKO rescues reactive astrocytes dynamics in vitro. By specific targeting of lesion-proximal reactive astrocytes in Nestin-Cre mice, we show that reduction of PTEN rescues glial scar formation in Nestin-Stat3+/− mice. These findings reveal novel intracellular signalling mechanisms underlying the contribution of reactive astrocyte dynamics to glial scar formation.

Novel biosensor reveals the regulation and coordination of GEF-H1 with protrusion machinery.
1Pharmacology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Cell Biology, University of Texas Southwestern, Dallas, TX, 3Immunology, University of Toronto, Toronto, ON

Rho family GTPases are molecular switches that control multiple cellular functions including cellular movement. Their activity is regulated with precise spatio-temporal dynamics by guanine exchange factors (GEFs). While biosensors have revealed the dynamics of Rho GTPases in living cells, little is known about the subcellular distribution and timing of GEF activation. Guanine exchange factor H1 (GEF-H1) activates RhoA at the leading edge of moving cells and plays a critical role in focal adhesion turnover and mechanosensing. GEF-H1 is unique among GEFs because it associates with microtubules (MTs). We identified a new mode of GEF-H1 regulation by Src kinase and used it to design a fluorescent biosensor that reports GEF-H1 activation in living cells. The biosensor was designed using general structure-based principles that could be extended to the other 68 members of the Dbl family of GEFs. Live cell imaging experiments revealed the spatio-temporal relationship between GEF-H1 activity and RhoA activity at the cell edge. GEF-H1 is activated during protrusion with precise timing and position relative to RhoA activity and edge dynamics. The biosensor also showed that GEF-H1 is localized at the MTs in its inactive state, and that GEF-H1 is active away from the MTs. Using a new quantitative image analysis method and imaging both MT and GEF-H1 activity in the same cell, we saw that MT tip dynamics control GEF-H1 activity in specific regions relative to cell protrusions. These results show that GEF-H1 regulates cell migration by mediating crosstalk between the MT and actin networks. Current studies exploring proteins that regulate GEF-H1, and the role of GEF-H1 in linking MT dynamics and focal adhesion turnover will be described.

*Ganoderma lucidum* extract reduces cell migration and invasion in triple-negative metastatic breast cancer.

A. Acevedo-Díaz1,2, G. Ortiz-Soto1, T.J. Rios3, I. Suarez Arroyo3, M.M. Martinez-Montemayor3;
1University Gardens High School, San Juan, PR, 2Biology Department, University of Puerto Rico Bayamon, Bayamon, PR, 3Department of Biochemistry, Universidad Central del Caribe School of Medicine, Bayamon, PR

Triple-negative metastatic breast cancer (TNMBC) is characterized by the absence of estrogen and progesterone receptors and the absence of HER2 overexpression. According to statistics, breast cancer (BC) is known as the leading cause of cancer among women in the United States and Puerto Rico. Approximately, 15% of all BCs and women typically display shorter overall survival and an early peak of distant recurrences at 3y after diagnosis. TNMBC is known to have an aggressive clinical behavior with a high risk of both local and distant relapses that frequently present as visceral and/or brain metastases. The treatments for TNMBC are limited besides the use of chemotherapy and currently there are no approved targeted therapies. The mortality of TNMBC could be a result of the lack of an effective treatment to decrease the migration of the cancer cells to other tissues. Hence, it is highly important to understand migration process of cancer cells and find effective therapies for TNMBC. Therefore, we aimed to test the effects of the medicinal mushroom *Ganoderma lucidum* extract (GLE) on TNMBC cell migration and the regulation of proteins involved in this process. MDA-MB-231 cells were treated with vehicle or 0.97 mg/mL (IC50) of GLE for 24hrs. The effect of GLE on cell migration was assessed by wound healing assay and fluorescence staining of F-actin. Additionally, cell invasion assay was performed using the Transwell Invasion Assay. The protein expression of Rac1/2/3, Cdc42, Lamellipodin and Rho was tested by immunoblotting. The activity of Rac1 was tested by a pulldown activity assay and immunoblotting. GLE decreased MDA-MB-231 cell migration as shown by reduced wound closure. Moreover, there was a significant reduction in the expression of Rac1/2/3, Cdc42, and Lamellipodin proteins. GLE also significantly decreased the activity of Rac1, and significantly decreased invasion of MDA-MB-231 cells after 24h treatment. Thus, we can conclude that our results suggest the potential of GLE as a natural anti-TNMBC migration agent. Long-range intercellular communication in collective cell migration.

A. Zaritsky1,2,3, Y. Tseng4, M. Rabadán4, S. Krishna4, M. Overholtzer4, A. Hall4, G. Danuser2,3;
1Molecular Cell Biology, Weizmann Institute of Science, Rehovot, Israel, 2Bioinformatics, UT Southwestern Medical Center, Dallas, TX, 3Cell Biology, UT Southwestern Medical Center, Dallas, TX, 4Cell Biology, Memorial Sloan-Kettering Cancer Center, New York, NY

Collective cell migration of cohesive groups involves intercellular mechanical communication transmitted between adjacent cells through cell-cell contacts to eventually drive long-range
communication. We discovered how local mechanical fluctuations induce long-range communication and identified some potential molecular players driving this mechanism. By designing and applying new analytical methods to migrating monolayers of epithelial cells, we find that cells at the front transmit mechanical cues by inducing normal and shear strains on neighboring follower cells. Accumulation and propagation of these mechanical cues over time and space create groups of cells that migrate and exert forces in a coordinated manner. Such motion patterns direct cells from within the monolayer toward the sites of shear-strain-induced motion at the monolayer front. These results provide a model of long-range mechanical communication between cells, in which local alignment of velocity and stress translates local mechanical fluctuations into globally collective migration.

Efficient collective migration depends on a balance between contractility, cytoskeletal rearrangements, and adhesions, all controlled by GTPases of the RHO family. Spatiotemporal analysis revealed a surprising role of the RHO GTPase RhoA in regulating long-range communication that was mirrored upon slight down-regulation of myosin-II contractility. A comprehensive screen uncovered a group of RhoA-activator guanine nucleotide exchange factors (GEFs) that are implicated in intercellular communication. Downregulation of these GEFs differentially enhanced propagation of guidance cues through the group, defining two functional clusters: RHOA-ARHGEF18 and ARHGEF3-ARHGEF28-ARHGEF11, with RHOC as an intermediate between them. We conclude that for effective collective migration the RhoA-GEFs/RhoA/C/actomyosin pathways must be optimally tuned to compromise between generation of motility forces and restriction of intercellular communication.

The ArfGAP Drongo regulates Myosin-II mediated contractility during the migration of Drosophila border cells.
C. Zeledon\textsuperscript{1}, X. Sun\textsuperscript{1}, C. Plutoni\textsuperscript{1}, G. Emery\textsuperscript{1};
\textsuperscript{1}\textsuperscript{IRIC, University of Montreal, Montreal, QC}

Cell migration is implicated in various important biological processes, notably it is central for the dissemination of cancer cells. Previously, our lab has showed that endocytosis regulates cell guidance and cell-cell coordination during collective cell migration. Our hypothesis is that other events of vesicular trafficking might be implicated in collective cell migration. Mainly, we propose that small GTPases of the Arf family, important for the formation of vesicles and sorting of cargo in these vesicles, and their regulators might regulate the localization of determinants of collective cell migration. During oogenesis in Drosophila melanogaster, a group of cells named border cells, migrate collectively towards the oocyte. We performed a candidate RNAi screen, to deplete Arf GTPases and their regulators specifically in borders cells. We found that every Arfs, two ArfGAPs and one ArfGEFs are necessary for normal border cell migration. However, we found that depletion of Arfs affects the integrity of the border cell cluster and cause a disruption the Golgi apparatus. Interestingly, depletion of the ArfGAP drongo did not disrupt the golgi apparatus or the formation of the border cell cluster, suggesting a specific role in border cell migration. Indeed, live-imaging showed that drongo depleted clusters are able to form protrusions at the front of migration but are unable to detach and migrate towards the oocyte. We later found that Myosin-II activity, which is normally localised at the front and back of the cluster, and is necessary for detachment was mislocalised in drongo depleted clusters. Active Myosin-II was dispersed around the cluster and significantly reduced at its back. Accordingly, we found an accumulation of the myosin phosphatase regulatory subunit Mbs at the back of the clusters depleted for drongo. Finally, we found in complementation assays that the function of Drongo during border cell
migration requires its ArfGAP activity. We are currently investigating a mechanism where *drongo* depletion leads to the overactivation of an Arf and promotes the recruitment of Mbs at the back of the cluster.

Overall, our work demonstrates that the ArfGAP Drongo is necessary for the collective cell migration of border cells by promoting the activity of Myosin-II at the back of the cluster through restriction of the spatio-temporal activity of the myosin phosphatase regulatory subunit Mbs.

**Alternative Polyadenylation of RECK Regulates Cell Migration and Invasion.**

H. Lee1, M. Mitra2,3, O. Bosompra2, N. Rashed4, H.A. Coller1,2,3;  
1Molecular Biology Interdepartmental Doctoral Program, University of California, Los Angeles, Los Angeles, CA, 2Department of Molecular, Cell and Developmental Biology, University of California, Los Angeles, Los Angeles, CA, 3Department of Biological Chemistry, David Geffen School of Medicine, University of California, Los Angeles, Los Angeles, CA, 4Department of Microbiology, Immunology, Molecular Genetics, University of California, Los Angeles, Los Angeles, CA

Cell migration is a highly conserved process involving cytoskeletal reorganization and restructuring of the surrounding extracellular matrix. We developed a model in which fibroblast migration and invasion are regulated by alternative polyadenylation (APA) of REversion-inducing-Cysteine-rich protein with Kazal motifs (RECK). RECK encodes a GPI-anchored protein that inhibits extracellular matrix metalloproteinases (MMPs) through its Kazal motifs. Previous studies found that RECK-/- MEFs show slower migration than wild type as a result of defective focal adhesion formation, increased levels of GTP-bound Rac1 and Cdc42 activity, and lower levels of detyrosinated tubulin that is associated with more stable tubulin in migratory cells. We found that a short RECK isoform generated by coding sequence APA plays an opposing role to the long RECK isoform, and promotes cell migration and invasion. We discovered that mRNA encoding the short RECK isoform is expressed at higher levels in proliferating cells (which are also more migratory), TGF-β treated fibroblasts, and cancer tissue. Knockdown of the shorter isoform of RECK resulted in reduced fibroblast migration and invasion, while knockdown of the canonical longer isoform of RECK lead to rapid fibroblast migration and invasion, implicating the short RECK isoform as a new player in fibroblast migration and invasion. We hypothesize that the short RECK isoform suppresses the activity of the long RECK isoform through protein-protein interactions. Our biochemical analysis revealed the interaction between short RECK and long RECK isoforms. We also found that the Kazal motif domain, that is important for suppressing MMP activity, was critical for interaction with the short RECK isoform and the short RECK isoform was able to compete with MMP9, but not MMP2, for binding to the Kazal motif region of the long RECK isoform. Furthermore, we discovered that both short and long RECK isoforms can affect tubulin post translational modification (PTM) levels, and that altering tubulin PTMs represents a functionally important mechanism by which RECK isoforms can affect cell migration. Finally, we show that tubulin PTM levels can be regulated by short RECK and this requires the presence of the long RECK isoform. Our studies provide a new paradigm for the mechanisms through which APA can affect cell migration and invasion using the example of RECK protein.

Gio2 protein modulates the migratory capability of prostate cancer cell lines downstream or independently of PI3K and RAC1 activation.  
S. Caggia$^1$, H. Chunduri$^1$, A.C. Millena$^1$, J.N. Perkins$^1$, S. Venugopal$^1$, M.C. Ordonio$^1$, B.T. Vo$^{1,2}$, C. Li$^2$, S.A. Khan$^1$;  
$^1$Center for Cancer Research and Therapeutic Development, Clark Atlanta University, Atlanta, GA,  
$^2$Department of Tumor Cell Biology, St. Jude Children’s Research Hospital, Memphis, TN  

Growth factors, cytokines, and hormones regulate migration and invasion in different cancer cell types, including prostate cancer cells. Previously we have shown that the migratory capability of prostate cancer cells depends on the activation of both G-protein coupled receptors (GPCRs) and PI3K/AKT/mTOR pathways. We have also shown that Gio2 protein has an essential role in migration of prostate cancer cell lines. The current study investigated the interaction among Gio2 and PI3K/AKT/RAC1 activation in the induction of migration in prostate cancer cells, in response to both GPCR and tyrosine kinase receptor (RTK) activation. Conditional knockdown of Gio2 by siRNA in PC3 and DU145 prostate cancer cell lines, generation of Gio2-deficient PC3 prostate cancer cell lines by CRISPR/Cas9 gene editing approach, and overexpression of constitutively active RAC1 protein in PC3 cells (PC3-RAC1Q61L), were performed, followed by migration and invasion assays. Western blots were used to validate the knockdown and knock out of Gio2 protein and to determine the activation of PI3-kinase pathway. G-Lisa assay for RAC1 and fluorescent staining were also performed. Pretreatment of PC3 cells with pertussis toxin (PTX) resulted in attenuation of transforming growth factor beta1 (TGFβ1) and oxytocin (OXT) induced migration and PI3K activation, without affecting EGF-induced PI3K activation and cell migration. Knockdown and knock out of endogenous Gio2 resulted in attenuation of cell migration and invasion in response to all ligands, but did not influence EGF-induced activation of PI3K pathway. These results suggest a role of Gio2 downstream or independent of PI3K/AKT/mTOR activation, in EGF-induced cell migration. Basal and EGF-induced activation of RAC1 in PC3 and DU145 cells were not affected after Gio2 knockdown. On the other hand knockdown of endogenous Gio2 in PC3-RAC1Q61L caused a significant reduction in the migratory behavior in EGF treated cells, indicating that Gio2 acts downstream or independent of RAC1. We also observed that knockdown of Gio2 in both parental PC3 and PC3-RAC1Q61L and in the Gio2-deficient PC3 prostate cancer cell lines resulted in reduced cell size, F-actin rearrangement and inhibition of lamellipodia formation, and these effects were not reversed by the ligands used in the present study. These results suggest that Gio2 protein acts at two different levels which are both dependent and independent of GPCR and PI3K signaling pathways, affecting cell migration and morphology of prostate cancer cells.

**Board Number: B652**  
Differential effect of Mammalian Target of Rapamycin Complexes 1 (mTORC1) and 2 (mTORC2) in the migration of Prostate Cancer cells.  
S. Venugopal$^1$, S. Caggia$^1$, S.A. Khan$^1$;  
$^1$Center for Cancer Research and Therapeutic Development, Clark Atlanta University, Atlanta, GA  

PI3K/AKT/mTOR pathway plays an essential role in the regulation of cell migration and invasion. Mammalian Target of Rapamycin (mTOR), a major component of PI3K/AKT pathway, exists in two distinct complexes-mTORC1 and mTORC2. Major regulators of mTORC1 and mTORC2 are two distinct proteins Regulatory-Associated Protein of mTOR (RAPTOR) and Rapamycin-Insensitive Companion of Tuesday-407
mTOR (RICTOR) respectively. Recent studies have shown that phosphorylation of Serine2488 on mTOR activates mTORC1 whereas phosphorylation of Serine2481 on mTOR activates mTORC2. The relative contribution of each complex towards cell migration is not well known. We observed that inhibition of RAPTOR and RICTOR individually using siRNA significantly decreased migration in PC-3 cells during a 5 hr Transwell migration assay. We also observed that inhibition of RAC1 (Ras-related C3 Botulinum Toxin Substrate 1, essential for cell migration) using RAC1siRNA or active RAC1 inhibitor NSC23677 had two effects. The first is a decrease in migration of PC-3 cells with/without EGF stimulation and the second a decrease in phosphorylation of mTORC2 but no effect on the phosphorylation of mTORC1 in the presences of EGF stimulation. Next, we developed PC-3 cell lines stably overexpressing EGFP-tagged Wild-Type RAC1 (RAC1WT) or constitutively active RAC1 (RAC1Q61L) by plasmid isolation, transfection, cell sorting and antibiotic selection. In PC-3 cell lines stably overexpressing RAC1WT or RAC1Q61L, we observed that the phosphorylation of mTORC2 is inhibited by NSC23677 in the presences of EGF whereas phosphorylation of mTORC1 is unaffected under similar treatment conditions. We also observed by immunoprecipitation and western blot analysis that RAC1 forms a complex with mTOR in PC-3 cells stably overexpressing RAC1WT or RAC1Q61L after stimulated with EGF. In conclusion, we propose that the interaction of RAC1 with mTOR lead to phosphorylation/activation of mTORC2 and in turn might affect cell migration in prostate cancer cells.

Phosphoinositides regulate cytoskeletal reorganization and extracellular matrix adhesion.

B.J. Patel1, C. Janetopoulos1, K.A. Myers1;

1biological sciences, university of sciences, philadelphia, PA

Angiogenesis is the process when new blood vessels are formed from existing blood vessels. During angiogenesis, endothelial cells (ECs) generate a polarized leading edge through a process that involves the coordinated reorganization of the actin and microtubule cytoskeleton. Cytoskeletal reorganization and EC branching are necessary to generate physical contacts between the cell and the extracellular matrix (ECM). Together these processes help drive directional migration, a critical component that aids in the formation of new blood vessels. The phosphatidylinositol lipids have been identified as key mediators for directed motility. Upon stimulation, phosphatidylinositol 3,4,5-triphosphate (PI3P) is synthesized from phosphatidylinositol 4,5-bisphosphate (PI(2)) by a family of phosphoinositide-3-kinases (PI3Ks) at the plasma membrane (PM). PM PI3P is important for actin polymerization at the leading edge of migrating cells through the activation of the small GTPase Rac1. PM PI3P is much more abundant when compared to PI(2). PI3P is thought to be generated at the PM at sites of focal adhesions (FA) and has been implicated in promoting activation of various FA-associated proteins. While PM PI3P restricts cortical actin polymerization, it is unclear how PM PI3P is organized in the cell or how it regulates cell polarity and migration. We hypothesized that the regulation of PM PI3P levels functions to locally modulate cytoskeletal organization and EC-ECM adhesion. To test this hypothesis, we used an inositol polyphosphate 5-phosphatase fused rapamycin-triggered heterodimerization strategy (iRAP) to deplete PM PI3P levels in ECs. Cells co-expressing GFP-actin/GFP-Paxillin, and iRAP with PI3P readouts were collected and analyzed by live cell imaging. Experimental data reveal that PM PI3P depletion disrupted acto-myosin bundles, inhibited the assembly of nascent FA, increased the number of mature FAs, and promoted oscillatory protrusions and retractions. Independent of PM PI3P localization, the PI3P biosensor localized to actin stress fibers associated with mature FA, and this localization was reduced by treatment with blebbistatin, supporting a role for myosin II contractility in the localization of PI3P near FAs. Thus, spatial and temporal dynamics of phosphoinositide levels modify EC morphology and polarity.
through actin reorganization and cell-ECM adhesion. Future investigations will focus on the role of both PIP2 and PIP3 in controlling EC polarization and FA assembly.

Plasma Membrane PI(4,5)P2 Threshold Regulates Cell Migration Speed and Morphology.
M. Beshay¹, N. Bawazir¹, J. Notino¹; C. Janetopoulos¹;
¹Biological Sciences, University of the sciences in Philadelphia, philadelphia, PA

During gradient sensing, many signaling and cytoskeletal markers become asymmetrically distributed, and cells establish a polarity circuit. A similar excitable network was shown in cells during cytokinesis. Phosphoinositide-linked signals at the poles of dividing cells were activated in a manner equivalent to those found at the front of migrating cells. Signals at the furrow between two daughter cells were similar in nature to those found at the rear of migrating cells. To further demonstrate the importance of plasma membrane (PM) PI(4,5)P2 in maintaining cell morphology and breaking cell symmetry during polarized morphologies, we have used the inducible rapamycin (iRAP) system. iRAP was used to recruit various enzymes to the PM that regulate PM PI(4,5)P2 levels. Cell migration and the localization of various signaling and cytoskeletal biosensors were then monitored and recorded when PI(4,5)P2 levels were depleted or elevated. We find that lowering PM (PI4,5)P2 levels inhibits cell excitability, contributes to cell rounding, and reduced rates of cell migration. Depletion of PM PI(4,5)P2 is excitatory and increases Ras and PI3 Kinase activity. Cells show a variety of phenotypes when PI(4,5)P2 levels are depleted, including oscillatory behavior and dramatic changes in cell morphology. Similar effects were observed in Dictyostelium cells lacking the PI5 Kinase (pik1), whose loss leads to dramatic decreases in PM PI(4,5)P2 levels. We also investigated the localization of ForminA, which has a putative PI(4,5)P2 motif. ForminA localizes in a reciprocal manner with that of a marker for Rac activity during cell oscillations, with ForminA moving to the cytosol and Rac moving to the PM during cell spreading. Interestingly, this ForminA also localizes to the rear of cells undergoing chemotaxis and is found at the furrow of dividing cells. Our data suggests that the PM levels of PI(4,5)P2 are critical for altering cell speed and morphology, with lower levels contributing to excitable networks controlling cell protrusions. PM PI(4,5)P2 levels above a threshold support regulators that contribute to quiescent membrane activity and actomyosin contraction. Interestingly, we find that lowering PIP2 levels alone does not appear sufficient for triggering these excitable networks, and another component is likely activated. We propose that this unknown molecule becomes positively charged during the formation of protrusions, and plays a major role in the transient binding affinity of proteins that are lipid anchored and have positively charged binding motifs.

Location-Dependent Responses to Epithelial Cell-Cell Contact – Tail Following Complements Contact Inhibition to Facilitate Collective Migration.
D. Li¹, Y. Wang¹;
¹Biomedical Engineering, Carnegie Mellon University, Pittsburgh, PA

Contact inhibition of locomotion (CIL), largely drawn from observations of head-on collisions between individual migrating cells, has been the predominant paradigm to describe contact-mediated interactions of migrating cells. However, it poorly accounts for the behaviors observed in collective migration of epithelial cells. Using micropatterned substrates to facilitate contacts between different
regions of cells, we found that CIL applies specifically to interactions with neighboring heads. Contacts with other regions elicited migratory responses towards the tails of other migrating cells, including the induction of a new migrating front from stationary cells, causing one cell to follow another. This novel behavior, termed contact promotion of locomotion (CPL), complements CIL to allow a more complete understanding of the migration of both individual cells within a population and cell collectives. We further deployed a single-file, cell train model based on micropatterned substrates to facilitate the investigation of the effects of these behaviors on collective migration. Cells in migrating trains showed a preference to follow predecessor cells over free space on branched micropatterns. Moreover, treatment with a Frizzled-Dishevelled inhibitor NSC 668036 ablates both the tail-following behavior of individual cells and the collective migration of cell trains, which implicates the Wnt signaling pathways in both CPL and collective migration and suggests that CPL is responsible for the tail following behavior of collective migration. Our findings extend the paradigm of CIL to provide a more complete picture of the effect of cell-cell contact on cell migration, and uncover a new mechanistic understanding of collective migration.

The *Drosophila* TNFα ortholog, Eiger, decreases tension and facilitates deformation in a neighboring tissue to expedite macrophage invasion.
A. Ratheesh\(^1\), J. Biebl\(^1\), A.M. Casano\(^1\), J. Vesela\(^1\), M. Smutny\(^1\), E. Papusheva\(^1\), D.E. Siekhaus\(^1\), A. Gyoergy\(^1\); 
\(^1\)Institute of Science and Technology Austria, Klosterneuburg, Austria

How changes in the tension and stiffness of the environment alter cell migration has been frequently studied *in vitro*, yet much less is known about such parameters affect migration in a living organism. We study the invasive movement of *Drosophila* macrophages (plasmatocytes) into the germband during development, a process that displays molecular and cellular similarities with vertebrate immune cell transmigration. Here we find that an intricate interplay between two neighboring tissues occurs during development to facilitate this tissue invasion by macrophages through the regulation of tissue tension. Eiger, the *Drosophila* ortholog of TNFα, is required in the amnioserosa, a tissue neighboring the germband, to facilitate macrophage invasion between the germband ectoderm and the mesoderm. Once the macrophages migrate up to the amnioserosa, Eiger is released and binds on the ectoderm to Grindlewald, which is also required for macrophage invasion. Eiger and Grindelwald act in the ectoderm to enhance the apical localization of a Crumbs complex component known to bind Myosin phosphatase, called Patj. Eiger and Grindelwald limit the apical localization of active Myosin and thus decrease apical tension, as assessed by laser cuts. The importance of this pathway is indicated by our ability to rescue the defect in macrophage germband invasion in *eiger* mutants through over-expression of Patj or RNAi-based downregulation of Myosin. 2-photon movies in *eiger* mutant embryos show no alteration in the speed of macrophage migration up to the germband but do reveal an increase in the time the first macrophage takes to enter into the germband and to move along the region where Myosin is enriched. We show through segmentation analysis of movies visualizing ectodermal cell outlines that *eiger* mutants display less and slower ectodermal cell deformation as the macrophage enters. As we see no evidence for a change in the force exerted by macrophages in the *eiger* mutant, our work supports the conclusion that higher stiffness in surrounding cells decreases cell migration in an *in vivo* context, and that Eiger acts to decrease tension and stiffness to expedite tissue invasion. Our findings contrast to prior results from other labs showing that increased stiffness of the ECM facilitates cell migration *in vivo*. We have evidence that in zebrafish TNFα also down-regulates Myosin activity to enhance the entry of macrophages into the developing brain to form microglia, arguing that this regulatory effect is not limited to the fly. Thus we demonstrate for the first time *in vivo* that the tension of surrounding cells can
limit tissue invasion and show that a TNFα family member acts to modulate this effect through a novel signaling pathway.

Regulation of traction force mediated by the calpain small subunit and Galectin-3.
I. Jang¹, S. Menon¹, K.A. Beningo¹;
¹Biological Sciences, Wayne State University, Detroit, MI

During cell migration, mechanical forces are generated by the acto-myosin cytoskeleton and transmitted to the extracellular matrix producing traction to move the cell forward. These forces are known as traction forces and are critical for cell migration. The Calpain family of proteases have been implicated in numerous aspects of cell migration, including the regulation of cell spreading, contraction and the formation and disassembly of adhesion sites. Calpain 1 and Calpain 2, the most well-characterized holoenzymes within the Calpain family, are proteolytically active only in the presence of the small subunit Calpain 4. Previous studies from our lab have shown that Calpain 4 regulates the production of traction force in migrating mouse embryonic fibroblasts (MEF), independent of the large subunit’s catalytic activity. Furthermore, we found that Calpain 4 is crucial for the tyrosine phosphorylation and secretion of Galectin-3, a galactoside-binding protein known to cluster and activate the integrin adhesion receptors. Additionally, secreted Galectin-3 can rescue the magnitude of traction forces, which is defective in Calpain 4-deficient cells. We recently determined that the inhibition of c-Abl kinase, which is known to phosphorylate Galectin-3 on tyrosine residues, decreased Galectin-3 secretion leading to lower traction forces. We also found that the phosphorylation of Galectin-3 on tyrosine 107 is essential for the signal transduction and the generation of traction forces. This study provides insight into the signaling mechanism through which Calpain 4 and secreted Galectin-3 regulates the production of traction forces, thus regulating cell migration.

Serine Threonine Kinase-40 (STK40) and Cell Migration: Interaction with Mitogen-Activated Protein Kinase (MAPK).
L. Yu¹, F. Tsai¹;
¹Department of Pharmacology, National Taiwan University College of Medicine, Taipei, Taiwan

Cell migration is important for embryonic development, tissue regeneration and cancer metastasis. Recent research identified cell migration-related genes, but how they crosstalk with each other remain unclear. To resolve this mystery, we conducted a “two-hit” cell migration screen using short hairpin RNA (shRNA) and small molecules inhibitors. Among our candidates, we are particularly interested in STK40, a putative serine/threonine kinase. Previous literature reports showed that STK40 knockdown increased cell motility. However, our two-hit screen revealed STK40 knockdown plus PD98059 (MEK inhibitor) resulted in a dramatic suppression of cell motility. We therefore hypothesize that STK40 interacts with MAPK signaling to regulate cell migration.
To validate this hypothesis, we first conducted various cell migration assays by analyzing different parameters to investigate how STK40 regulates cell migration in epithelial and endothelial cells. We discovered that STK40 improved speed in both cell lines and improved coordination in SAS. Our immunofluorescent assays also showed that altering STK40 level altered E-cadherin and phalloidin, which may explain STK40 improvement in coordination. Further exploration will aim at how STK40 and...
MAPK regulate cell migration, hoping to disclose the mechanism of the regulation of STK40 in cell migration.

Cellular externalization control of actin-binding protein profilin-1 is a novel mechanism for MKL-dependent regulation of cell migration.
D. Gau1, M. Joy1, R. Prywes2, P. Roy3;
1Bioengineering, University of Pittsburgh, Pittsburgh, PA, 2Biology, Columbia University, New York, NY

Megakaryoblastic leukemia (MKL)/serum-response factor (SRF)-mediated gene transcription orchestrates the dynamic remodeling of the actin cytoskeleton which includes control of a wide range of genes including SRF itself and others related to structural and regulatory components of the actin cytoskeleton. In this study, we demonstrate that MKL impacts the cellular level of profilin-1 (Pfn1), a key regulator of actin cytoskeletal dynamics and cell migration. Modulation of Pfn1 by MKL occurs through change of expression of signal transducer and activator of transcription 1 (STAT1) that is dependent on its SAP-domain function rather than its conventional SRF-mediated action. Unexpectedly, we found that MKL modulates Pfn1 through controlling its cellular externalization. Finally, we demonstrated that MKL can affect cell migration through controlling Pfn1 thus establishing a functional link between MKL and Pfn1 in the context of cell migration. Collectively, these findings reveal a novel regulatory mechanism of cell migration downstream of MKL that extends beyond and above its SRF-mediated action and involves cellular retention control of actin-binding proteins.

A polymorphism of BLT2 leads to an enhanced ligand sensitivity.
J. JANG1, J. Kim3;
1Department of Biotechnology, College of Life Sciences and Biotechnology, Korea University, Seoul, Korea, South

Recently, single-nucleotide polymorphisms (SNPs) in G-protein coupled receptors (GPCRs) have been suggested to contribute to physiopathology and therapeutic effects. Leukotriene B4 receptor 2 (BLT2), a member of the GPCR family, plays a critical role in the pathogenesis of several inflammatory diseases, such as cancer and asthma. However, no studies on BLT2 SNP effects have been reported to date. In this study, we demonstrate that BLT2 SNP (rs1950504, Asp196Gly), a Gly-196 variant of BLT2 (BLT2 D196G), causes enhanced cell motility under low-dose stimulation of its ligands. In addition, we demonstrated that Akt activation and subsequent production of reactive oxygen species (ROS), both of which act downstream of BLT2, are also increased by BLT2 D196G in response to low-dose ligand stimulation. Furthermore, we observed that ligand binding affinity of BLT2 D196G was enhanced compared to BLT2. Through homology modeling analysis, it was predicted that BLT2 D196G loses ionic interaction with R197, thereby potentially resulting in increased agonist-receptor interaction. This report is the first SNP study on BLT2 and shows that BLT2 D196G enhances ligand sensitivity and thereby increases cell motility in response to low-dose ligand stimulation.

The NDR kinase Tricornered regulates membrane handling and collective cell migration in the Drosophila egg chamber epithelium.

A.M. Williams¹, S. Horne-Badovinac¹, M.V. Yow²;

¹Molecular Genetics and Cell Biology, University of Chicago, Chicago, IL, ²Florida International University, Miami, FL

Development and wound healing depend on tissue rearrangements mediated by collective cell migration. We study a highly coordinated collective cell migration that occurs in the follicular epithelial layer of the Drosophila egg chamber. The follicular epithelial cells migrate along a basement membrane extracellular matrix (ECM) surrounding the egg chamber. This migration is essential for the elongated shape of the mature egg. We take advantage of this model system to identify proteins and processes required for coordinated cell migration. Two proteins essential for egg elongation are the NDR kinase Tricornered (Trc) and its activator Furry (Fry). Loss of these proteins results in round eggs and loss of planar actin polarization at the basal surface of follicle cells, two hallmarks of migration defects. Here, we show using live imaging that Trc and Fry are required for collective follicle cell migration and maintenance of the structure of the basal plasma membrane adjacent to the ECM. Trc localizes to the plasma membrane and to membrane-adjacent vesicle-like structures. Loss of Trc or Fry by RNAi or in mutant clones causes excess membrane shedding from the rear of each migrating cell. We also observe this phenotype when endocytosis is disrupted, suggesting that Trc may regulate endomembrane trafficking. We have previously shown that the atypical cadherin Fat2 is localized to the trailing edge of follicle cells and signaling through Fat2 is essential for cell-cell interaction during migration. Loss of Trc causes Fat2 at the trailing edge to become more dispersed, likely through disruption of overall trailing edge membrane structure. This poor organization may affect the ability of Fat2 to mediate cell-cell interaction, thereby blocking migration. In future work, I aim to determine 1) the mechanism by which Trc regulates endomembrane trafficking and 2) if Trc regulates follicle cell migration through Fat2.

Effect of PI3 Kinase Inhibition on Human Dermal Fibroblast and Human Epidermal Keratinocyte Wound Healing.

K.M. Chambers¹, Z. Spivey¹, B.S. Mandavilli¹;

¹Thermo Fisher Scientific, Eugene, OR

Cell proliferation and cell migration are two essential parts of normal wound healing. Both of these cellular functions are regulated by phosphoinositide 3-kinases (PI3-kinases). PI3 Kinases regulate cellular proliferation through their activation of the G-protein, Rac GTPase. Rac GTPase activation activates AKT causing a series of interactions whose downstream affect activates mTOR, downregulating apoptosis and upregulating the cell cycle resulting in increased proliferation (Rafalski and Brunet, 2011; Peltier et al, 2007). PI3 Kinase’s role in cell motility is not as clearly defined. What is known is that RAS binds directly to PI3 Kinase to increase cell motility. Preventing RAS from binding to PI3 Kinase results in upregulation of E-cadherin expression due to an increase in expression of the protein Reelin. This increase in focal adhesion protein decreases cell motility and migration (Castellano et al, 2016). Additional data has shown that PI3 Kinase regulates actin through regulation of the protein Cofilin (Kolsh et al, 2008). We used cell tracking reagents and live cell kinetic assays for a quantitative analysis of the effects of PI3 kinase inhibition on dermal fibroblast and epidermal keratinocyte wound healing.

**Immunohistochemical Analysis of Singed Protein in Wild-Type and CASK Knockout Fly Lines.**

S. VanHorn, A. Farthing, M. Kaschalk, K. Robinson, D. Mohn, J.S. Sanford;

1Biological and Allied Health Sciences, Ohio Northern University, Ada, OH

_Drosophila_ border cell migration is a process whereby a cluster of 8-10 specialized follicle cells known as border cells transport two non-motile follicle cells, known as polar cells, to the oocyte during oogenesis in the fly. _Drosophila_ egg chambers are comprised of a single oocyte and 15 supportive nurse cells. In turn, the oocyte and nurse cells are surrounded by a single layer of follicular epithelial cells. Arrival of the border cell cluster to the oocyte occurs during stage 10 _Drosophila_ egg chamber development. The transported polar cells will ultimately form the micropyle, the structure which permits sperm entry during fertilization events. Egg chambers in which the cluster fails to reach the oocyte by stage 10 are said to exhibit defects in border cell migration. Although this process has been investigated from a developmental biology perspective, it has also recently been recognized that border cell migration provides an attractive system to study coordinated cell movement. Recent RNA interference studies suggest that knockdown of the CASK (Ca2+/-CaM-dependent serine protein kinase) protein results in incomplete border cell migration. However, the molecular mechanisms by which CASK influences this critical cellular process have yet to be elucidated. In order to gain further insight into the function of CASK in _Drosophila_ border cell migration, immunohistochemical analysis using the border cell specific protein Singed was performed in four wild-type fly lines (Oregon R, yw, w1118, p33) and the p18 (CASK knockout) fly line. Results of the stained protein staining demonstrate successful labeling of border cell clusters in >200 egg chambers in each of the aforementioned fly lines. Future work will focus on quantitative analysis of stage 10 ovaries to determine whether CASK knockout flies demonstrate defects in border cell migration as suggested by previous RNA interference studies.

**Board Number: B664**

**Validation of CASK gene expression in Drosophila ovaries.**

C. Wirth, M. Guthrie, H. Dyer, J.S. Sanford;

1Biological and Allied Health Sciences, Ohio Northern University, Ada, OH

CASK is a Ca2+/-CaM-dependent serine protein kinase belonging to the Membrane Associated Guanylate Kinases (MAGUK) protein family. All MAGUK family members contain PDZ, SH3, and GK domains. However CASK is unique in that it possesses an additional N-terminal CaMK-like domain. This distinct structure allows CASK to function as a scaffolding molecule for channels and receptors at cell-cell junctions. Recent work in _Drosophila_ has shown that CASK is also involved in regulating coordinated cell movement. Specifically, an RNAi screen demonstrated that knockdown of CASK results in defective border cell migration. Border cell migration is a process by which two non-motile follicular epithelial cells known as polar cells are transported from the anterior end of the developing egg chamber to the developing oocyte by specialized cells known as border cells. This process serves as an important model of collective cell movement _in vivo_. Despite this potential role for CASK in border cell migration, little work has been done to characterize CASK gene or protein expression in _Drosophila_ ovary. Gene prediction models and ModENCODE data suggest that there are seven CASK isoforms expressed in _Drosophila_ ovaries (CASK-A, -B, -D, -E, -F, -G, -H). To verify the expression of each of these isoforms in _Drosophila_ ovaries, primer sets were designed to detect each of the seven CASK isoforms. Previous work
demonstrated that each isoform is expressed in w1118 (wild-type) pooled Drosophila ovary samples, but expression was variable when analyzed across three independently pooled w1118 samples. Current work focused on isolation of new RNA samples from the w1118 wild-type fly line, as well as two additional wild-type fly lines - yw (yellow white) and OreR (Oregon R). RNA was isolated from three pooled samples of w1118, yw and OreR total fly and ovary homogenates and cDNA was synthesized using the Superscript IV first-strand cDNA synthesis kit. As variability between samples has been a limiting factor in the verification of CASK isoform expression, each cDNA sample was validated using primer sets to the Rp49 housekeeping gene and the MAGUK family gene, Dlg (Discs Large). PCR with the control primers on the independently pooled samples demonstrated equivalent expression levels across samples for both primer sets. Future work will involve standard reverse transcriptase-PCR on the validated cDNA with each of the seven CASK isoform primer sets to authenticate CASK gene expression across pooled samples in three separate wild-type fly lines. Characterizing CASK isoform expression within Drosophila ovary tissue will provide insight into which isoform may be mediating cell movement during border cell migration.

Generation of UAS-CASKRA-GFP and UAS-CASKB-GFP Transgenic Constructs.
J. Sanner1, K. Robinson1, E. Olah1, J.S. Sanford1;
1Biological and Allied Health Sciences, Ohio Northern University, Ada, OH

Border cell migration is a developmentally regulated process in Drosophila oogenesis in which two nonmotile polar cells are transported from the anterior of the egg chamber to the oocyte by a group of 4-6 motile cells known as border cells. Given the plasticity of the Drosophila model system, border cell migration has served as a noteworthy model of collective cell migration. Calcium/calmodulin-dependent serine protein kinase (CASK) belongs to the membrane-associated guanylate kinases (MAGUK) protein family and recent RNA interference screens in Drosophila ovary have suggested that knockdown of this protein results in defective border cell migration. Drosophila express two major classes of CASK isoforms, known as CASK alpha and CASK beta isoforms. The CASK alpha isoforms encode a truncated CASK protein possessing the canonical MAGUK domains, PDZ (PSD-95-Dlg-Zo1), SH3 (Src Homology 3) and GK (Guanylate Kinase) domains. The CASK beta isoforms encode the full-length protein, which possesses each of the above domains as well as an additional N-terminal CamK-like domain and two L27 (Lin-2/Lin-7) domains. Previous work has not determined which class of isoforms is responsible for the cell migration defects observed in during Drosophila oogenesis. Moreover, no work has been done to characterize the molecular means by which CASK may contribute to cell movement en masse. In order to begin to delineate the function of CASK in border cell migration, the current work focuses on the generation of both pUAS-CASKRA-GFP and pUAS-CASKB-GFP constructs for production of transgenic fly lines. The CASK_RB open reading frame was previously PCR amplified and the results presented here demonstrate successful subcloning into the pENTR-D-TOPO entry vector to yield the pENTR-D-TOPO-CASKRB. The CASKRA open reading frame has also been obtained in a pFlc vector backbone. Future work on this project will involve performing a Gateway cloning reaction to yield the desired pUAS-CASKB-GFP construct and subcloning of CASKRA into the pENTR-D-TOPO entry vector. As there is no commercially available antibody to Drosophila CASK, generation of these transgenic fly lines will allow for characterization of CASK’s subcellular localization within the Drosophila egg chamber, thereby providing valuable insight into CASK’s potential role in border cell migration. Moreover, these fly lines will allow for rescue experiments with CASK knockout fly lines to determine which CASK isoforms are necessary for successful coordinated cell movement.

PI(3,4)P2-Directed Negative Feedback Control of Ras Activity in Dictyostelium.
M. Edwards1, X. Li2, P.N. Devreotes1;
1Cell Biology, Johns Hopkins University School of Medicine, Baltimore, MD

Ras proteins serve as key mediators of the downstream signaling response evoked by guidance cue receptor activation and are therefore important regulators of cell migration. In Dictyostelium, the landscape of Ras regulation by guanine nucleotide exchange factors, GEFs, which promote signaling and GTPase-accelerating proteins, GAPs, which inhibit Ras signaling, is very unclear. Our recent work implicates phosphatidylinositol 3,4-bisphosphate, PI(3,4)P2, in the regulation of Ras activity at the leading edge of migrating cells. PI(3,4)P2 like many phosphoinositides, regulates membrane localization of proteins via an interaction with lipid binding motifs such as pleckstrin homology, PH, domains. A genome-wide search for PH domains with high similarity to the PI(3,4)P2-binding PH domain of polarity regulator CynA, identified several PH domain containing GAP proteins. Live cell microscopy revealed a transient localization of these GAPs to the base of cup-shaped macropinosome crowns in Dictyostelium. Depleting cellular PI(3,4)P2 by knocking out enzyme Dd5p4 which converts PI(3,4,5)P3 to PI(3,4)P2, blocked the localization of GAPs to the cup shaped protrusions. The size, duration and frequency of initiation of Ras patches were all increased in Dd5p4− cells. Chemotaxis to cAMP was also impaired in Dd5p4− cells. These findings point us to the hypothesis that Ras activity at cellular protrusions is regulated by the PI(3,4)P2-dependent localization of GAP proteins.

Proper actin network architecture enforces polarization during cell migration.
B.R. Graziano1; A. Diz-Muñoz2; O.D. Weiner1;
1Cardiovascular Research Institute, UCSF, San Francisco, CA, 2Cell Biology and Biophysics, EMBL, Heidelberg, Germany

Efficient cell migration requires that actin assembly is spatially restricted to form a single leading edge in response to external stimuli. In neutrophils, cells of the innate immune system that rely on chemotaxis to track down pathogens, the protrusive force of actin polymerization leads to increases in membrane tension. These tension increases confine subsequent actin polymerization to a single site at the leading edge, producing a well-defined polarity axis. A multitude of actin assembly pathways function alongside one another to drive neutrophil migration, but it remains unclear whether different types of actin networks can generate similar membrane tension increases in response to polarity cues. The WAVE regulatory complex (WRC), an actin nucleation-promoting factor, plays a central role in directed migration by organizing the assembly of highly-branched actin networks at the leading edge of cells. Here, we assess the role that actin network organization plays in generating plasma membrane tension by using CRISPR-Cas9 to disrupt WRC in neutrophil-like HL-60 cells. WRC-null cells failed to maintain a single axis of polarity and instead simultaneously formed multiple sites of protrusion initiation in a non-polarized fashion. Consistent with their inability to restrict polarization, WRC-null cells also showed impaired membrane tension generation. The polarity defect was rescued by driving increases in membrane tension via hypo-osmotic treatment, demonstrating that membrane tension generation...
relies on WRC-dependent actin assembly. Surprisingly, WRC-null cells produced significantly higher levels of actin polymer, in contrast to previous observations that cellular actin polymer levels and the amount of tension experienced by the plasma membrane are highly correlated. Our results show that actin assembly via WRC efficiently drives increases in membrane tension to provide long-range negative feedback to protrusion formation. WRC-dependent actin polymerization ensures that migrating neutrophils maintain a single ‘front-to-back’ polarity axis.

**ARF1 recruits RAC1 with mutually dependent regulatory circuits in neutrophil chemotaxis.**

Y. Mazaki¹, Y. Onodera², T. Higashi¹, T. Horinouchi¹, T. Oikawa³, H. Sabe²;
¹Department of Cellular Pharmacology, Graduate School of Medicine, Hokkaido University, Sapporo, Japan, ²Department of Molecular Biology, Graduate School of Medicine, Hokkaido University, Sapporo, Japan

**Background:** The small GTPase ARF1 mediates membrane trafficking mostly from the Golgi, and is essential for the G protein-coupled receptor (GPCR)-mediated chemotaxis of neutrophils. In this process, ARF1 is activated by the guanine nucleotide exchanger GBF1, and is inactivated by the GTPase-activating protein GIT2. Neutrophils generate the Gβγ-PAK1-αPIX-GIT2 linear complex during GPCR-induced chemotaxis, in which αPIX activates RAC1/CDC42, which then employs PAK1. However, it has remained unclear as to why GIT2 is included in this complex.

**Results:** We investigated the association between ARF1 and RAC1/CDC42 during the f MLP-stimulated chemotaxis of HL60 cells. We found that the silencing of GBF1 significantly impaired the recruitment of RAC1 to the leading edges, but not PAK1, αPIX, RAC2, or CDC42. A significant population of RAC1 colocalized with ARF1 at the leading edges in stimulated cells, whereas f MLP activated both ARF1 and ARF5. Consistently, the silencing of ARF1, but not ARF5, impaired the recruitment of RAC1, whereas the silencing of RAC1 did not affect the recruitment of ARF1 to the leading edges.

**Conclusions:** Our results indicated that the activation of ARF1 triggers the plasma membrane recruitment of RAC1 in GPCR-mediated chemotaxis, which is essential for cortical actin remodeling. Thus, membrane remodeling at the leading edges appears to precede actin remodeling in chemotaxis. Together with the fact that GIT2, which inactivates ARF1, is an integral component of the machinery activating RAC1, we proposed a model in which the ARF1-RAC1 linkage enables the regulation of ARF1 by repetitive on/off cycles during GPCR-mediated neutrophil chemotaxis.

**CCR7 homo-dimerization regulates CCR7 ligand-dependent cell migration and signaling.**

H. Hayasaka¹, D. Kobayashi¹,², M. Endo¹, H. Hojo³, M. Miyasaka⁴,⁵,⁶;
¹Department of Life Science, Kindai University, Faculty of Science and Engineering, Higashiosaka, Japan, ²Department of Pharmacology, Wakayama Medical University, Wakayama, Japan, ³Institute for Protein Research, Osaka University, Suita, Japan, ⁴Institute for Academic Initiatives, Osaka University, Suita, Japan, ⁵WPI Immunology Frontier Research Center, Osaka University, Suita, Japan, ⁶MediCity Research Laboratory, University of Turku, Turku, Finland

Chemokine receptors contribute to various cellular processes including cell migration, proliferation and survival. The CCR7 plays pivotal roles in T cell migration from the blood and dendritic cell migration from the peripheral tissues into secondary lymphoid tissues, and tumor cell metastasis to lymph nodes.
Although a previous study suggested that the efficacy of CCR7 ligand-dependent T cell migration correlates with CCR7 homo- and heterodimer formation, the exact extent of contribution of the CCR7 dimerization remains unclear. In this study, we demonstrated a direct contribution of CCR7 homo-dimerization to CCR7-dependent cell migration and signaling. Induction of stable dimerization by the inducible dimerization system (iDimerize) showed that CCR7 homo-dimerization enhanced CCR7-dependent cell migration and ligand binding, whereas CXCR4/CCR7 hetero-dimerization showed little effect. When CCR7 homo-dimerization was inhibited by a synthetic peptide derived from the CCR7 fourth transmembrane domain, CCR7-dependent cell migration, ligand-dependent CCR7 internalization, ligand-induced actin rearrangement, and Akt and Erk signaling were all significantly decreased. The CCR7-derived peptide impaired ligand-induced cell migration in CCR7-expressing breast cancer cells and human peripheral blood T cells as well. Our study indicates that CCR7 homo-dimerization critically regulates CCR7 ligand-dependent cell migration and intracellular signaling in multiple cell types.

**The involvement of SAMSN1 in mast cell dynamics.**

A.C. Santana¹, M.F. Cândido¹, D.A. Souza-Junior¹, C. Oliver¹, M.C. Jamur¹;

¹Department of Cell and Molecular Biology and Pathogenic Bioagents, Ribeirão Preto Medical School, University of São Paulo, Ribeirão Preto, Brazil

Mast cells (MCs) are multifunctional cells derived from bone marrow, that reside in connective tissue at the interface between the host and the outside environment. Upon activation, MCs produce and release a large range of biologically active mediators. SAMSN1 is a member of a novel gene family of putative adaptor and scaffold proteins containing SH3 and SAM (sterile alpha motif) domains. In the present study, for the first time, SAMSN1 was detected in MCs, both by Western blots and by immunofluorescence. In order to investigate the role of SAMSN1 in MCs, RBL-2H3 MCs were knocked-down (KD) for SAMSN1 using shRNA. SAMSN1 was reduced about 60% in the KD cells when compared to non-transduced RBL-2H3 MCs. Since SAMSN1 is known to be involved in reorganization of the actin cytoskeleton in other cell types, the function of SAMSN1 in mast cell migration was characterized using CCL3 as a chemoattractant in a Transwell system. After 3 hours of incubation, the migration rate of KD RBL-2H3 MCs was about 40% less when compared to non-transduced RBL-2H3 MCs. MC migration was then investigated in Bone Marrow derived MCs (BMMCs) from SAMSN1 deficient mice (C57BL/KaLwRijHsd) and wild type (WT) mice using Stem Cell Factor (SCF) as a chemoattractant in a Transwell system. After 3 hours of incubation, the migration rate of BMMCs from SAMSN1 deficient mice was 40% less than when compared to BMMCs from WT mice. Since migration rates were reduced in SAMSN1 deficient cells, in vitro, and MCs can be recruited to peripheral sites by various stimuli, MC recruitment in vivo was investigated. MC recruitment to the peritoneal cavity was characterized after iP injection of the chemoattractants SCF or Interleukine-3 (IL-3). After injection of SCF, SAMSN1 deficient mice had approximately 40% fewer MCs recruited to the peritoneal cavity when compared to WT mice. While, after injection of IL-3, the number of MCs recruited to the peritoneal cavity of SAMSN1 deficient mice was 50% less than when compared to WT mice. The number of MCs at peripheral sites was also lower in the SAMSN1 deficient mice. Metachromatic MCs were 50% and 30% lower respectively in the skin and tongue of SAMSN1 deficient mice in comparison to WT mice. These findings indicate that SAMSN1 plays a role in MC migration, recruitment and distribution. The results from this study contribute to a better understanding of the role of SAMSN1 in MCs and may provide additional therapeutic approaches to the treatment of allergic and inflammatory processes.

MAL2 overexpression induces cell membrane protrusion formation, and decreases cell migration via its FPAP motif in liver-derived cancer cells.
A. López-Coral$^1$, P.L. Tuma$^1$
$^1$Biology, The Catholic University of America, Washington, DC

Over 80% of all human carcinomas are derived from polarized epithelial cells that are characterized by the loss of or failure to achieve polarity. Thus, it is important to consider how loss or dysregulation of polarized protein trafficking contributes to malignant transformation. This is of particular interest to us because MAL2 (myelin and lymphocyte protein 2) - a protein that we have been investigating in studies of polarized hepatic trafficking for several years - is highly up-regulated in a host of human cancers including renal carcinoma, cholangiocarcinoma, and cancers of the stomach, breast, ovary and pancreas. High MAL2 expression has also been linked to a bad prognosis in patients with ovarian or pancreatic cancer, yet how MAL2 overexpression leads to cancer progression is not known. To identify possible mechanisms, we overexpressed WT MAL2 in hepatoma-derived Clone9 cells that lack endogenous MAL2. We determined that MAL2 overexpression led to actin-based protrusion formation with MAL2 localized to their tips. Because the MAL2 cytosolic N-terminus encodes V PPPP and FPAP sequences that resemble the F/L/W/YPPP recognition sites for EVH1 (enabled, VASP, homology1) motifs present in the actin-associated Ena/VASP proteins, we engineered recombinant adenoviruses with either or both of these proline-rich motifs mutated to alanines. In cells expressing the FPAP or double mutant, actin protrusion were not observed, implicating the FPAP as the responsible motif. Surprisingly, Boyden chamber assays indicated that migration was not enhanced in MAL2 overexpressing cells which we confirmed with scratch assays imaged with the CytoSmart live cell imaging platform, and MTT cell proliferation assays. Similarly, human-derived hepatocellular carcinomas Hep3B cells with endogenous MAL2 displayed abundant protrusions formation and decreased migration. MAL2 knockdown reversed these phenotypes. Because invasive cells display altered polarity with directional membrane delivery and recycling to the invasive front, we predict that MAL2-induced actin protrusions may explain its role in regulating vesicle delivery to the migrating front. We further predict that this is mediated by MAL2 dual specificity in associations with rafts and actin binding proteins, a possibility we continue to explore.

Cxcl12a/Cxcr4b and the transcription factor Myca orchestrate cell migration during zebrafish pronephros repair.
T. Yakulov$^1$, A. Todkar$^1$, K. Slanchev$^1$, A. Bona$^{1,2,3}$, L. Baur$^1$, J. Hochrein$^4$, M. Boerries$^{4,5}$, G. Walz$^{1,6}$
$^1$Renal Division, University Freiburg Medical Center, Faculty of Medicine, University of Freiburg, Freiburg, Germany, $^2$University of Freiburg, Faculty of Biology, Freiburg, Germany, $^3$Spemann Graduate School of Biology and Medicine (SGBM), University of Freiburg, Freiburg, Germany, $^4$Institute of Molecular Medicine and Cell Research, Faculty of Medicine, University of Freiburg, Freiburg, Germany, $^5$German Cancer Consortium, Freiburg and German Cancer Research Center (DKFZ), Heidelberg, Germany, $^6$BIOSS Center for Biological Signalling Studies, University of Freiburg, Freiburg, Germany

Acute kidney injury represents a frequent complication of severe human disease characterized by a rapid loss of renal function. Despite improvements in supportive care, the overall morbidity and mortality rates have remained unchanged. To study the immediate repair mechanisms after acute
In kidney injury, the zebrafish pronephros was ablated with a high-energy laser during the first two days post fertilization, and the repair response was monitored by high-resolution video-microscopy. In one-day-old embryos pronephric tubules were repaired by an actomyosin-based mechanism that irreversibly occluded the injured pronephric tubules. In contrast, pronephric injuries in two-day-old embryos were repaired by a rapid migratory response that re-established the patency of the tubules. This repair response was characterized by accelerated migration, occurred independently of fluid flow, cilia, Wnt signaling and in the absence of epithelial-to-mesenchymal de-differentiation, and reversed the direction of the posterior-to-anterior collective cell migration that shapes the proximal pronephros during organogenesis. Gene expression analysis of the two developmental stages uncovered the chemokine cxcl12a and the transcription factor myca as putative candidates involved in the migratory repair response. Indeed, two-day-old embryos deficient for cxcl12a or its receptor cxcr4b exhibited striking repair abnormalities. Similar repair defects were observed after pronephric injury of myca-deficient embryos. The defective repair after myca knockdown was partially rescued by cxcr4b overexpression, suggesting that myca acts in part through upregulation of cxcr4b. In contrast to their essential role in collective cell migration of the posterior lateral line primordium, both cxcl12a and cxcr4b were dispensable for pronephric collective cell migration. Confirming the zebrafish results, kidney-specific knockout of Cxcl12 and Myc in mice delayed the recovery after ischemic/reperfusion injury. Transcriptional analysis of Cxcl12 and Myc deficient kidneys revealed increased Cxcr4 expression as well as suppressed mitochondrial functions and reduced retinoic acid metabolism. All-trans retinoic acid, which is known to stimulate Cxcr4 expression and mitochondrial metabolism, improved renal recovery after ischemic/reperfusion (I/R) injury. Our findings suggest that cxcl12a and myca are up-regulated in two-day-old embryos to facilitate rapid cell migration in response to injury, and to overcome the actomyosin-based repair mechanism utilized by one-day-old zebrafish embryos. Cxcl12 and Myc contribute to the early recovery after I/R injury of the kidney, establishing the pronephros injury model as a tool to identify molecules involved in kidney repair and to design novel therapeutic approaches.

Collective dynamics over long time scales and large length scales reveals distinct cell migration phenotypes.

R.M. Lee, H. Yue, C.H. Stuelten, W. Rappe, C.A. Parent, W. Losert; 1School of Medicine, University of Maryland, Baltimore, MD, 2Institute for Physical Science and Technology, University of Maryland, College Park, MD, 3Department of Physics, University of California, San Diego, CA, 4Laboratory of Cellular and Molecular Biology, Center for Cancer Research, National Cancer Institute, National Institutes of Health, Bethesda, MD, 5Department of Physics, University of Maryland, College Park, MD

Migrating cells play a role in diverse biological processes which can incorporate both individual cell motion and collective behavior. As the role of collective motion becomes clearer, especially in diseases such as metastatic cancer, there is growing interest in the emergent properties of collective migration. In this study, we analyze the collective migration of cell sheets using particle image velocimetry (PIV), an approach which is being increasingly used to study migration due to its ease of application. In our analysis, we show that PIV can be used to study multiple length and time scales and can yield insight into biological mechanisms that play a role in collective behavior.

The properties of each cell in a migrating cell sheet interact to lead to experimentally observed collective motion. By comparing experimental PIV flow fields from migrating MCF10A cells to the behavior of simulated cell groups, we connect individual cell properties to collective behavior over the

**Tuesday-420**
millimeter-scale of the cell monolayer. We find that cell migration at the boundary can affect migration within the monolayer without the need to introduce leader cells at the boundary or specify large-scale features in the simulations. Our model suggests that collective motion can be enhanced by increasing the cells’ sense of polarity or by increasing the cells’ overall activity.a

In addition to tissue-scale trends in collective behavior, migrating cell groups include localized dynamic features which can change over multiple time scales. We developed a set of measurement techniques to extract multiple features of collective motion, including the chaotic character of the cell sheet. By applying these techniques to both non-malignant (MCF10A) and tumorigenic (MCF10CA1a) breast epithelial cells, we find differences in collective behavior that are not found from measuring speed alone. We use these techniques to show that these cell lines vary in their response to a perturbation to E-cadherin, a cell-cell adhesion molecule. MCF10A cells use E-cadherin for short time coordination of collective motion yet remain coordinated over hours even with decreased E-cadherin expression. In contrast, the migration behavior of MCF10CA1a cells shows decreased collective dynamics and is insensitive to the change in E-cadherin expression.b

Our analysis provides further evidence of the applicability of PIV for understanding collective migration. These analysis techniques—which can be applied directly to phase contrast, time lapse images—allow for the measurement of collective behavior over large length and time scales. These measurements can be used to understand collective migration on scales which are relevant to processes such as cancer metastasis.

Cytoskeletal dynamics during wound reepithelialization in vivo.

A.S. Kennard1, J.A. Theriot1,2,3; 1Biophysics Program, Stanford University, Stanford, CA, 2Howard Hughes Medical Institute, Stanford University, Stanford, CA, 3Biochemistry, Stanford University, Stanford, CA

A critical step in wound healing is reepithelialization, or migration of epithelial cells into a wounded region. Several recent studies in vivo have revealed the tissue-scale patterns of growth and migration during epidermal reepithelialization, but a detailed understanding of the cytoskeletal dynamics in individual cells is lacking. We have observed the migration of the basal epidermal cells of embryonic zebrafish during reepithelialization at high spatial and temporal resolution, using spinning disk confocal microscopy. These basal epidermal cells are also known as keratocytes, and while isolated keratocytes have been studied extensively in culture for their rapid and persistent migration, much less is known about their physiological function in vivo.

We have found that keratocytes in vivo initiate rapid and dramatic migration en masse within minutes of tissue wounding. This study has revealed several novel insights: First, keratocytes adopt an elongated “squid-like” morphology as they migrate, which differs dramatically from their characteristic shape in culture; this suggests that the physical environment of the tissue significantly impacts keratocyte migration. Second, during reepithelialization keratocytes separate from each other, unlike in collective migration in cultured monolayers, where cells often remain attached even as they migrate. Third, cell stopping at the end of reepithelialization is accompanied by a burst of myosin localization at the back of the lamellipodium. Together, these results suggest that collective migratory responses differ markedly in vivo and ex vivo, particularly in the nature of the physical contact between cells. Furthermore, these results provide insight into the dynamics of cell collectives when they stop migrating, which has been difficult to observe in tissue culture models of reepithelialization. Future work promises to clarify...
molecular details about the dynamics of adhesions and myosin localization during reepithelialization, shedding light on this classic example of cell migration in an in vivo context.

Electric Fields Coalesce Lipid Raft and Caveolin to Direct Cell Migration.
B. Lin¹, S. Tsao¹, A. Chen², S. Hu², L. Chao², P. Chao¹;
¹Institute of Biomedical Engineering, National Taiwan University, Taipei, Taiwan, ²Chemical Engineering, National Taiwan University, Taipei, Taiwan

In development and wound healing, endogenous electric fields (EFs) promote and direct cell proliferation and migration. Surface proteins have been proposed as sensors of the electrophoretic and electroosmotic forces that polarize cell membranes and intracellular signaling events. Yet modification of surface protein charges or alternating field directions offer conflicting evidences. We hypothesize that dynamic membrane nanodomains, rich in highly charged glycolipids, are the primary sensors of EFs. Theoretical modeling reveals EF-induced lipid raft polarization and aggregation. Indeed, super-resolution microscopy demonstrates that applied EF polarizes lipid raft distribution and increases their sizes. Disruption of lipid rafts abolishes directional migration and intracellular signaling polarization, while inhibition of signaling molecules or actin polymerization does not change raft distribution. Furthermore, EF induces caveolin oligomerization and preferential distribution. Caveolin knockdown suppresses EF-induced directional migration and intracellular signaling polarization. Interestingly, although inhibition of signaling molecules does not suppress caveolin or raft polarization in EF, functional blocking of integrin reduces caveolin polarization. Inhibition of rafts and integrin polarization from caveolin knockdown suggests reciprocal interactions amongst raft, integrin and caveolin, and the integrity of all three components are necessary for EF-directed migration. In summary, lipid rafts respond to EFs as mobile complexes that polarize, coalesce, and partition membrane proteins, and in turn activate intracellular signaling events to orient cell migration. Our results establish a fundamental mechanism for cell electrosensing and provide a new role in lipid raft mechanotransduction.

Directed Schwann cell migration can be guided by extracellular mechanical gradients.
E.B. Evans¹, S.W. Brady¹, A. Tripathi¹², D. Hoffman-Kim¹;
¹Department of Molecular Pharmacology, Physiology, Biotechnology, Brown University, Providence, RI, ²Center for Biomedical Engineering, Brown University, Pr, RI

Peripheral nerve injuries often result in significant disability and greatly reduced quality of life. Successful nerve regeneration depends upon directed migration of specialized repair-state Schwann cells (SC) across a nerve defect. Following migration, these repair SCs provide directional guidance for severed axons to regrow and restore function back to their innervation target. During this regenerative process, the critical features displayed by these SCs are directed migration and elongated cellular morphologies. Although several groups have studied directed migration of SCs in response to chemical or topographic cues, the current understanding of how the mechanical environment influences migration remains largely understudied and incomplete. Therefore, the focus of this study was to evaluate SC migration and morphodynamics in the presence of stiffness gradients, which revealed that SCs can follow extracellular gradients of increasing stiffness, in a form of directed migration termed durotaxis. On laminin-coated polyacrylamide substrates embedded with either a shallow (0.04 kPa/mm)
or steep (0.97 kPa/mm) stiffness gradient, SCs displayed durotaxis, increasing both their speed and directionality along the gradient materials, fabricated with elastic moduli in the range found in peripheral nerve tissue (0.05-0.54 kPa or 0.87-12.99 kPa). Uniquely and unlike cell behavior reported in other cell types, the durotactic response of SCs was not dependent upon the slope of the gradient. When we examined whether durotaxis behavior was accompanied by a pro-regenerative SC phenotype, we observed altered cell morphology, including increases in spread area and the number, elongation, and branching of the cellular processes, on the steep but not the shallow gradient materials. This phenotype emerged within hours of the cells adhering to the materials and was sustained throughout the 24 hour duration of the experiment. Control experiments also showed that unlike most adherent cells, SCs did not alter their morphology or cytoskeletal architecture in response to uniform materials of different stiffnesses (0.05, 0.54, 0.87, and 12.99 kPa). This study is notable in its report of durotaxis in response to a stiffness gradient slope, which is two orders of magnitude less than reported elsewhere in the literature, suggesting SCs are highly sensitive detectors of mechanical heterogeneity. All together, this work identifies durotaxis as a new migratory modality in SCs, and further shows that the presence of a stiffness gradient of 0.97 kPa/mm can support a pro-regenerative cell morphology, which mimics the specialized in vivo phenotype of repair-state SCs.

Plasma membrane PI(4,5)P2 levels regulate chemotactic signaling pathways and actin networks in Dictyostelium.
N.S. Bawazir1, M. Beshay1, A. Ring1, C. Janetopoulos1;
1Biological Sciences, University of the Sciences, philadelphia, PA

Phosphatidylinositol 4,5-bisphosphate (PIP2) has been shown to be involved in the chemotactic signaling pathways. However, PIP2 has been largely underappreciated as a regulatory component in this signaling network. In a polarized Dictyostelium, the PI3’Kinase (PI3K) translocates to the plasma membrane (PM) of the leading edge while the tumor suppressor PTEN distributes to the rear of the cell. Higher PIP2 levels at the back are maintained through the PIP2 binding and activity of PTEN, in a positive feedback loop. PI5 kinase (PI5K) which is activated downstream of protein kinase B also contributes to PIP2 synthesis across the entire cell PM. However, PI3K and phospholipase C (PLC) use PIP2 as a substrate, so it is locally depleted at the leading edge of a migrating cell. We have found that the activity of the GTPase Ras is reciprocally regulated with PTEN localization, and our work suggests that PIP2 levels set up a threshold preventing the activity of signaling molecules normally active at the leading edge of a cell. To test this, we used Dictyostelium mutant strain lacking the type I PI5K, pikl, (pikl-). These cells have highly reduced PIP2 levels and higher Ras activity compared to wild-type cells. We found that pikl- resemble other phenotypes observed when we use an inducible system to deplete PIP2. We observed that typical leading edge biosensors diffuse to the cytosol when the pikl- round-up and translocate back to the PM when pikl- cells spread. These observations suggest that PIP2 levels go down as cells spread, and elevate as cells round up and contract. F-actin polymerization also occurs as the cell spread. Remarkably, Ras and PI3K biosensors were still activated on the PM when actin polymerization was inhibited with Latrunculin A (LatA). Interestingly, the crescent signaling responses in LatA-treated pikl- cells were reminiscent of responses seen in pten- cells. The lower levels of PM PIP2 in pikl- cells is likely below the minimal level of PIP2 needed to block Ras activity contributing to the excitable cell phenotype observed.

Inter-species repression of light-dependent photoresponses in diatoms.
S.A. Cohn¹, M. Lynam¹;
¹Biological Sciences, DePaul University, Chicago, IL

Diatoms, the single-celled siliceous golden algae ubiquitous to aquatic communities, are crucial primary food sources to numerous marine and freshwater ecosystems. In order to understand the structure and maintenance of healthy aquatic ecosystems it is important to understand the ecological factors regulating the ability of motile diatoms to successfully migrate through their local assemblages in order to successfully exploit resources such as light and nutrients. Previously, our lab has shown how several large single-celled diatom species display characteristic responses to local conditions such as temperature and light. We determined that several of these conditions such as adhesion and directional responses can be modified by the presence of other diatom species, and that this effect can be dependent on the relative abundance of diatom species present. For example, previous studies on light-stimulated direction change indicated that Stauroneis (Stauroneis phoenicenteron) cells had a 2-3 fold longer response time (i.e. slower, repressed response) when in the presence of increasing densities of Craticula (Craticula cuspidata) cells, while Cratiula showed no such density dependent change (Diatom Research, 2016, 31:173–184). In our current study, we measured the time-dependence of this effect, generating a mixed assemblage of Stauroneis and Craticula cells, and measuring the light-stimulated direction change response time of both Craticula and Stauroneis as a function of the duration of their co-incubation. Our results confirm that Stauroneis cells are repressed in the presence of Craticula, showing a response time that increases within 20-30 minutes. Stauroneis cells show an average response time of 29 ± 2 s within the first 0-10 minutes after incubation with Craticula, which increases significantly to 50 ± 5 s for cells 20-30 minutes after incubation (P < .006). The Craticula in the mixed assemblage shows no significant repression in responsiveness over this same period of time, with an average response time of 13 ± 1 s (P = 0.51 for differences over time). Stauroneis in the absence of any Craticula also show no significant change in response time over a period of about an hour, with an average response time of 37 ± 2 s (P = 0.65 for differences over time). These studies suggest that there is some type of inter-species effect between Stauroneis and Craticula that represses the light-stimulated response time of Stauroneis, but not Craticula, and may aid in the cells’ ability to have niche partitioning and greater ecological success in algal communities. This work was supported by grants through the DePaul College of Science and Health, the DePaul University Research Council, and equipment purchased previously through NSF Grant IBN-9982897.

¹Biophysics Program, Stanford University, Stanford, CA, ²Department of Physics, University of California San Diego, San Diego, CA, ³Department of Chemical Engineering, Stanford University, Stanford, CA,
⁴Department of Applied Physics, Stanford University, Stanford, CA, ⁵Department of Materials Science and Engineering, Stanford University, Stanford, CA, ⁶Department of Biochemistry, Stanford University, Stanford, CA, ⁷Department of Microbiology and Immunology, Stanford University, Stanford, CA, ⁸Howard Hughes Medical Institute, Stanford University, Stanford, CA

Tuesday-424
Neutrophil chemotaxis to sites of inflammation and infection is one of the first steps in a healthy immune response. In their surveillance of the human body, neutrophils must undergo polarized migration over long distances through a host of different physical environments - in the bloodstream, along blood vessel walls, and within many mechanically distinct tissues. The long-term goal of this research is to understand how neutrophils regulate their actin cytoskeleton in order to maintain polarized migration through dynamic physical settings. Using high-speed microscopy of neutrophil-like HL-60 cells, we have shown that cell leading edge shape undergoes micron-sized fluctuations that dynamically appear and equilibrate on the order of seconds. We have developed image analysis tools to quantify properties of these fluctuations, which we use as a read-out of the biochemical and physical feedback mechanisms used to maintain polarization. In addition, we have developed a minimal physical model of actin growth against a membrane to interpret these results, predict how changes in properties of actin growth affect leading edge dynamics, and identify candidate actin binding proteins that are likely to regulate polarity maintenance. This minimal model recapitulates many aspects of lamellipodial behavior in vivo, such as treadmilling and decay of actin intensity away from the leading edge. In the future we will iteratively test and update this model to determine the minimal set of feedback interactions that can reproduce polarized cell migration behavior. We will then use the model to predict how neutrophils employ these feedback mechanisms to respond to forces in their environment - informing how neutrophil migration, and thus immune function, might vary between tissues with different mechanical properties.

Cellular decision-making in symmetric directional dilemmas.
A. Hadjitheodorou1,2,3, J. Jorgensen4, F. Ellett5, D. Irimia4, J.A. Theriot2,3;
1Bioengineering, Stanford University, School of Medicine, Stanford , CA, 2Biochemistry, Stanford University, School of Medicine, Stanford, CA, 3Howard Hughes Medical Institute, Stanford, CA, 4Surgery, BioMEMS Resource Center, Massachusetts General Hospital, Harvard Medical School, Boston, MA

Neutrophils are the most abundant circulating leukocytes in humans, comprising the first line of innate immune defense. As neutrophils migrate towards sites of infection and inflammation they encounter a highly heterogeneous environment. Tasked to navigate through microscale obstacles, neutrophils continuously engage in decision-making processes. Through genetic and pharmacological loss-of-function experiments, we know many of the key components required for neutrophil chemotaxis. However, there are still fundamental gaps in our understanding of how these components interact to generate directional decisions in symmetry-breaking situations.
We investigate how neutrophil-like cells make directional decisions when presented with symmetric directional dilemmas. To this end, we are challenging single HL-60 cells with microfluidic devices that harbor symmetrically bifurcating migration channels. We found that cells that encounter symmetric bifurcations exhibit two different decision-making modes. In the first, upon reaching the bifurcation the cell immediately begins to migrate along one direction. In the second, the cell extends a leading edge along both directions of the bifurcation and subsequently retracts the leading edge from one side, continuing to migrate along the other direction. In the later case, we have seen no measurable difference in the leading edge actin intensity until very late in the decision process. Additionally, the positioning of the nucleus and that of the microtubule organizing center do not have a predictive value. Lastly, under conditions of extreme confinement, cell motility becomes bleb-driven and a third decision-making mode arises, where a cell seemingly selects a direction right away only to change it later.
By precisely controlling the cellular environment and measuring the intrinsic biochemical and mechanical interactions between regulatory molecules and structural components we aspire to build a model for cellular decision-making that accounts for cytoskeletal dynamics and signaling activity.

**Regulation of Haptotaxis via Dynamic Lamellipodia.**  
S.J. King, S.L. Craig, S.B. Asokan, S.P. Zimmerman, J.D. Rotty, B.M. Stramer, M. Parsons, J.E. Bear;  
1Lineberger Comprehensive Cancer Center, The University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Randall Division of Cell and Molecular Biophysics, King’s College London, London, United Kingdom

Cells in vivo migrate in response to directional cues such as differing concentrations of extracellular matrix (haptotaxis). However, a complete mechanistic understanding of how cells sense and respond to haptotactic cues is lacking. In order to generate the forces required to drive cell migration, actin filaments must be nucleated and organized in a precise manner. One primary mechanism by which new actin filaments are nucleated is the Arp2/3 complex. In order to dissect the mechanism of haptotaxis on fibronectin, an agnostic approach using microfluidic chambers that allow direct imaging of fibroblast haptotaxis on gradients of fibronectin was utilized. The requirement for the Arp2/3 complex for haptotaxis was confirmed via knockdown, knockout and inhibition in a range of cells, indicating that this result is not cell type specific. We utilized knockdown and inhibitors to elucidate a pathway for haptotaxis, as well as kymography and FRAP to study cellular and actin dynamics during haptotaxis.

From this we recently elucidated the haptotaxis pathway (King SJ et al., JCS 2016) whereby differential engagement of integrins triggers a Src/Rac/WAVE pathway that leads to Arp2/3 activation. Resulting in differential actin dynamics and protrusion dynamics, ultimately leading to directed migration towards higher concentrations of extracellular matrices. Interestingly, merely the presence of a lamellipodium has been shown to be insufficient to regulate haptotaxis; fascin knockdown cells display lamellipodia but cannot haptotax on fibronectin (Johnson HE et al., JCB 2015). In this paper we hypothesized that fascin may direct the formation of the lamellipodium via filopodia to regulate haptotaxis. Utilizing fascin phosphorylation mutants that disrupt fascin/actin binding (Zanet J et al., JCB 2012; Villari G and Jayo A et al., JCS 2015), in a knockdown rescue model, we are exploring the role of fascin in haptotaxis and the dynamics of the cytoskeleton. Interestingly, we have discovered that fascin’s ability to bundle actin is dispensable for haptotaxis. Fascin is regularly misregulated during cancer as are many of the proteins involved in haptotaxis; therefore, a full understanding of its role in haptotaxis will likely contribute to a greater understanding of cancer progression with therapeutic benefits.

**PI(3,4)P2, a new player in chemotaxis?**  
X. Li, P.N. Devreotes;  
1Department of Cell Biology, The Johns Hopkins University School of Medicine, Baltimore, MD

Motile cells can detect shallow gradients of specific chemical signals in their environments and migrate accordingly. This directed cell movement is defined as chemotaxis and is essential for various cell types to carry out their biological functions. During chemotaxis front proteins are recruited to extending pseudopods, which themselves are concentrated at the anterior of the cell. Conversely, back proteins dissociate from nascent pseudopods. I am interested in studying the events occurring at the trailing edge of migrating cells, what back proteins bind to, and how back components regulate polarity. We
identified a Pleckstrin Homology domain (PH domain) containing protein, CynA, which localizes strongly to the lagging edge of cells and is involved in symmetry breaking and promotes polarity. Furthermore, we found CynA preferentially binds to P(3,4)P2 over PIP3 on lipid strips and on reconstituted lipid vesicles. P(3,4)P2 is an important player in signal transduction in chemotaxis. However, the dynamics and mechanisms of P(3,4)P2 mediated signal transduction in this process remain largely unknown. We used this novel P(3,4)P2 biosensor to investigate the role of CynA in chemotaxis. Our data indicated that in uniformly stimulated cells, CynA-GFP-CynA falls off the membrane and translocates to the cytosol, which suggests that P(3,4)P2 levels decrease upon cAMP stimulation. In addition, we studied the dynamics of P(3,4)P2 localization during chemotaxis using CynA PH dimer- KIKGR, a photoconvertible green-to-red fluorescent protein. We found CynA PH dimer- KIKGR localizes in the lagging edge of the cells, as well as in vesicles coming from the protrusions at the leading edge. Our observations suggest that vesicle trafficking might be the source of P(3,4)P2 gradient from the trailing to the leading edge of the migrating cells.

The Role of Integrin-dependent Paracrine Signaling from Keratinocytes in Regulating Myofibroblast Differentiation.

R. Zheng1, W.M. Longmate1, J. Kenney1, C.M. DiPersio1, L. Van De Water1; 1Regenerative Cancer Cell Biology, Albany Medical College, Albany, NY

During wound healing, keratinocytes promptly restore the epidermal barrier and secrete paracrine factors that regulate wound cell functions. Dysregulation of this paracrine signaling can potentially contribute to a spectrum of pathologies: from wounds that fail to heal to those that are fibrotic, such as hypertrophic scars. Our labs have recently established that keratinocyte integrins α3β1 and α9β1 play critical roles in the regulation of wound paracrine signaling by demonstrating that epidermal α3β1 promotes angiogenesis, but α9β1 negatively regulates these α3β1-dependent paracrine effects through paracrine stimulation of endothelial cells (Longmate et al., J Cell Bio, 2017). We suspect that integrin-dependent paracrine signaling from keratinocytes may also play a role in regulating differentiation of myofibroblasts, the cell type that deposits and contracts the ECM during scarring and fibrosis. Recently we determined that conditioned medium (CM) derived from α3+ expressing mouse keratinocytes (α3+ MK) induces expression of cyclooxygenase 2 (COX-2) in fibroblasts. Exogenous prostaglandin E2 (PGE2), one product of the COX-2 pathway, represses markers for myofibroblasts such as TGF-β-induced expression of alpha smooth muscle actin (α-SMA) and formation of stress fibers. In addition, PGE2 suppresses TGF-β-mediated nuclear translocation of myocardin related transcription factor A (MRTF-A). Furthermore, COX-2 knockdown in fibroblasts reduces PGE2 levels and relieves the suppression of α-SMA expression. These in vitro data support a role for fibroblast COX-2-dependent, PGE2 signaling in modulating TGF-β-induced myofibroblast differentiation. Building on our earlier finding that α3β1 induces matrix metalloproteinase 9 (MMP-9) expression in MK cells (Iyer et al., J Cell Sci. 2005; Missan et al., 2015; Longmate et al., J Cell Bio. 2017), we now find that GM6001 (a broad-spectrum inhibitor of MMPs) and a MMP-2/9 specific inhibitor, each suppresses the ability of CM from α3+ MK cells to induce fibroblast COX-2 expression. Furthermore, either gelatin-agarose-mediated depletion of MMP-2/9 in α3+ MK CM, or dicer-substrate siRNA-mediated knockdown of MMP-9 in α3+ MK cells, attenuates α3β1-dependent induction of fibroblast COX-2. Importantly, CM from MK cells that express both integrins α3β1 and α9β1 (α3+/α9+ MK) induces COX-2 in fibroblasts to a lesser degree than CM from α3+ MK cells.
alone, consistent with our hypothesis that α9β1 suppresses the paracrine signaling functions of α3β1. Our findings support a novel role for coordinated functions of keratinocyte integrins α3β1 and α9β1 in controlling the secretion of paracrine factors such as MMPs that regulate fibroblast gene expression and differentiation during wound healing.

Interplay between cell-cell and cell-extracellular matrix forces regulate myocardial proliferation in the heart.
C. Zhang1, G.L. Radice1, S. Emms1,2;
1Center for Translational Medicine, Thomas Jefferson University, Philadelphia, PA, 2Biology Department, Haverford College, Haverford, PA

Cells sense and transduce mechanical signals through cell-extracellular matrix (ECM) adhesions and cell-cell adhesions. After birth, contractile force generation and tissue stiffness increase as cardiac output increases to support the needs of the newborn organism and its growing heart. During this postnatal period, the N-cadherin complex assembles at the intercalated disc (ICD) as integrin-ECM adhesions decrease, accompanying the switch from hyperplastic to hypertrophic growth. However, little is known regarding the reciprocity between integrin and N-cadherin adhesions in the regulation of cell cycle withdrawal that occurs in cardiomyocytes after birth. Alpha-catenin function as mechanosensors and transduce the intercellular force from N-cadherin to the actin cytoskeleton. To investigate mechanotransduction in the heart, cardiac-specific αE- and αT-catenins double knockout (DKO) mice were generated. The reorganization of N-cadherin and integrin-ECM complexes was examined at postnatal day (P) 4, P7, P14, and P60. DKO hearts exhibited aberrant N-cadherin localization accompanied by alteration of α5/β1 integrin distribution. Normally found at the lateral membrane, α5 and β1 accumulated at the ICD with disrupted N-cadherin adhesion. FN matrix assembly, as monitored by immunofluorescent staining and its insolubility in the detergent deoxycholate (DOC), was increased in DKO hearts. Meanwhile, focal adhesion kinase (FAK) was activated in early postnatal DKO hearts. Complementary experiments performed with deformable substrata demonstrated that stiffness-mediated proliferation was dependent on FAK activity. Finally, treatment of DKO pups with the lysyl oxidase (LOX) inhibitor, β-aminopropionitrile (BAPN), was sufficient to reduce cardiomyocyte proliferation to wild-type levels. This data demonstrates that α-catenins regulate the balance between cell-cell and cell-matrix adhesions, which, in turn, controls cardiomyocyte proliferation, thus providing a molecular explanation for loss of regenerative potential shortly after birth.

Laminin 521 Enhances the Expansion and Engraftment of Mouse Satellite Cell-Derived Myoblasts.
P.R. August1, C. Penton1, M.J. Pincus1;
1Discovery Biology, ICAGEN, Tucson, AZ

Large-scale expansion of myogenic progenitors is necessary to support the development of high throughput, bioengineered cellular assays in vitro and to develop cellular therapies for rare muscle diseases. A significant challenge exists to significantly expand myogenic progenitors since they progressively lose their ability to differentiate when cultured and passaged long term in vitro. In order to
overcome this challenge, we evaluated the consequence of propagating mouse and human myogenic stem cell progenitors on various extracellular matrices to determine if they could enhance long-term myogenic potential. We comprehensively examine the effect of physiologically relevant laminins, laminin 211 and laminin 521, compared to traditionally utilized ECMs (e.g. laminin 111, FN, and matrigel) to assess their capacity to preserve myogenic stem cell potential. Laminin 521 supported the increase of myogenic proliferation in early phases of expansion and was the only substrate facilitating high-level fusion following more than 8 passages in mouse cultures. In human cultures, laminin 521 also supported increased proliferation during expansion and superior differentiation with myotube hypertrophy and increased nuclear spacing. In addition we performed engraftment studies in NOD/SCID mice using these ECMs and established that laminin-521 was superior to LN-111 and matrigel expanded cells. These results suggest that laminin-521 could be employed to facilitate the development of future cellular therapy approaches that employ satellite cells.

The role of αvβ5 integrin in axon specification of cerebellar granule cell precursors.
A. Abe1,2, K. Hashimoto1,2,3, A. Akiyama1, Y. Miyamoto1,2, Y. Hayashi4;
1Humanities and LifeSciences, Ochanomizu University, Tokyo, Japan, 2Human Life Innovation, Ochanomizu University University , Tokyo, Japan, 3Research Fellow DC-2, JSPS, Tokyo, Japan, 4Life Science, Asahikawa Medical University, Hokkaido, Japan

Vitronectin (VN), which is an extracellular matrix protein, is known to be involved in the regulation of proliferation and differentiation of cerebellar granule cell precursors (CGCPs) in mice. We previously revealed that VN promotes the progress of the initial differentiation stage of CGCPs. However, it has not been identified which receptor for VN is involved in the function of VN in CGCPs. A prime receptor candidate for VN is integrin (Itg). It is known that αvβ3 Itg and αvβ5 Itg are expressed in CGCPs. Then, we examined which Itg serves as a receptor for VN in CGCPs and what phenomenon the receptor contributes to in the initial differentiation stage of CGCPs. First, the effects of the knockdown (KD) of αv, β3, β5 Itg by the siRNAs on the proliferation and differentiation of CGCPs were analyzed by immunohistochemistry of the CGCPs. The KD of αv Itg and β3 Itg up-regulated the number of proliferation marker-positive cells, but the KD of β5 Itg up-regulated the number of TAG1, a marker of initial differentiation, -positive cells in CGCPs. These results of β5 Itg, not β3 Itg, is consistent with our previous results of VN. This finding motivated us to check the role of β5 Itg as a receptor for VN. The KD of β5 Itg using shRNA-expression lentivirus abrogated the promotion of initial differentiation stage progression in CGCPs by VN, indicating that αvβ5 Itg as a receptor of VN contributes to the progress of initial differentiation stage in CGCPs. Next, we focused axon specification, which has been reported to be observed in the initial differentiation stage of CGCPs and speculated that VN and αvβ5 Itg contribute to axon specification in the initial differentiation stage of CGCPs. To check this speculation, we examined the effect of VN and β5 Itg on the axon specification of CGCPs. The knockout of VN and the KD of β5 Itg up-regulated the ratio of CGCPs with no axon, and the addition of VN and the over-expression of β5 Itg up-regulated the ratio of CGCPs with 2 or more axons. These results indicated that αvβ5 Itg and VN contributes to the axon specification in CGCPs. The axon specification is known to be an essential process in the initial differentiation stage. It is suggested that the progress of the initial differentiation stage is suppressed by the inhibition of the axon specification by the knockout of VN and the KD of β5 Itg. Moreover, the effects of addition of VN were abrogated by KD of β5 Itg. Taken together, αvβ5 Itg is served as a receptor for VN in the initial differentiation stage in CGCPs and has the critical role to specify axon in CGCP.

The planar cell polarity protein Vangl2 regulates cell-extracellular matrix interactions underlying proper membrane protrusive activity.
T.N. Jessen¹, A. Love¹, J.R. Jessen¹;
¹Biology, Middle Tennessee State University, Murfreesboro, TN

Planar cell polarity proteins are implicated in a variety of morphogenetic processes including embryonic cell migration. The transmembrane protein Vang-like 2 (Vangl2) is specifically required for planar cell polarity and directed migration during zebrafish gastrulation. These cell behaviors occur in the context of a fibrillar fibronectin-containing extracellular matrix (ECM). While cell-ECM interactions are thought to regulate cell migration, it is unclear how Vangl2 influences these events. Using a cell culture model system, we previously showed that human VANGL2 negatively regulates membrane type-1 matrix metalloproteinase (MMP14) and activation of secreted matrix metalloproteinase 2 (MMP2). We have now investigated the functional relationship between VANGL2, integrin αβ3, and MMP2 activation. We provide evidence that VANGL2 regulates cell adhesion to the ECM proteins fibronectin, laminin, and vitronectin. Inhibition of MMP14 activity suppressed the cell adhesion defect in VANGL2 siRNA transfected cells. Furthermore, our data show that MMP14 and integrin αv are both required for increased proteolysis by VANGL2 knockout cells. Lastly, our data suggest that integrin αvβ3 is a novel VANGL2 binding partner. These findings begin to dissect the molecular underpinnings of how VANGL2 regulates MMP activity and cell adhesion to the ECM. Previous data established that, compared to wild type, vangl2/trilobite mutant zebrafish gastrula cells lack directionality and meander during their migration towards the dorsal body axis. Notably, we have reported that vangl2/trilobite mutant embryos also have increased Mmp activity and decreased fibronectin ECM assembly. Using time-lapse confocal imaging we now show that loss of zebrafish Vangl2 function increases the number of both filopodia-like and larger membrane protrusions in migrating gastrula cells. This phenotype is accompanied by decreases in polarized protrusive activity and cell migration directness. To determine the role of the ECM in membrane protrusion formation, we performed protrusion analysis on wild-type cells injected with fibronectin morpholinos. Our data show that embryos with reduced fibronectin protein expression exhibit membrane protrusion formation similar to vangl2/trilobite mutant cells, suggesting that defective cell-ECM interactions underlie at least a portion of the mutant phenotype. Together, our in vitro and in vivo data suggest a model whereby Vangl2-dependent regulation of cell-ECM interactions is required for proper membrane protrusive activity and directed cell migration.

Integrin αvβ3 and α6β1 cross-talk of dermal fibroblasts on integrin specific peptide polysaccharide matrix.
K. Hozumi¹, S. Enomoto¹, Y. Teranishi¹, F. Katagiri¹, Y. Kikkawa¹, M. Nomizu¹;
¹Sch Medicine, Tokyo Univ Pharm Life Sci, Hachioji, Japan

A limited number of cross-talks between different integrin subtypes had been identified. Here, we focused on various cross-talks of two different subtypes of integrins and investigated the mechanisms using the unique integrin binding peptides conjugated chitosan matrices. Five different integrin binding peptides, FIB1 (integrin αvβ3), EF1zz (integrin α2β1), S31 (integrin α3β1), CS1D (integrin α4β1), and A2G10 (integrin α6β1), were individually mixed, and ten different two-peptides mixed chitosan matrices
were prepared. Human dermal fibroblast (HDF) attachment activities to the ten different mixed peptide-chitosan matrices were different depending on the combination of peptides and their mixture ratios. Six different pair of mixed peptides-chitosan matrices did not show any specific variation by mixture of peptides, and three mixtures (FIB1/A2G10−, FIB1/CS1D−, and EF1zz/CS1D-chitosan matrices) promoted HDF attachment. Of the three HDF attachment promoting combinations, FIB1/A2G10-chitosan matrix significantly promoted HDF attachment and spreading. FIB1 is fibronectin derived RGD containing peptide that binds integrin αvβ3, and A2G10 is derived from laminin α2 chain that binds integrin α6β1. The promotion of HDF attachment was conspicuous when A2G10 and FIB1 was mixed with 3:7 molar ratio. Since FIB1 include RGD in its sequence, laminin derived RGD containing peptide of A99 was examined to clarify this promotion, and A99/A2G10-chitosan matrix was prepared. A99/A2G10-chitosan matrix promoted HDF attachment as same as FIB1/A2G10-chitosan matrix. Further, the promotion of cell attachment was also observed laminin-111 and fibronectin mixture. From these results, we could identify the specific combination of integrin-integrin cross-talks that promotes the cell attachment using the mixed peptides chitosan matrix method.

DDesmoplastic-ECM induces aberrant active α5β1 integrin endocytosis to sustain a pro-pancreatic cancer desmoplastic stroma phenotype.  
J. Franco-Barraza1, T. Luong2, N. Shah3, E. Cukierman1; 
1Cancer Biology, Fox Chase Cancer Center, Philadelphia, PA

Pancreatic ductal adenocarcinoma (PDAC) presents one of the highest mortality rates amongst all neoplasias. The desmoplastic (Desmo) microenvironment, characteristic of this malignancy, plays a pivotal role in its aggressive progression. This pro-tumor niche is produced and sustained by activated (i.e., Desmo) cancer-associated fibroblasts (CAFs). We have previously demonstrated the occurrence of a CAF Desmo phenotype correlated to bad patient outcomes. This phenotype is characterized by an aberrant intracellular accumulation of active α5β1 integrin. Using our in vivo-mimetic 3D human stroma system, we were able to induce this phenotype on human naïve pancreatic stellate cells by culturing these into Desmo CAF-derived extracellular matrices (ECMs). We found that the intracellular accumulation of active α5β1 integrin depends on αvβ5 activity, and that this integrin crosstalk is needed to maintain the CAF-like phenotype. The hypothesis being tested in this study postulates that Desmo-ECM-induced alterations to α5β1 integrin trafficking dynamics, induced by outside-in αvβ5 integrin signaling, are responsible for the intracellular sequestering of active α5β1, which in turn fuels a forward loop to sustain and propagate the CAF Desmo phenotype.

Our data suggests that in response to Desmo-ECM, CAFs display changes in the expression and regulation of key vesicle transport molecules, such as Cav1, Rab27, CLIC3 and CD81 and that these changes are lost in CRISPR edited αvβ5 integrin-null CAFs. These results prompted the notion that alterations in endocytic routes of active α5β1 integrin-containing vesicles are triggered by CAFs binding to Desmo-ECM. Moreover, knockdown of CD81 expression prevented the intracellular accumulation of active α5β1 integrin and resulted in the reversion of the pro-PDAC CAF phenotype back to an anti-tumor, akin to normal stroma, phenotype. These findings suggest a potential clinical relevance for gauging PDAC’s stromal phenotypes in patients. Moreover, our results could facilitate the potential development of new therapeutic targets aimed to reprogram Desmo stroma and harvest its natural tumor-restrictive benefits.

Tuesday-431
Fibrinogen is a major blood plasma protein which is converted into fibrin by thrombin to form fibrin clot. Fibrinogen is involved in a variety of biological functions, such as thrombus formation, inflammation, wound healing and leukocyte adhesion. Fibrinogen consists of six polypeptide chains in two sets of three polypeptides (α, β, γ) and of three domains with two distal and one central domains. It was shown that the central and distal domain of fibrin bind to β2 integrin on leukocyte via I domain of α subunit of β2 integrin. In this study, we further characterized fine structure of central domain of fibrin responsible to β integrin binding, by using ELISA type binding analysis with fibrin derived proteins. As results, the β chain of fibrin central domain bound to αX-I domain at a high level and α chain bound a less extent level, suggesting that the β chain of fibrin fragment E and a major binding site for αX-I domain. To further characterize the major site in β chain of fibrin fragment E, peptide inhibition experiment was carried out. As a result, peptide corresponding to G14~A25 region of the β chain has an inhibition effect on the αX-I domain binding to β chain of fibrin fragment E. Therefore it is likely that G14~A25 region of the β chain is a major binding site. In addition G29~D40 region of α chain in recognized as a binding site and G17~C28 region of α chain as a minor binding site for αX-I domain. Besides there two regions, other sites of fibrin fragment E still has a possibility as binding regions but in less significant manner.

The nervous system can mitigate an exacerbated pro-inflammatory immune response in an immunosuppressive setting. Studies also suggest that neurotransmitters can trigger immune responses such as cytokine secretion, integrin expression, and chemotaxis. We observed a basal expression of receptors for glutamate on mouse T lymphocytes. Both CD4+ and CD8+ T cells significantly upregulated expression of glutamate receptors (GluRs) following TCR stimulation, with CD8+ T cells maintaining a higher and prolonged receptor expression than CD4+ T cells. Concomitant with the upregulation of T cell activation molecules CD69, CD25 and CD44, proliferating CD8+ T cells presented higher levels of GluR3 and GluR1 when compared with non-proliferating cells, as well as a higher production of IFN-γ and granzyme B. We also evaluated the role of neurotransmitters in modulating and/or activating T cells in mammary (4T1HA) tumor model that express viral hemagglutinin (HA) as a defined immunodominant antigen of low avidity. We observed that HA-reactive CD8+ T cells in the tumor-infiltrate showed an upregulated expression of GluR3 and GluR1 receptors when compared with control group. Although the dynamics of glutamate receptor signaling on T cell function is not completely clear, the blockade of GluR signaling by using specific antagonists down regulates expression of activation markers as CD69 and
CD25, impairs T cell proliferation, however, it does not interfere with their cytolytic activity neither their ability to express effector molecules. Early TCR mediated molecular pathways are also affected by GluR signaling, suggesting an interaction between them. Overall, data suggest that glutamate might have a costimulatory effect on T cell activation and could be a promising strategy for enhancing anti-tumor T-cell immunity, most likely by increasing T cell survival.

Genetic dissection of Cell-ECM adhesion in vivo using CRISPR/Cas9-mediated genome engineering of the Talin locus.

D. Camp¹, V. solyanova¹, A.Q. Xu¹, B. Goult², G. Tanentzap³;
¹Cellular Physiological Sciences, University of British Columbia, Vancouver, BC, ²School of Biosciences,, University of Kent, Canterbury, United Kingdom

Cell adhesion to the extracellular matrix is of fundamental importance to the development of multicellular organisms. This process entails the coordinated assembly of the integrin family of adhesion receptors with cytoplasmic proteins complexes required to regulate integrins and transduce their signal. An essential component of these complexes is the cytoskeletal protein talin, which is required for integrin function and regulation. Talin has essentially two functions orchestrating the assembly of the intracellular adhesion complex, which associates with integrin, and regulating the affinity of integrins for the ECM. Talin is a large 270-kDa protein comprised of multiple domains capable of a wide variety functions such as scaffolding, adaptor, regulatory and mechanotransduction. These are believed to enable talin to precisely regulate integrins in wide variety of developmental processes. To understand the role of these different domains, our group and others have performed extensive structure-function analysis through the expression of specific Talin mutants in Drosophila Melanogaster. Although instrumental, an important caveat of these studies was the resulting ectopic expression of the Talin constructs. To circumvent this problem, we have established a CRISPR/Cas9 strategy to efficiently engineer the endogenous Talin locus. Through this method, we successfully generated mutant flies by specifically mutating key residues and allowing us to directly assay these modifications in vivo in the context of Drosophila development. We present here our findings on 3 different talin mutants. The first one, K17E, targets a site in the FO subdomain of the talin head previously shown to be able to bind rap-1, a small GTPase known as a master regulator of cytoskeletal remodeling. Surprisingly, phenotypic studies of this mutant revealed that this site is essential for talin function. Indeed, K17E embryos were unable to localize talin to integrins leading to severe adhesion defects. This indicates that direct Rap1 binding to talin is required for its proper localization. This novel model of Talin recruitment to the integrins redefines the previous canonical view where Rap1 was thought to not interact directly with talin, but through the adaptor protein RIAM. The remaining mutants target the two principal talin actin binding sites, ABS2 and ABS3. Here, we separately investigated the roles of each to precisely dissect their contribution to talin function. Our results suggest that each actin binding site has distinct function in the establishment and maintenance of Cell-ECM adhesion. Together these results shed new insight on talin function and opens new interesting prospects with the future analysis of additional talin mutants.

Mechanical and Signaling Roles for Keratin Intermediate Filaments in the Assembly and Morphogenesis of Mesendoderm Tissue at Gastrulation.
P.R. Sonavane¹, C. Wang², B. Dzamba¹, G.F. Weber³, A. Periasamy⁴, D.W. DeSimone¹;
¹Department of Cell Biology, University of Virginia, Charlottesville, VA, ²Physics Department, Central College, Pella, IA, ³Department of Biological Sciences, Rutgers University-Newark, Newark, NJ, ⁴Keck Center for Cellular Imaging, Department of Biology, University of Virginia, Charlottesville, VA

Coordination of individual cell movements is critical for the assembly and morphogenesis of tissues at gastrulation. These movements generate forces but how cells respond to and transmit these forces remains unclear. Xenopus mesendoderm cells employee integrin based adhesions to migrate collectively along a fibronectin (FN) substrate assembled by blastocoel roof (BCR) cells. One question still to be addressed is the distribution of individual cell traction stresses that are involved in propelling this tissue across the BCR. Traction force microscopy (TFM) was used to detect and quantify traction stresses generated by cells within the mesendoderm tissue. We demonstrate that leading edge cells are primarily responsible for generating traction stresses necessary for migration and that these stresses are balanced by intercellular stresses in following row cells. This arrangement of traction stresses is further reflected in the morphology of these cells. Leading edge cells extend broad stable lamellipodia while following row cell protrusions are smaller, more dynamic and include long filopodial-like structures. TIRF microscopy of cells expressing GFP-tagged paexillin reveals mature focal adhesions (FAs) formed by cells at the leading edge with rapid turnover of smaller FAs evident in following row cells. A gradient of Rac1 activity was detected in leading edge cells expressing a FRET-based biosensor, with highest Rac1 activity noted in forward protrusions. Increased Rac1 activity coincides spatially with highest traction stresses generated by the leader cells. Following row cells lack a Rac1 activity gradient. Keratin(8) intermediate filaments (IFs) are known to localize at cell adhesions in mesendoderm cells in response to anisotropic tension on C-cadherin adhesions (Weber et al. 2012. Dev Cell 22, 104-115). Depletion of keratin(8) IFs with antisense morpholinos results in higher traction stresses in following row cells, misdirected protrusions, and the formation of actin stress fibers anchored in streak-like focal adhesions. A connection between Rac1 and keratin(8) IFs was explored using a photoinducible Rac1 construct to increase Rac1 activity in targeted regions of the cell. Local activation of Rac1 activity resulted in reduced keratin(8) filaments and increased lamellipodial protrusions. Morpholino knockdown of keratin(8) IFs also resulted in disruption of the Rac1 activity gradient. Together, these results suggest a functional antagonism between Rac1 and keratin (8) IFs. We propose that maintenance of mechanical integrity in the mesendoderm by keratin intermediate filaments is required to balance forces within the tissue and to coordinate collective cell movements. This work was supported by USPHS grant GM094793.

Mechanosensitive cadherin adhesion and its regulation.
R. Koirala¹, A. Priest¹, C. Yen¹, S. Sivasankar¹;
¹Physics and Astronomy, Iowa State University, Ames, IA

Mechanical signals are essential for the formation, differentiation, and remodeling of tissue. Classical cadherin cell-cell adhesion proteins play key roles in sensing mechanical forces and transducing them
into biochemical signals. While the functional consequences of cadherin adhesion have been extensively studied, little is known about the molecular mechanisms by which cadherins sense extracellular mechanical stimuli and regulate adhesion. To address this critical gap, we used an integrated approach that tightly couples highly predictive computer simulations, ultrasensitive single molecule Atomic Force Microscopy, and precise manipulation of cadherin interactions with the cytoskeleton. Our results show that: (i) cadherin ectodomains adhere in two conformations that respond to mechanical stimuli in distinctly different manners, by either strengthening or weakening adhesion [1, 2]; (ii) cadherins interconvert between these alternate conformations [3]; and (iii) cadherin ectodomain conformation is regulated by the highly dynamic actin cytoskeleton. Our results provide a mechanistic understanding of how the cytoskeleton regulates cadherin adhesion and cadherin response to extracellular mechanical stimuli.

Mutations disrupting planar cell polarity alter Celsr1-mediated cell adhesion and dynamics.
S.N. Stahley1, D. Devenport1;
1Molecular Biology, Princeton University, Princeton, NJ

Planar cell polarity (PCP), the collective and organized polarization of cells along a tissue plane, is fundamental to early embryonic development and tissue organization in complex, multicellular organisms. Compromised PCP results in severe developmental disorders including neural tube defects, ciliopathies and cardiomyopathies. A hallmark feature of PCP is the asymmetric localization of core PCP components at intercellular junctions. This junctional PCP complex is thought to be organized via homophilic interactions of the principle PCP protein, Celsr, a large atypical cadherin. While important developmental roles for Celsr at the tissue-level have been established, an understanding of Celsr extracellular cell-cell interactions at the individual cell and molecular level is lacking. The overall goal of this work is to elucidate how Celsr1 mediates adhesive interactions to coordinate asymmetrical PCP protein localization and function. Using a combination of junctional recruitment and cell aggregation assays in cadherin-free K562 cells, we confirmed that mouse Celsr1 mediates calcium-dependent, homophilic cell adhesion through its cadherin repeat-containing extracellular domain. Interestingly, disease-associated PCP variants Celsr1Crsh and Celsr1Scy, which harbor mutations in the extracellular cadherin domains, mediated cell aggregation comparable to wildtype (WT). However, these mutants lack the ability to enrich at epithelial cell junctions, suggesting that intercellular adhesion alone cannot fully explain Celsr1 functions. Surprisingly, Celsr1Crsh aggregates segregated from Celsr1WT clusters when mixed, demonstrating this single point mutation generates a novel Celsr variant with altered homophilic binding properties. Further observations suggest Celsr1Crsh is defective in lateral clustering, which may function to stabilize and reinforce the adhesive complex. Celsr1Crsh displayed broader cell surface distribution and reduced junction localization relative to WT in K562 cells. Further, the stable association of Celsr1 at the membrane, which depends on Celsr1’s extracellular domain, was substantially reduced.

Tuesday-435
in the Celsr$^{1\text{Crsh}}$ mutant. Together, our data indicate that Celsr1 mediates homophilic adhesion and that perturbing its adhesive properties compromises functional PCP. Based on the altered distribution, stability and adhesive properties of Celsr$^{1\text{Crsh}}$ protein, we hypothesize that this mutation may lie within a cis-interacting region that functions to stabilize and reinforce the adhesive complex. Domain mapping, biochemical approaches and advanced imaging techniques are ongoing to detail Celsr’s function as an intercellular bridge to mediate PCP complex assembly, maturation and functional asymmetry.

Organization of E-cadherin on the cell surface of A431 cells.
J. Choi¹, C. Chen¹, I. Indra¹, R. Troyanovsky², S.M. Troyanovsky¹;
¹Dermatology, Northwestern University, Feinberg School of Medicine, Chicago, IL

Adherens junctions (AJs) are major intercellular adhesion structures in vertebrates. Despite the critical role of AJs in tissue integrity and morphogenesis, the detailed organization of their key protein, E-cadherin inside and outside of AJs remains controversial. According to the traditional point of view, AJs are formed by E-cadherin clustering in cell-cell contacts. This model was recently challenged by Single Molecule Localization Microscopy (SMLM) experiments, which detected structurally identical E-cadherin clusters all over the cell surface of A431D cells (Wu et al., 2015, Dev Cell, 32:139-54). This observation implied that E-cadherin clustering is not a key process in AJ assembly. Since A431D cells are highly abnormal, we re-investigated the E-cadherin organization using SMLM on the surface of A431D parental A431 cells. Using E-cadherin tagged with photoswitchable fluorescent protein Dendra2, we showed that AJs in these cells can reach more than one µm in length and consist of tightly packed cadherin clusters with crystal-like density interspersed within sparser cadherin regions. No E-cadherin clusters were found outside of AJs. To exclude the possibility that such extrajunctional clusters were overlooked because of their small size, the weakness of Dendra2 fluorescence, and/or the presence of endogenous E-cadherin, we analyzed A431 cells in which the latter was knocked-out. The extracellular region of the recombinant E-cadherin in these cells was tagged by GFP and was located in SMLM by monovalent Alexa Fluor 647-conjugated anti-GFP nanobody. This approach confirmed that E-cadherin is a monomer outside of AJs. These results strongly support the idea that cadherin clustering is an essential mechanism of AJ assembly and is triggered by adhesive cadherin-cadherin interactions.

The role of cadherin compensation during adherens junction assembly and maintenance in MDCK cells.
B.G. Ayee¹, A.J. Rodriguez¹;
¹Biological Sciences, Rutgers University Newark, Newark, NJ

The process of cadherin switching is one of the most notable indicators of Epithelial to Mesenchymal Transition (EMT). A classic example of this type of switch is during cancer metastasis where there is often a shift in the expression of Epithelial cadherin (E-cad) to Neural cadherin (N-cad) with in a tumor. Depending on the cell type, numerous cadherins are expressed at any given time. In this study we investigated two of the most abundant cadherins in the Madin Darby canine kidney (MDCK) cell line, E-cadherin and Placental cadherin (P-cad). While E-cadherin is well known for its ability to initiate epithelial junction assembly as well as maintaining proper tissue permeability, P-cadherin has primarily been studied within the context of collective cell migration and tissue tension. We looked at P-cadherin

Tuesday-436
expression and localization during adherens junction assembly when E-cadherin expression and function were perturbed. Using the calcium switch method to synchronize junction assembly, we discovered P-cadherin’s expression and localization to be similar to E-cadherin’s. We also looked at both the localization and expression levels of P-cadherin within E-cadherin overexpressing cells and noted significant changes in its localization. These findings support the cadherin compensation hypothesis, whereby one cadherin could be forced into multiple roles depending on a change in another cadherin’s expression. Lastly, we investigated the affect of the cadherin compensation process on downstream signaling pathways by looking at a common signal component, the small Rho GTPase Cdc42. Given Cdc42’s known roles in actin cytoskeletal remodeling, necessity for junction assembly, and its role in establishing polarity, and necessity for directed cell migration, we investigated the localization and activity of Cdc42 following E-cadherin perturbation. Finally, we investigated the changes in cadherin expression and contact localization following Cdc42 inhibition. We expect this research will be used to better understand one of the more critical mechanisms during cancer metastasis and provide novel insight to prevent cancer progression.

Branched actin networks at endothelial adherens junctions push against each other to maintain cadherin transinteraction.
N. Efimova\(^1\), T.M. Svitkina\(^1\);
\(^1\)Biology, University of Pennsylvania, Philadelphia, PA

Adherens junctions (AJs) are mechanosensitive cadherin-based intercellular adhesions that extensively interact with the actin cytoskeleton and carry most of the mechanical load at cell-cell junctions. Both Arp2/3 complex-dependent actin polymerization, which generates pushing force, and nonmuscle myosin II (NMII)-dependent contraction, which produces pulling force, are necessary for AJ morphogenesis. Which of these actin systems interacts with AJs is unknown. Their specific contribution to AJs is also not fully understood with the role of Arp2/3 complex-dependent nucleation in mature linear AJs being especially obscure. By platinum replica electron microscopy of endothelial cells, we show that VE-cadherin immunogold colocalizes with Arp2/3 complex-positive branched actin network in different types of AJs, while actin-NMII bundles are located more distally. The branched networks at AJs consist of two oppositely oriented subsets with VE-cadherin in the middle. After inhibition of the Arp2/3 complex, mature linear AJs split with detergent-insoluble VE-cadherin remaining at the gap edges. In contrast, VE-cadherin is lost from gap edges following detergent extraction in cells with inhibited actin-myosin contractility. We propose that Arp2/3 complex-dependent branched actin networks push against each other to maintain trans-interaction between VE-cadherins of contacting cells, whereas NMII activity stabilizes adhesion complexes at the cytoplasmic faces of the AJ. Additionally, tangential actin bundles serve as a launch pad for assembly of the junctional branched networks and as a structural base that restrains pushing force generated by the branched network and its retrograde flow within a narrow space between contacting cells. Our data provide an important conceptual framework to explain results of functional experiments that target various components and regulators of the actin cytoskeleton AJs.

Essential Role of Obscurin Kinase Domain-1 in Cardiac Cell Adhesion and Communication by Regulating the Phosphorylation of N-Cadherin.
L. Wang1, L.R. Hu1, C. Yankaskas2, K. Konstantopoulos2, A. Kontrogianni-Konstantopoulos1;
1Biochemistry and Molecular Biology, University of Maryland School of Medicine, Baltimore, MD,
2Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD

Obscurin-B is a giant protein composed of adhesion and signaling motifs. Our earlier work demonstrated that the serine/threonine kinase domains (Kin1 & Kin2) of obscurin-B are enzymatically active [1]. Particularly, Kin1 undergoes autophosphorylation, and phosphorylates the cytoplasmic domain of N-cadherin (N-cad) in vitro [1]. We now show that endogenous obscurin-B containing Kin1, co-localizes with N-cad at cell junctions in neonatal rat ventricular myocytes (NRVM), and that their distribution is coordinated and regulated by Ca2+. Consistent with this finding, ectopically expressed, constitutively active Kin1 (Kin1-CA) preferentially targets to the cell membrane where it forms a complex with N-cad. Overexpression of Kin1-CA significantly increases cardiomyocyte aggregation, adhesion, intracellular communication, and stiffness, as shown by aggregation, dispase, dye transfer, and atomic force microscopy assays, respectively. Given that N-cad is a substrate of Kin1 in vitro and has a well-documented role in modulating cell adhesion, gap junction assembly, and cell stiffness, we postulated that Kin1-CA might exert these effects, at least in part, via phosphorylation of N-cad. To assess this hypothesis, we first used 2D electrophoresis to examine the phosphorylation profile of N-cad in situ. Overexpression of Kin1-CA results in a major shift of N-cad spots towards a lower pH, which is indicative of the generation of less positively charged or more phosphorylated species, thus suggesting that N-cad is a substrate of Kin1 in vivo, too. This observation was supported by mass spectrometry, which revealed that Kin1 phosphorylates N-cad at Ser-788, and the use of phospho-specific antibodies, which confirmed the presence of phosphorylation at Ser788 in cardiac lysates. Importantly, phosphorylation of N-cad at Ser788 was significantly enhanced (~3-fold) following insulin stimulation, implying its physiological relevance. Overexpression of phospho-mimetic N-cad (Ser788Glu), but not phospho-ablated N-cad (Ser788Ala), in NRVM significantly increased the rate of dye transfer, suggesting that Kin1 enhances gap junction communication through phosphorylation of N-cad. We are currently examining the effects of phospho-mimetic N-cad on cell aggregation, adhesion and stiffness using our established approaches. In summary, our studies are the first to show that Kin1 plays key roles in cardiomyocyte adhesion, communication and stiffness, at least in part via phosphorylation of N-cad at Ser788. While the regulation of E-cad via phosphorylation has been extensively studied, little is known about the regulation of N-cad. Our studies are therefore highly novel with important functional implications for cardiac structure and function for both N-cad and obscurin-B.

Barrier enhancing function of Src and VE cadherin phosphorylation in endothelial cells revealed by synthetic biology approach.
J. Klomp1, R. Rebiai1, V. Huyot1, K.B. Collins1, A.B. Malik1, A.V. Karginov1;
1Department of Pharmacology, University of Illinois at Chicago, Chicago, IL

Permeability of the endothelial monolayer is regulated at the level of adherens junctions (AJs), multiprotein structures mediating cell-cell interactions. Src tyrosine kinase can stimulate AJ disassembly, but its activity is also required for AJ formation, suggesting a dual function for Src in
regulation of the endothelial barrier. However, defining a barrier protective role for Src has been difficult due to limitations of current methods. To overcome existing limitations we employed novel protein engineering technology that provides tight temporal regulation of Src kinase activity in living cells. This allowed us to identify a previously undescribed role for Src in the regulation of endothelial barrier function. Src activation resulted in a distinct biphasic temporal effect on endothelial permeability. Initially, Src induction led to strengthening of endothelial barrier and accumulation of VE cadherin at the AJs. Only prolonged activation of Src increased barrier permeability. Importantly, activation of another Src Family Kinase (SFK) member, Lyn, only promoted barrier permeability, suggesting that the barrier enhancing function is specific to Src. Src-mediated transient barrier strengthening was accompanied by formation of morphologically distinct reticular AJs. Reticular AJs were found in areas of overlap between contiguous endothelial cells, and exhibited reduced localized permeability. Organization of reticular AJs suggests that they form in membrane protrusions. In agreement with this hypothesis, we observed increased formation of lamellipodia that occurred concurrently with Src-mediated formation of reticular AJs. Interestingly, Src-induced barrier enhancement was also accompanied by robust phosphorylation of VE cadherin. However, VE cadherin phosphorylation did not affect its interaction with binding partners, p120- and β-catenin, and it did not disrupt VE cadherin localization to AJs. Furthermore, VE cadherin phosphorylation at Tyr731 was required for Src-mediated barrier enhancement. Therefore, our results reveal an unexpected protective role for Src and VE cadherin phosphorylation in the regulation of endothelial permeability. To further support these observations, we also show that activity of SFKs and VE cadherin phosphorylation on Tyr731 are required for barrier enhancing effect of S1P treatment. Our studies also demonstrate that Src activity mediates recovery of the endothelial barrier after thrombin treatment. These data support a novel role for Src uncovered by a synthetic biology approach, and indicate that Src signaling mediates barrier enhancement in endothelial cells downstream of physiological stimuli.

1Department of Clinical Medicine,, Aarhus University, Aarhus, Denmark, 2Department of Molecular Biology and Genetics, Aarhus University, Aarhus, Denmark, 3 Department of Microbiology and Immunology Department of Pediatrics, Stanford University, Stanford, United States, 4 Interdisciplinary Nanoscience Center,, Aarhus University, Aarhus, Denmark

Enteropathogenic Escherichia coli (EPEC) is a major cause of childhood diarrhea and causes significant morbidity and mortality in developing countries. To design intervention strategies towards EPEC infections, molecular understanding of the infection strategy is essential. Upon infection, EPEC attaches to the surface of the small intestinal epithelial cells, where it secretes several virulence factors, modifying the cell surface, strengthening EPEC attachment, and promoting growth of microcolonies on the epithelium. EPEC attachment disrupts many structural and functional components within the host cell, and recruits several basolateral proteins to the apical microcolonies. EPEC produces its own receptor, Tir (Translocated intimin receptor), which is translocated into the host cell plasma membrane by the type III secretion system (T3SS). Here, Tir serves as a receptor for the EPEC adhesin intimin, which enables tight attachment of EPEC to the host cell. We discovered that E-cadherin is one of the basolateral proteins recruited to EPEC microcolonies on the apical surface, and explored the significance of this observation. Using fluorescently tagged E-cadherin, we confirmed that E-cadherin is indeed
recruited to the EPEC infection site. Time-lapse imaging revealed that recruitment occurs at later stages of infection. To test the role of E-cadherin in attachment and microcolony formation, we pre-incubated the bacteria with the soluble extracellular domain of E-cadherin before infection. This significantly decreased EPEC adhesion to the host cells, indicating that the extracellular domain of E-cadherin can bind EPEC and block attachment to host cells. We found that Tir/Intimin facilitated this binding, since addition of purified Tir to a non-pathogenic E. coli strain BI21 expressing intimin was sufficient to promote E-cadherin binding. Direct interaction between the soluble domains of intimin and E-cadherin was also detected in vitro, using a far-western interaction assay. Altogether, our data indicate that the Tir-intimin complex formation promotes recruitment of E-cadherin, which stabilizes EPEC attachment to host cells at later stages of infection. This molecular complex may be an attractive target to block colonization of the cell surface by pathogenic bacteria.

Adherens junctions sense and propagate mechanical forces by coupling the acto-myosin contractile apparatus of adjacent cells. Zonula Adherens (ZA) in simple epithelial polarized cells exemplifies this property of adherens junctions. It is a specialized zone where apically concentrated E-cadherin is coupled to perijunctional actomyosin bundles to generate tension. RhoA signaling and actin regulators play an essential role in generating tension and maintaining the integrity of the ZA. We have now identified a novel mechanism in which RhoA signaling is stabilized at the ZA by anillin and myosin II. This is achieved by recruitment and stabilization of a pool of anillin by myosin II at the ZA in the interphase MCF-7 cells. The junctional anillin, then imparts cortical stability to active RhoA by binding to RhoA-GTP through its Anillin Homology (AH) domain. Anillin stabilized GTP-RhoA is then accessed by effectors like ROCK1 and mDia1 to generate junctional tension. Depletion of Anillin resulted in reduced RhoA signaling at ZA and resulted in reduced junctional tension. Interestingly, anillin’s ability to potentiate RhoA signaling is co-opted by the transcription factor Snail for expulsion of cells from monolayer and also to maintain epithelial cohesivity during collective migration of cells. These results highlight a novel extramitotic role for anillin in regulating RhoA signaling at the zonula adherens.

The vascular barrier that separates blood from tissues is actively regulated by the endothelium and is essential for transport, inflammation, and hemostasis. Hemodynamic shear stress plays a critical role in maintaining endothelial barrier function, but how this occurs remains unknown. Here, using an engineered organotypic model of perfused microvessels and confirming in mouse models, we identify that activation of the Notch1 transmembrane receptor directly regulates vascular barrier function through a non-canonical, transcription independent signaling mechanism that drives adherens junction assembly. Shear stress triggers proteolytic activation of Notch1 and the release of the Notch1 transmembrane domain, which is the key domain that mediates barrier establishment. Expression of the Notch1 transmembrane domain is sufficient to rescue Notch1 knockout-induced defects in barrier function, and does so by catalyzing the formation of a novel receptor complex in the plasma membrane consisting of VE-cadherin, the transmembrane protein tyrosine phosphatase LAR, and the Rac1 GEF Trio. This complex locally activates Rac1 at cell-cell contacts to drive the formation of cortical actin fibers, strengthen adherens junctions, and establish barrier function. Canonical Notch transcriptional signaling is highly conserved throughout metazoans and is required for many processes in vascular development, including arterial-venous differentiation, angiogenesis, and remodeling; here, we establish the existence of a previously unappreciated non-canonical cortical signaling pathway for Notch1 that regulates vascular barrier function, and thus provide a mechanism by which a single receptor might link transcriptional programs with adhesive and cytoskeletal remodeling.

Establishment and maintenance of the epidermis is coordinated by progenitor cells residing in the deepest basal layer that are tightly adherent to each other and to cells in the spinous layer above them. Our lab and others have shown that basal cells promote differentiation by two discrete mechanisms: 1) “delamination,” or detachment of basal cells from the underlying basement membrane; and 2) “asymmetric cell divisions,” perpendicular orientation of the mitotic spindle to specify daughter cells of different fates. Interestingly, both of these processes require remodeling of adhesions in a coordinated manner.

In the developing epidermis, it is well established that during oriented cell divisions, positioning of mitotic spindle is directed by LGN (\textit{Gpsm2}), an intracellular scaffolding protein that localizes to the cell cortex during mitosis. It remains poorly understood how LGN is differentially localized in basal progenitors during either planar (generally thought to be symmetric) or perpendicular (asymmetric) orientation. Our lab has previously shown that LGN is localized to the apical cell cortex during
perpendicular divisions in epidermis, where it can promote perpendicular divisions which promote stratification. However, in oral epithelia and developing hair placodes, LGN can display different patterns of cortical localization where it promotes distinct division orientations. While distinct patterns of cortical LGN distribution are likely to underlie the choice between symmetric and asymmetric divisions, little is known about how LGN localization is regulated either by intrinsic or extrinsic cues. Cadherins are an essential class of cell-cell adhesions that maintain skin integrity at apical junctions through the formation of adherens junctions (AJ). Prototypical E-cadherin (Cdh1) has been proposed to influence the cortical localization of LGN by a direct interaction between its juxtamembrane-domain (JMD) and tetra-tricopeptide (TRP) motifs of LGN. A highly-conserved aspartic acid residue (D758) in the JMD is required for this interaction. While this residue is conserved in most other cadherins, P-cadherin (Cdh3) has a glycine substitution which should render it incapable of binding LGN. Indeed, we have found that Pcad and LGN are localized to mutually exclusive cortical domains in basal cells, while Ecad shows significant colocalization with LGN at the apical cell cortex. This suggests that both Ecad and Pcad may have different functions in regulating the localization of LGN. We find that epidermal Ecad loss increases the frequency of oblique divisions at the expense of perpendicular divisions, but interestingly, LGN expression appears to be unaffected. This suggests the effect of Ecad on spindle orientation may not be entirely mediated by LGN.

Adherens Junction Components Regulate Mitotic Spindle Orientation in Embryonic Epidermis.
K.J. Lough, K.M. Byrd, C. Patino-Descovich, D.C. Spitzer, A.J. Bergman, S.E. Williams;
1Genetics and Molecular Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Oral Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 3Cell Biology and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC, 4Pathology and Lab Medicine, University of North Carolina at Chapel Hill, Chapel Hill, NC

Adherens junctions (AJs) are cell-cell adhesion complexes consisting of transmembrane cadherins which link to the actin cytoskeleton via the catenins and associated scaffolding molecules. Cadherins form homodimers in trans and bind directly to the catenins via their cytoplasmic tail. In turn, α-catenin binds to tensile F-actin via its C-terminus, producing an open "loaded" conformation allowing for vinculin binding. In turn, vinculin binds additional actin filaments, theoretically increasing potential load. Previous studies have demonstrated that afadin, also an F-acting binding molecule, can bind α-catenin via a proximal region theoretically only exposed in the loaded conformation. Other studies have shown that afadin is essential for normal orientation of the mitotic spindle and capable of binding directly to the spindle orientation protein LGN. Interestingly, previous results have shown that α-catenin null mutants displayed abnormal spindle orientation in the epidermis. Taken together, these data suggest a role for components of the AJ in regulating proper orientation of the mitotic spindle either via a direct link to the spindle orientation machinery, or via maintenance of cortical, actin-dependent tension. The goal of this study is to investigate a link between numerous AJ components and mitotic spindle orientation and to elucidate the mechanism(s) governing previously observed mitotic phenotypes. Our data demonstrate that afadin, α-catenin, vinculin, and E-cadherin are all essential for normal spindle orientation in the embryonic mammalian epidermis. Surprisingly, loss of afadin or α-catenin does not perturb early apical recruitment or accumulation of LGN despite subtle effects on the upstream polarity cue, Par3. However, both afadin and α-catenin mutants demonstrate a novel mitotic phenotype where the spindle is unlinked from apical orientation cues specifically at the metaphase-anaphase transition. Furthermore, we were able to detect errors in the maturation of nascent adhesions in afadin mutant cell lines, in vitro. Of particular interest, it appears afadin is required for normal recruitment of vinculin to Tuesday-442
the AJ, loss of which reduces staining of the tension-dependent α18 epitope of α-catenin. Taken together, our data suggest adherens junctions regulate spindle orientaiton, in vivo, potentially by maintaining cortical tension or rigidity during the metaphase-anaphase transition.

Cardiomyocytes Assemble Force-Resilient Adherens Junctions through Vinculin and Afadin.
C.D. Merkel¹, Y. Li¹, Q.S. Raza¹, R.M. O'Dowd², A.V. Kwiatkowski¹;
¹Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

With every heartbeat, the junctional complexes that couple cardiomyocytes must transmit the mechanical forces of actomyosin contraction while maintaining adhesive homeostasis. Cardiomyocytes are linked end-to-end by intercalated discs (ICDs), specialized junctions that couple cell signaling, electrical and mechanical operations. The adherens junction (AJ) couples the actomyosin network to the ICD to provide structural integrity and mechanical continuity. However, little is known about how the actin cytoskeleton is linked to the ICD or how ICD AJs resist the mechanical forces of contraction to preserve tissue integrity.

The core of the AJ is the cadherin-catenin complex, and alpha-catenin is the primary link between the AJ and actin. In epithelia, the AJ senses and responds to mechanical force through tension-dependent changes in alpha-catenin conformation that reveal binding sites for actin-binding proteins like vinculin and afadin. To understand the AJ-actin interface at the ICD, we combined proteomics with confocal and electron microscopy to define the composition and architecture of AJs in mouse neonatal cardiomyocytes. We first used proximity biotinylation and mass spectrometry to identify proteins associated with the N-cadherin cytoplasmic tail along the ICD membrane. A number of alpha-catenin ligands were identified, including vinculin and afadin. Immunostaining revealed that both were recruited to myofibril integration sites at AJs in cardiomyocytes. Transmission electron microscopy revealed that myofibrils were coupled at chevron-shaped AJs, similar to junctions between mature cardiomyocytes in the heart and reminiscent of tension-bearing tricellular AJs in epithelia.

We postulated that vinculin and afadin were recruited to alpha-catenin to strengthen the AJ-actin interface at the ICD. To delineate roles of alpha-catenin, vinculin and afadin ligand recruitment and AJ stability, we built a series of EGFP-tagged N-cadherin:alpha-catenin fusion constructs. We found that vinculin and afadin were recruited independently to the N-cadherin:alpha-catenin fusions in a tension-dependent manner. Vinculin recruitment was sufficient to localize and stabilize N-cadherin at the ICD membrane in cardiomyocytes, suggesting that vinculin stabilizes the AJ at sites of myofibril integration. In contrast, afadin recruitment was sufficient to localize N-cadherin but did not promote N-cadherin stability, indicating that afadin alone cannot replace vinculin in linking AJs to myofibrils. We propose a model in which alpha-catenin, vinculin and afadin cooperate to form a force-resilient AJ that anchors myofibrils at the ICD membrane and establishes mechanical continuity between cardiomyocytes.

Talin is related to cadherin-mediated cell-cell adhesions through its direct-binding domains to catenins.
D.M. Patel1, W.M. Morgan1, F. Zhang1;
1Molecular Cellular Pharmacology, University of Miami, Miami, FL

Talin was molecularly considered to be exclusively involved in integrin-mediated adhesions between cells and matrix/cells. Our previous study found that a C-terminal region of talin resultant from a calpain proteolytic cleavage, called the VAD fragment, is located within cadherin-mediated cell-cell contacts and enhances this type of adhesion complex. However, it still remains unknown how talin, or its fragment, relates to the cadherin adhesion complex. In this study, by using immuno-coprecipitation and Mass Spectrometry, we found that the VAD fragment of talin has previously unknown binding capacities for beta- and alpha-catenins, which are well-established components within the cadherin complex. By using purified recombinant proteins, we confirmed that the VAD fragment of talin has direct binding affinities for both catenins. Furthermore, the presence of the VAD fragment appears to drastically enhance the interaction between alpha- and beta-catenins, which would explain the functional role of the VAD fragment in enhancing cadherin-based adhesions. Finally, by expressing smaller truncations of the VAD fragments fused with fluorescence proteins in mammalian cells, we found that several discreet domains are required for the localization of the fragment into the cadherin mediated adhesion sites. Our study is among the first to suggest that talin contains direct binding capacities to catenins, which may constitute a novel mechanism mediating the interaction between integrin- and cadherin-based adhesions.

E-cadherin mediated homotypic cell–cell interaction confers cytokine independence in human erythroleukemia.
S. Chakapalli1, M.C. Morris1, Z. Barati1, V. Cheriyath1;
1Biological and Environmental Sciences, Texas AM University–Commerce, Commerce, TX

Pure erythroid leukemia (PEL) is a rare and aggressive cancer (~3 months of average survival from diagnosis) with unknown etiology. Since cytokine signals control hematopoietic stem cell functions, we hypothesized that cytokine-independent survival and proliferation of erythroid progenitor cells is crucial for PEL development. To test this hypothesis, a novel cytokine-independent subline, UT-7/EI, was developed from erythropoietin (Epo)-dependent erythroleukemic progenitor cell line UT-7/Epo. The UT-7/EI cells survived without Epo and formed aggregates as they proliferated, suggesting augmented cell-cell adhesion. In agreement with this, differential gene expression profiling and network analysis uncovered the enrichment of E-cadherin (CDH1)-mediated homotypic cell-cell adhesion pathway in UT-7/EI cells. The upregulation of CDH1 mRNA and protein was further validated using qRT-PCR (6.5-fold relative to UT-7/Epo, p < 0.01) and immunoblot analysis. In confocal imaging studies, E-cadherin-β-catenin adhesion complexes were concentrated at adherence junctions of UT-7/EI cells. Moreover, calcium chelation abrogated cell-cell adhesion and induced the death of UT-7/EI cells. To further understand the role of CDH1 in cytokine-independent survival of UT-7/EI, its expression by Epo was investigated. Relative to untreated controls, Epo suppressed the expression of CDH1 in UT-7/EI cells at 24 hrs (4.3-fold), 48 hrs (16.7-fold), and 72 hrs (12.8-fold) with a corresponding increase in SNAIL2 expression (4.9-fold at 48 hrs), a repressor of CDH1 transcription (p < 0.01). Consequently, Epo abrogated the cell-cell adhesion of UT-7/EI cells without affecting their viability. These results suggest
that CDH1 and Epo-dependent survival pathways are mutually exclusive. In CFU-GEM assay, UT-7/E1 cells formed erythroblast-like colonies with positive heme staining and high CD36 expression (3.22-fold relative to UT-7/Epo, p ≤ 0.05), a marker of immature erythroblasts in PEL. In summary, our study identified a role for CDH1-mediated cell-cell adhesion pathway in developing cytokine-independence in PEL. Therefore, suppression of CDH1-mediated homotypic cell-cell adhesion may improve therapeutic outcomes in cytokine-independent PEL.

Analysis of biological networks with biomimetic microsystem platforms.
M.Y. Sun, K.J. Kruse, J. Klomp, F. Huang, P.N. Kanabar, M. Maienschein-Cline, Y.A. Komarova; 1Pharmacology, University of Illinois at Chicago College of Medicine, Chicago, IL, 2Research Resources Center, University of Illinois at Chicago, Chicago, IL

Post-translational modifications and nonsynonymous single nucleotide polymorphisms can significantly alter protein biological function and influence responses of individuals to pathogens, medications, and diseases. Understanding how small changes in protein composition influence specific communication with other proteins is of greatest importance for personalized medicine. Here, we describe a novel system approach for analysis of complex interactions within biological systems. Using His-tagged proteins covalently-linked to Ni-NTA beads as a biomimetic microsystem platform in combination with matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) followed by our enrichment pathway, we analyzed how phosphorylation of End Binding protein 3 (EB3) influences the protein complex formation and signaling networks in primary human endothelial cells. We found that this EB3 “phospho-switch” resulted in increased activation of the cell-cell adhesion pathways and decreased activation of the cell proliferative pathway. We propose this microsystem platform may be a valuable tool in identifying activation of different biological networks upon changes in protein structure, which can be found in disease states.

Differential Recruitment of Afadin and EPLIN to E-cadherin Adhesions.
V. Maruthamuthu, S. Chatterji; 1Mechanical Aerospace Engineering, Old Dominion University, Norfolk, VA

E-cadherin adhesions are essential for the dynamic events of morphogenesis as well as for the maintenance of the architecture of adult epithelial tissues. In epithelial tissues, E-cadherin from one cell binds to E-cadherin from the neighboring cell, couples to the actin cytoskeleton in each cell and transmits cell-generated actomyosin forces across the tissue. However, it does so at cell-cell interfaces that have multiple types of cell-cell adhesions molecules which may or may not influence E-cadherin function, depending on the context. To clearly delineate the function of E-cadherin adhesions alone in organizing the actin cytoskeleton, we created a biomimetic interface with oriented, immobilized E-cadherin ectodomains that supports the formation E-cadherin adhesions alone, with C2bb epithelial cells. In contrast to glass surfaces coated with randomly oriented E-cadherin ectodomains, this interface avoids the formation of other adhesions such as focal adhesions. We wanted to determine how certain key proteins implicated in linking E-cadherin to the actin cytoskeleton are localized at E-cadherin adhesions in the absence of other cell-cell adhesions. We found that afadin, which is a cytoplasmic partner of the nectin adhesion molecule, can be recruited to E-cadherin adhesions in the absence of
nectin based adhesions. In contrast, we found that EPLIN, which has been shown to link the E-cadherin-catenin complex to F-actin, did not concentrate at E-cadherin adhesions. Rather, it localized to actin filaments proximal to E-cadherin adhesions. These results show how different proteins that can constitute the E-cadherin-actin link can be differentially localized in the presence of just E-cadherin adhesions.

Septins regulate VE-cadherin – mediated junctional integrity of human endothelial monolayers.
J. Kim1, J. Cooper1;
1Biochemistry and Molecular Biophysics, Washington University St. Louis, St. Louis, MO

The junctional integrity of endothelial monolayers plays crucial roles in controlling transmigration of molecules and immune cells. Both scanning electron microscope (SEM) and transmission electron microscope (TEM) images of the junctions of human microvascular endothelial monolayers showed dynamic features of membrane, which suggested that membrane-associated proteins regulated junctional integrity. In this study, we demonstrated that Septin protein regulated VE-Cadherin-mediated junctional integrity. Immunofluorescence staining showed that septin2 was localized at the junctions of endothelial cell monolayers, yet was not co-localized with VE-Cadherin and actin filaments. Structured illumination microscope (SIM) super-resolution images showed curve and scallop-shaped polymer at the junctions, especially, at the regions where membrane dynamically protruded. Here, we have found that shRNA technique-mediated septin 2 suppression altered the arrangement of VE-Cadherin at the junctions and up-regulated expression levels of VE-Cadherin, which contributed to the reduction of transendothelial electric resistance (TEER) and transmigration event of immune cells. All together, we suggested that cytoskeletal protein, septin2 played an important role in junctional integrity of endothelial monolayers.

The interplay of WAVE-dependent branched actin and Cadherin junction components promotes Cadherin trafficking and junctional maturation.
S. Sasidharan1, S. Borinskaya1, M. Soto1;
1Department of Pathology, RWJMS-Rutgers University, Piscataway Township, NJ

Our lab studies embryonic morphogenesis in C. elegans. Our earlier work showed that branched actin, powered by the WAVE/SCAR and Arp2/3 complexes, promotes polarized events during epithelial tissue development. These events include epidermal cell migration during ventral enclosure, and the polarized formation of the embryonic intestine. The principal indicators of a fully polarized epithelial cell are apical junctions, which promote adhesion and communication between the cells. Actin is essential for cell polarity and is an integral component of the epithelial apical junction, yet the interactions of branched actin regulators with apical junction components are not completely clear. Conflicting findings have further raised questions on its role. It is widely accepted that branched actin contributes to the initial formation of apical junctions. However, only recently has the role of branched actin and its regulators in junctional maturation been established. The C.elegans Apical Junction (Ce AJ) contains independent complexes, the cadherin/catenin complex (CCC), and the DLG-1/AJM-1 complex (DAC).The C. elegans CCC is comprised of homologs of classical E-cadherin (HMR-1), α-catenin (HMP-1), β-catenin (HMP-2). In this study we address how branched actin regulators contribute to apical junction maturation. We have
used live imaging of C. elegans embryos and newly available CRISPR-tagged strains (from our lab and the Goldstein lab) to define the developmental time course of accumulation of apical junction components relative to the branched actin regulators WVE-1 and ARP-2/ARX-2 as the embryonic intestinal epithelium becomes polarized. Live imaging of WVE-1 and Cadherin components allow us to address how the WAVE complex and Cadherin components regulate each other to promote the development of the apical junction. Newly developed transgenic and endogenously tagged strains allow us to image intestinal apical actin enrichment in live embryos undergoing junction formation to clarify in a better way how the two main C. elegans apical junction complexes contribute to apical actin during development. Our FRAP studies suggest that WAVE contributes to Cadherin trafficking by regulating the dynamics of Cadherin turnover at the developing apical junction. Comparison of the WAVE effects on Cadherin dynamics to known trafficking components identifies a new role for WAVE dependent branched actin in Cadherin trafficking at the apical junction. Thus, in this study we propose a developmental model for junction formation where branched actin regulators are tightly interconnected with Cadherin junctions through their previously unappreciated role in Cadherin transport.

VE-PTP Scaffold Function in Adherens Junction Stabilization.
V. Juettner¹, Y. Komarova¹, D.E. Leckband², A. Dan²;
¹Pharmacology, University of Illinois at Chicago, Chicago, IL, ²Chemistry, University of Illinois at Urbana-Champaign, Urbana, IL

Vascular Endothelial Protein Tyrosine Phosphatase (VE-PTP) is an endothelial-specific phosphatase that dephosphorylates multiple proteins including Vascular Endothelial (VE)-cadherin, the main adhesion protein of the adherens junctions (AJ). However, the basal role of VE-PTP in stabilization of VE-cadherin adhesion complexes remains unclear. VE-cadherin establishes adhesion events through trans-interaction with opposing VE-cadherin molecules at AJs. In resting endothelial monolayers, it undergoes continues exchange between junctional and cytosolic pools. Using VE-cadherin tagged with the photoconvertable protein Dendra2, we have demonstrated that VE-PTP regulates basal VE-cadherin steady-state kinetics at AJs in a phosphatase-independent manner. Overexpression of wild-type (WT) or phosphatase “dead” VE-PTP mutant similarly decreased the VE-cadherin dissociation rate from AJs as compared to control cells expressing empty vector. In agreement with these results, VE-PTP depletion increased VE-cadherin dissociation rate. Because Rac1 stabilizes AJs by reducing mechanical tension across VE-cadherin adhesion, we analyzed junctional activity of Rac1 as well as the tension applied to VE-cadherin using respective FRET biosensors. We observed that overexpression of VE-PTP caused both Rac1 activation at AJs and reduction of tension across VE-cadherin adhesion, accompanied by an inhibition of RhoA activity. VE-PTP knockdown decreased Rac1 activity, increased RhoA activity, and increased tension/stress at AJs. Interestingly, binding partner studies indicate that VE-PTP binds to and inhibits GEF-H1, a RhoA activator. Further studies will elucidate the role of VE-PTP in endothelial barrier stabilization through GEF-H1 interaction.

TRIP6 inhibits the Hippo signaling pathway in response to tension at adherens junctions.
S. Dutta1, S. Mana-Capelli2, I. Dasgupta1, D. McCollum1;
1Biochemistry and Molecular Pharmacology, University of Massachusetts Medical School, Worcester, MA

The Hippo pathway regulates cell proliferation, contact inhibition, apoptosis, and stem cell maintenance and differentiation. The pathway responds to changes in the mechanical environment of the cell including tension across the tissue. Although tension is an important regulator of various cellular behaviors, how tension is sensed and the signal transduced to control Hippo pathway activity is unclear. The Hippo pathway kinases LATS1/2 regulate cellular responses to mechanical stimuli through the transcriptional co-activator YAP. Here, we show that the human LIM domain protein TRIP6 acts through LATS1/2 to regulate YAP activity and localization in response to tension at cell-cell junctions. TRIP6 binds directly to LATS1/2 and inhibits its activity. TRIP6 can inhibit LATS1/2 activation by competing with the LATS1/2 activator MOB1 for binding to LATS1/2. We show that TRIP6 recruits LATS1/2 to cell-cell junctions in response to tension. Conditions that reduce tension at cell junctions by inhibition of actin stress fibers (by treatment with actin or myosin disrupting drugs, serum starvation, or high cell density) block both TRIP6-LATS1/2 binding and localization to cell-cell junctions. In contrast, stretching cells stimulates recruitment of TRIP6 and LATS1/2 to adherens junctions. TRIP6 binds to the known tension responsive adherens junctions protein vinculin, and binding of TRIP6 to vinculin is also tension sensitive. Tension-dependent recruitment of TRIP6 to adherens junctions, TRIP6-LATS1/2 binding, and YAP activity all depend on vinculin. Together these results indicate that TRIP6 acts as part of a mechanical sensor at adherens junctions to mediate cellular responses to tension across tissues through control of the Hippo signaling pathway.

Alpha-T-catenin N-terminus functions with the M-region to regulate vinculin binding.
J.A. Heier1, S. Pokutta2, B. Weis2, A.V. Kwiatkowski3;
1Dept. of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA, 2Dept. of Structural Biology, Stanford University, Stanford, CA

Cardiomyocyte contractions place unique physical and regulatory demands on the protein complexes that join these cells together to form the heart. Cardiomyocytes are connected by intercalated discs (ICDs), specialized junctions that couple signaling and mechanical operations. The ICD comprises adherens junctions (AJs) and desmosomes that connect the actin and intermediate filament cytoskeletons, respectively, to the plasma membrane. The core of the AJ is the cadherin-beta-catenin complex, and alpha-catenin serves as the primary link between the complex and actin. Two alpha-catenin proteins are expressed in the mammalian heart, alpha-E(Epithelial)-catenin and alpha-T(Testes)-catenin. Mechanical tension regulates alpha-E-catenin conformation: actomyosin-generated force stretches the M(middle)-region to reveal binding sites for cytoskeletal proteins like vinculin. Intramolecular interactions maintain the alpha-E-catenin M-region in an autoinhibited state to limit vinculin binding in the absence of force. However, little is known about the molecular properties of alpha-T-catenin. Here we show that the alpha-T-catenin N-terminus cooperates with the M-region to regulate vinculin binding. Limited proteolysis experiments revealed that the alpha-T-catenin M-region adopts a more open conformation than alpha-E-catenin. Furthermore, isothermal titration calorimetry
(ITC) experiments showed that the alpha-T-catenin M-region binds vinculin D1 (N-terminus) with low nanomolar affinity, demonstrating that the alpha-T-catenin M-region is not autoinhibited. However, the alpha-T-catenin head domain (N-terminus plus M-region) binds vinculin approximately 1000-fold more weakly, suggesting that the N-terminus influences M-region binding to vinculin. The beta-catenin/N-cadherin complex binds alpha-T-catenin with a similar affinity to that of alpha-E-catenin but, notably, beta-catenin binding does not affect the interaction between alpha-T-catenin and vinculin. Finally, experiments in epithelial cells show that alpha-T-catenin can recruit vinculin to cell-cell contacts. Together, our results suggest that the N-terminus functions with the M-region of alpha-T-catenin to regulate vinculin binding. We postulate that the distinct molecular properties of the alpha-T-catenin M-region are optimized to meet the structural and mechanical demands of adhesion along the ICD membrane in cardiomyocytes.

**Evolutionary Rate Covariance (ERC) analysis identifies regulators of intercellular adhesion in Drosophila.**

Q.S. Raza¹, R. O’Dowd¹, Y. Hong¹, N.L. Clark², A.V. Kwiatkowski¹;
¹Dept. of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA; ²Dept. of Computational Systems Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Adherens junctions (AJs) are cadherin-based complexes that are required for cell-cell adhesion. It is critical to understand the genetic basis of these structures since their disruption is the primary cause of many developmental abnormalities and deadly diseases. Cadherins recruit the cytosolic catenin proteins p120-catenin, beta-catenin and alpha-catenin to form the core cadherin:catenin complex. Many secondary binding proteins, such as vinculin, afadin and ZO-1 have been identified in recent years as important catenin binding partners that regulate and stabilize AJs. Nevertheless, additional proteins may influence AJ biology. To identify genes that regulate AJ biology, we used a computational Evolutionary Rate Covariation (ERC) analysis screen to identify genetic components of the cadherin regulatory machinery. ERC relies on the principle that genes that function in common pathways and complexes have evolutionary rates that covary between species. ERC analysis has been used to identify novel gene functions in yeast, flies and mammals. We applied ERC analysis to generate a list of >100 genes with high ERC values relative to Drosophila shotgun (DE-cadherin). To test whether the identified genes function in cadherin-based adhesion, we used an in vivo RNAi-based knockdown approach in the Drosophila egg chamber to examine follicular epithelium (FE) organization and border cell (BC) migration. In the FE, we generated clones of RNAi expressing cells by using FRT/FLP recombination system in conjunction with GAL4-UAS expression system. Interestingly, knockdown of the candidate genes did not disrupt FE organization. It is possible that the AJs in this tissue are resilient to minor genetic perturbations induced by RNAi expression. Next, we used a silo-GAL4 construct to drive expression of RNAi specifically in the BCs. In contrast to FE, knockdown of multiple (18/35 tested) candidate genes caused either a delay in BC migration or disrupted BC cluster adhesion. BC migration and adhesion are cadherin-dependent, suggesting that these genes play a direct or indirect role in regulating AJs. Notably, mammalian orthologs of several identified genes – including CG16952 (Btbd7), CG42684 (Rasal2) and PDZ-GEF (Rapgef6) – have potential roles in AJ formation. For example, Btbd7 is a known nuclear repressor, which regulates E-Cadherin transcription and epithelial cell motility, and Rasal2 is a tumour suppressor with roles in epithelial to mesenchymal transition. Our results suggest that ERC analysis is an effective tool to identify components of the AJ complex in Drosophila. Our study also highlights the number of genes that converge together to regulate AJ-mediated intercellular adhesion.

Identification of cardiomyocyte adhesion complexes by proximity proteomics.

Y. Li¹, C.D. Merkel¹, X. Zeng¹, N. Yates¹, A.V. Kwiatkowski¹;
¹Dept. of Cell Biology, University of Pittsburgh School of Medicine, Pittsburgh, PA

Cell-cell adhesion is essential for tissue function and integrity. Cardiomyocytes possess a specialized adhesion architecture, the intercalated disc (ICD), adapted to withstand the forces of contraction. The ICD is composed of adherens junctions, desmosomes and gap junctions. Adherens junctions, through their direct linkage to actin cytoskeleton, transduce contractile force across neighboring cardiomyocytes. The core of the adherens junction is formed by the cadherin-catenin complex. N-cadherin is the classical cadherin expressed in cardiomyocytes; however, the proteins associated with the N-cadherin complex along the ICD membrane are largely unknown. We used biotin ligase-mediated proximity labeling and mass spectrometry to identify proteins in close proximity to the C-terminus of N-cadherin in mouse primary neonatal cardiomyocytes. We identified over 250 proteins. Approximately 120 are recognized components of the E-cadherin interactome in epithelial cells and 30 are known ICD proteins. Notably, more than 100 of the identified proteins are neither associated with the adherens junction in epithelia nor recognized at ICD proteins. Enrichment analysis suggested that these novel proteins are highly enriched in cardiovascular disease related proteins. Protein interaction networks constructed using known protein interactions provide a holistic view of cytoplasmic complex organization along the ICD. Our study is among the first to identify and resolve the proteins associated with N-cadherin at cardiomyocyte cell-cell contacts. We identified more than one hundred novel protein components of the adhesion complex, providing a proteomics-based reference for the adherens junction complex in cardiomyocytes.

Three-dimensional modeling of metastatic breast cancer dormancy using tunable PEG-based hydrogels.

S. Pradhan¹, J.H. Slater¹;
¹Department of Biomedical Engineering, University of Delaware, Newark, DE

Metastasis is the leading cause of breast cancer-related mortality, with only a few palliative treatment options available for patients. One of the major challenges of targeting metastatic disease is the presence of disseminated tumor cells (DTCs), that lie dormant in secondary organotropic niches within the body for extended periods of time. Specifically targeting these DTCs as an approach towards reducing metastatic outbreaks is difficult owing to their quiescent behavior, poorly understood cellular characteristics, and limits of clinical detection. Tumor dormancy is manifested in one of two ways: cellular dormancy (G0-G1 arrest) or dormant micrometastasis (angiogenic dormancy). Targeting the dominant mechanism determining metastatic breast tumor dormancy is of prime interest toward suppressing metastatic outbreaks and improving patient survival rates.

To establish an in vitro system for improved understanding, detection, and treatment of dormant breast cancer, we have developed a three-dimensional (3D) hydrogel culture platform for the recapitulation of key microenvironmental features of the dormant niche. In this study, we encapsulated MDA-MB-231
metastatic breast cancer cells within cell-responsive peptide-conjugated poly(ethylene glycol diacrylate) hydrogels and maintained them in 3D culture for 15 days. The hydrogel stiffness and cell-adhesiveness were modulated through the introduction of additional crosslinking polymer networks and cell-adhesive ligands to cover a wide range of extra-cellular matrix (ECM) characteristics. MDA-MB-231s encapsulated within these hydrogel matrices were investigated for viability (via Live/Dead staining), early-stage apoptosis (via Annexin V staining), and proliferation (via EdU staining) every 5 days post-encapsulation for a total of 15 days.

Our results indicate that cancer cell dormancy is dually dependent on cell-adhesiveness and matrix stiffness. Increasing stiffness leads to reduced proliferation but also increased apoptosis while increasing matrix adhesiveness leads to higher proliferation. The cell proliferation and viability were quantified to vary between 5-10% and 80-90% respectively under the tested conditions, thereby demonstrating that an optimum matrix formulation has been devised that restricts proliferation of cancer cells through cellular dormancy while still maintaining high viability in 3D culture. This platform is being further implemented to provide insight into the cellular and molecular characteristics of dormant breast cancer cells and to facilitate investigation of organotropite dormancy behavior that could aid in future cancer drug discovery initiatives.

Matrix malleability regulates cancer cell migration through confining microenvironments.
K.M. Wisdom1, K. Adebowale2, R. Desai3, L. Hodgson4, O. Chaudhuri1;
1Mechanical Engineering, Stanford University, Stanford, CA, 2Chemical Engineering, Stanford University, Stanford, CA, 3School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, 4Gruss-Lipper Biophotonics Center, Albert Einstein College of Medicine, Bronx, NY

Breast cancer cells must invade and migrate through basement membranes (BM) to metastasize during ductal carcinoma progression. Studies of cancer cell invasion and migration have shown that there are two modes: one that is protease-independent, involving cells squeezing through micron-sized pores, and one that is protease-dependent, involving cells biochemically degrading matrix with invadopodia protrusions. Invasion of the BM is thought to require protease degradation, due to its confining, nanometer-sized pores. However, many studies investigating how pore size limits invasion have utilized rigid or elastic pores. In contrast, many physiological tissues and extracellular matrices (ECM) are viscoelastic, with matrix able to flow in response to applied forces. Matrix flow can be plastic or irreversible, making the matrix “malleable”. Malleability can be related to matrix viscosity, but is distinct from matrix stiffness. Here, we show that matrix malleability enables invasion and migration of breast cancer cells through confining microenvironments. We developed a set of interpenetrating network (IPN) hydrogels for 3D culture in which malleability could be modulated independent of stiffness, and which were nanoporous, minimally degradable, and presented BM ligands. Strikingly, cells in high malleability IPNs exhibited spread morphologies and carried out protease-independent migration through the nanoporous IPNs, while cells in low malleability IPNs mostly stayed rounded and did not migrate. Mechanistically, cells in high malleability IPNs first extended invadopodia protrusions, identified by localization of cortactin and Tks5. Invadopodia exerted both protrusive and contractile forces to initiate invasion. Then, cells generated protrusive forces at the leading edge during migration, plastically opening channels in the matrix to migrate through. While the function of invadopodia was thought to be exclusively for ECM degradation, these results demonstrate an additional function of invadopodia is in generating force. These findings reveal a new mode of protease-independent migration, in which cells generate force to migrate through confining matrix if the matrix is sufficiently malleable.

Synergistic regulation of skeletal muscle maturation with sphingosine-1-phosphate and biomimetic matrix nanotopography.

J.H. Tsui\(^1\), K. Janebodin\(^{1,2,3}\), N. Ieronimakis\(^{1,3,4}\), D.M. Yama\(^1\), H.S. Yang\(^{1,5}\), R. Chavanachat\(^1\), H. Lee\(^6\), M. Reyes\(^{3,7}\), D.H. Kim\(^1\);

\(^1\)Bioengineering, University of Washington, Seattle, WA, \(^2\)Anatomy, Mahidol University, Bangkok, Thailand, \(^3\)Pathology, University of Washington, Seattle, WA, \(^4\)Clinical Investigation, Madigan Army Medical Center, Tacoma, WA, \(^5\)Nanobiomedical Science, Dankook University, Cheonan, Korea, \(^6\)Chemistry, KAIST, Daejeon, Korea, \(^7\)Pathology, Albert Einstein College of Medicine, Bronx, NY

Study Objective: We have developed an approach in which the benefits of biomimetic matrix nanotopography and sustained sphingosine-1-phosphate (S1P) signaling could be harnessed synergistically to induce the formation of structurally organized skeletal muscle tissues that are more mature.

Methods: Substrate Fabrication and Functionalization with S1P: Substrates were generated using a capillary force lithography (CFL) technique in which PLGA is nanopatterned with a mold applied with constant pressure and heat. For this study, substrates with 800 x 800 x 600 nm (groove width x ridge width x groove depth) feature sizes were used. Fabricated substrates were functionalized with S1P using 3,4-dihydroxy-L-phenylalanine (DOPA).

Cell Isolation and Culture: Mice were sacrificed 3 days after cardiotoxin-induced injury. Injured muscles were harvested under sterile conditions and digested tissue was passed through strainers to remove debris, muscle fibers, and multinucleated cells. Resulting mononuclear cells were then seeded onto each respective substrate and cultured for 10 days.

Results: Nanopatterned substrates induced a greater degree of structural organization in the form of aligned myotubes. These substrates also appeared to enhance the myogenic development of cultured progenitor cells, as a greater number of MHC+ myotubes were observed in the patterned environment. When coupled with S1P signaling, myogenesis and subsequent maturation was further enhanced. The expression of \textit{MyoD}, \textit{MyoG} and \textit{Myh15}, which are expressed in late-stage or terminally differentiated muscle cells, was greater in cells not only on patterned substrates, but also significantly in cells on substrates with 175 \(\mu\)M S1P. Experiments were conducted to determine whether the maturation observed as a result of the synergistic signaling from S1P and nanopatterning translated to improvements in myotube function. Myotube contraction displacement and velocity, as well as Ca\(^{2+}\) flux, was significantly increased in tissues cultured on nanopatterned substrates with 175 \(\mu\)M S1P. Flox-out of S1P receptor 1 in cultured cells resulted in a lack of S1P-mediated maturation, while nanotopographical guidance cues were still observed to exert an effect.

Conclusions: We have demonstrated that by harnessing signaling cues from both biomimetic nanotopography and S1P, it is possible to enhance the maturation and overall function of cultured skeletal muscle progenitors all without the need for incorporating multiple growth factors.

A contractile hoop stress aids in balancing sudden hydrostatic pressure perturbation in a tubular epithelium.
D. Maity\textsuperscript{1}, S.X. Sun\textsuperscript{1,2}, Y. Chen\textsuperscript{2};
\textsuperscript{1}Chemical and Biomolecular Engineering, Johns Hopkins University, Baltimore, MD, \textsuperscript{2}Mechanical Engineering, Johns Hopkins University, Baltimore, MD

Epithelium lines major organs where functional tubular structures consist of polarized and differentiated epithelial cells, such as endothelium lining the arterial walls and kidney proximal tubule epithelium. These epithelia are constantly subjected to hydrostatic pressure stresses which can result in ruptures. As seen in aging and inflammation, epithelium rupture imposes detrimental effects. Therefore it is important to understand how epithelium maintain homeostasis upon rapid changes in hydrostatic pressure that might result in ruptures.

We have developed a microfluidic device to investigate the response of epithelium to hydrostatic pressure changes. A mono-layered MDCK\textsubscript{II} epithelium lines a tubular channel in collagen (7mg/ml rat-tail Type-I) of diameters ranging from 75um to 150um. Via time-lapse imaging, the dynamics of the collagen channel with and without an epithelium were measured in response to varied hydrostatic pressure perturbations (~1kPa). A rapid increase in channel diameter was first detected because of the elasticity of the tissue, followed by the drop from the maximum to a constant value for a long period, dictated both by elasticity and permeability of the material. The dynamics can be modeled in terms of poro-elastic responses. Our hypothesis was tested in collagen gels formed at different gelation temperatures and cross-linking conditions. While the system without cells deformed by ~5\%, the epithelium deformed by ~2\% upon sudden increase in hydrostatic pressure. It was found that epithelium balances the effect of sudden perturbation by a contractile hoop stress. Theoretical modelling revealed that this constant hoop stress acts in a way that the outcome is an increment in the effective stiffness of the epithelial layer (previously reported to be ~10-20kPa) and that it exists in a pre-stressed condition. This suggests that the epithelium behaves in a non-linear regime even at low levels of perturbation as opposed to previous findings.

Quite intriguingly, upon perturbation by higher hydrostatic pressures(~2-5kPa), the tubular epithelium manifested identical responses as the collagen, suggesting the contractile hoop stress by epithelium is disrupted under such condition. In summary, we have devised a platform to simulate the tissue responses to hydrostatic perturbations and characterized the differential dynamic behaviors upon variable parameters.

T is for Tension: Micropatterns, Machine Learning, and the Role of the Microenvironment in Mesoderm Induction.
N.D. Rochman\textsuperscript{1}, Q. Smith\textsuperscript{1}, A.M. Carmo\textsuperscript{1}, D.K. Vig\textsuperscript{1}, S.X. Sun\textsuperscript{1}, S. Gerecht\textsuperscript{1};
\textsuperscript{1}Chemical and Biomolecular Engineering, The Johns Hopkins University, Baltimore, MD

Rapid advancements in stem cell biology over the past two decades have motivated exciting new directions in tissue engineering. As the possibility of tissue and complete organ culture in vitro moves closer to reality, the need for an efficient production of fully specified cell populations is moving to the fore. In contrast to the large body of literature uncovering a myriad of chemical cues which can be used to achieve efficient directed differentiation, there has been relatively little investigation into the role of
the mechanical microenvironment. In this work, we discuss the interplay between cytoskeletal tension and cell-cell contact during mesoderm induction. Decreasing cell density increases tension and we show that at early stages of mesoderm commitment, increasing tension increases Brachyury expression and thus differentiation efficiency. On the other hand, we show that without sufficient cell-cell contact, at late stages of mesoderm commitment there appears to be an absence of endothelial committed populations. Only in the unique microenvironment at the edge of small patterns do we find the balance of high cell-cell contact and high tension to generate both high differentiation efficiency and spatial organization. We go on to develop a learning algorithm used to predict which environments are likely to give rise to differentiated populations and those which may remain stem. Hopefully these predictions may be used to aide the design of new tools for directed differentiation.

Plasticity in cell migratory modes on orthotropic fiber architectures.
A. Jana\textsuperscript{4}, J. Singh\textsuperscript{3}, L. Singh\textsuperscript{1}, A. Franco\textsuperscript{3}, B. Behkam\textsuperscript{1}, A.S. Nain\textsuperscript{1};
\textsuperscript{1}Department of Mechanical Engineering, Virginia Polytechnic Institute and State University, Blacksburg, VA, \textsuperscript{2}Department of Biomedical Engineering and Mechanics, Virginia Polytechnic Institute and State University, Blacksburg, VA, \textsuperscript{3}Department of Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR

Cell migration is crucial in wound healing, organ development, tissue regeneration as well as pathological conditions such as cancer metastasis. It is now well appreciated that biophysical cues imposed by the fibrous extracellular matrix (ECM) immediately surrounding the cell regulate its migratory behavior. Cells migrate efficiently (high persistence over long distances) through the ECM by adopting a variety of shapes and motility mechanisms \((1, 2 \text{ and } 3D)\) as they squeeze, push or tug through the dense or sparse and aligned or random ECM in a process commonly referred to as plasticity. Cell migration \textit{in vitro} has been traditionally studied on 2D flat surfaces, and recently in 3D gels. These studies have highlighted the responsiveness and plasticity of cell migration to material stiffness, but lack the ability to capture the role of ECM fiber curvature, orientation, and organization on migration in a repeatable and controlled manner. Here, we demonstrate that crosshatch fiber networks of controlled inter-fiber unit cell spacing \((3,6,18,36 \text{ and } 54 \mu\text{m})\) regulates plasticity of the migratory phenotype \((1, 2 \text{ and } 3D)\) of metastatic thyroid cancer (Hras1) cells. Contrary to intuition, cells on dense networks \((3 \text{ and } 6 \mu\text{m})\) exhibit polarized migration in shapes as observed in 3D gels. At medium spacing \((18 \text{ and } 36 \mu\text{m})\), cells attain traditional 2D shapes of a broad leading edge and a narrow trailing edge, with the migration described by a diffusive random walk model. Finally, at large spacing \((54 \mu\text{m})\), cells attain stable non-migratory kite shapes at intersections or migratory spindle 1D shapes on suspended fibers in between the fiber intersections. Cells in dense networks have elongated morphologies (aspect ratio: \(5.5\pm0.2\)) and short focal adhesion cluster (FAC) lengths resulting in fastest migration. The migration speed decreases with increasing scaffold porosity due to longer FAC lengths (FAC length: \(5\pm0.4, 3.8\pm0.2, 7.7\pm0.3, 12.9\pm1.4, 15\pm0.8 \mu\text{m}\) and Speed: \(46.9\pm4.6, 41.7\pm2.8, 33\pm2.7, 31\pm2.3, 25.3\pm1.5 \mu\text{m}/h\) on 3, 6, 18, 36 and 54 \(\mu\text{m}\) respectively). This consequently affects the dynamics of migration, as wider spacing networks favor a distinctive \textit{recoil} of the trailing edge, which causes the nucleus to undergo rapid deformation followed by a gradual relaxation. Thus, faster relaxation times of the nucleus are recorded in cells moving on dense networks, thereby indicating potentially softer cell bodies, which is generally considered a biophysical marker for enhanced metastatic potential. Taken altogether, our approach of precisely controlling fiber diameter and spacing provides new means to study plasticity in cell migration and notably for the first time shows that anisotropic substrates are not the ‘only’ requirement for achieving persistent cell migration.

Penetrability of Prostate Tumor Cells Grown in 3D Culture by Prostate Targeting Agents.
T.C. Anderson¹, E.A. Pattie², N.A. Omar³, N.M. Rasid¹, J. Fung¹, R.L. Walden², F. Griessel³, I.M. Evans¹;¹GSOLS, Rochester Institute of Technology, Rochester, NY

Properly modeling tumor anatomy remains an issue in understanding aspects of cancer, such as metastatic potential, and in designing agents which effectively penetrate the tumor mass. Objective: The purpose of this project is to develop tissue culture methods which allow tumor cells to grow as a 3D tumor mass rather than as a flat 2D culture. Methods: Culturing via cellular matrices such as Matrigel allows the ability to culture cancer cells into spheroids, which model better a tumor’s anatomy. Results: Such culture methods allow for the testing of Targeted Molecular Imaging Agents (TMIAs) which bind to specific biomarkers on the cancer cells allowing measurement of the number of biomarker molecules on a tumor cell and testing the TMIAs' penetrability. The localization of our TMIAs, A1 and B1, which are bound to the dye Cy5.5, was tested on the prostate cancer line C4-2 which overexpresses the marker prostate specific membrane antigen (PSMA). 3D culturing and spheroid formation of the line was achieved by changing the Matrigel concentration. The cell line PC-3 (PSMA-) was used for the negative control to demonstrate specificity of the TMIA. Conclusion: It was demonstrated that the TMIAs were able to penetrate the internal cells of the spheroids and bind to the PSMA molecules on the surface of the cells. This may allow the TMIAs to be effective in various applications including treatment and in-vivo tumor imaging. Determining the binding of TMIAs to target cancer cells should facilitate the development of TMIAs and result in molecules which target to metastatic tumors illuminating their presence, size, and structure thus allowing better clinical treatment and hopefully enhanced cancer survival.

Cell-cell adhesion and myosin activity controls the curvature-dependent cortical actin assembly in mammary gland epithelium.
W. Jung², K. Elawad², S.H. Kang¹, Y. Chen¹;¹Mechanical Engineering, Johns Hopkins University, Baltimore, MD

It has been demonstrated in recent studies that geometry might play an important role in cell behaviors, ranging from mucus production, cell migration and the origination and prorogation of cancer stem cells. Despite the studies on potentially curvature-sensitive proteins at the nanoscale, it is not clear how cells sense curvature and other geometric parameters at cellular and multi-cellular-level. To systematically study whether and how curvature determines cell behaviors, we developed a technique combining 3D printing and soft lithography to fabricate open channels with radii ranging from 40µm to 90µm. We examined various protein expression levels of mouse mammary epithelial cells EPH4-EV cells at different curvatures. EPH4-EV cells are used to simulate the formation of mammary gland epithelium, which has been observed previously to exhibit differential phenotypes depending on the local geometry of the mammary ducts. We found that cortical actin is 1.3-fold more enriched in cells grown on curvature of 1/60µm and 1.5 fold more enriched in 1/40µm when compared to curvature of 1/90µm. Inhibiting myosin phosphorylation via blebbstatin restored the cortical actin formation in cells cultured in channels of high curvatures, implying myosin is involved in curvature-dependent cortical actin assembly. Furthermore, it was also observed that cell-cell contact is required in the curvature-dependent cortical
actin assembly. The prominent cortical actin assembly usually seen at 1/40μm and 1/60μm was not
detected when the cell seeding density resulting in sparse cell-cell contact. Our finding suggests myosin-
mediated cortical actin assembly might be a length scale-appropriate machinery for curvature sensing at
the multi-cellular level.

Maskless Quantitative Multi-protein Photopatterning to orchestrate cellular microenvironment.
L. Bonnemay1, M. Opitz1, J. Ruaudel1, N. Ziane1, P. Strale1;
1ALVEOLE, Paris, France

Cell biology is faced with significant challenges when attempting to create complex microenvironments
to unravel intricate mechanisms involved in cell adhesion, cell polarity, cell migration etc... These
challenges can be overcome by molecular printing which involves the controlled deposition of molecules
on a substrate at the micrometer scale. These approaches have developed tremendously in the past few
years and micropatterned substrates are now routinely used for biological research. To yield biologically
relevant data, printed biomolecules should mimic the complexity of the in vivo microenvironment.
Micrometer-scale gradients of multiple proteins are thus highly desirable. Here we present a maskless
quantitative multi-protein photopatterning solution which is based on the light-induced molecular
adsorption of proteins (LIMAP) technology. This system combines a UV illumination module and a
specific photoactivatable reagent (PLPP). The combined action of UV-light and PLPP locally degrades
antifouling polymer brushes allowing for the adsorption of proteins in a well-defined area. PRIMO relies
on a wide-field DMD-based projection system coupled to an epifluorescence microscope to project
custom-defined patterns of UV light onto a cell culture surface. As a result, micrometer scale patterns
are generated within seconds. The remaining background allows for the sequential patterning of
multiple proteins. Controlled protein gradients of custom-defined shape can also be patterned. In
addition, PRIMO technology allows micro-manufacturing by photopolymerization of UV-sensitive
materials and protein patterning onto pre-existing 3D surfaces.
This technology empowers biomedical research in neurobiology, immunology, stem cell biology,
oncology and tissue engineering.

New approach to forming embryoid bodies of ES cells by using Low Adhesive Scaffold Collagen.
S. Kunii1, Y. Ohnuki2, K. Morimoto1;
1Genetic Engineering, Kindai University, Kinokawa, Japan, 2Biotechnology, University of Yamanashi, Kofu,
Japan

[Objective] Embryonic stem (ES) cells are having an ability to differentiate and proliferate. That is, it has
the feature of propagating (self-replicating) while retaining the ability (pluripotency) to differentiate into
any cell constituting the tissue of the body. Generally, ES cells form planar colonies in maintenance
culture with or without feeder cells. On the other hand, when ES cells are differentiated into tissue cells,
cell aggregates called as embryoid bodies (EB) are formed. These days, we succeeded in developing low
adhesive scaffold collagen (LASCol, patent pending). On LASCol-coated dish, cells form spheroid. In this
study, we report that ES cells spontaneously form EB weakly adherent to LASCol. [Methods] Two types
of culture dish, coated with LASCol or gelatin, were used. Mouse ES cells were cultured on each coat
dish in which feeder cells were previously cultured. GFP fluorescence observation was used to
distinguish ES cells from feeder cells. To evaluate undifferentiated potential, we examined the alkaline phosphatase (ALP) activity of the ES cells and the mRNA expression levels of undifferentiation-related genes (Oct-4 and Nanog). The motility of EB was monitored by time-lapse observation with a microscope. [Results] Feeder cells and ES cells independently adhered to LASCol, and ES cells collided each other one after another and got to form EB with well maintaining ALP activity. No feeder cells existed in EB, and besides, ES cells on LASCol formed EB even without feeder cells. We confirmed that the undifferentiation potency of ES cells on LASCol was kept as similarly as gelatin-coated dish culture. [Summary and Conclusions] We demonstrated that LASCol has the ability to form embryoid bodies of ES cells and to maintain undifferentiated potential. [Funding] This work was supported by the Adaptable and Seamless Technology Transfer Program through target-driven R&D, AMED (AS2414037P to K.M.) and JST (AS2715177U to K.M.).

Development, regeneration and cancer involve changes in cell mechanical properties that lead to drastic transitions in tissue geometry and dimensionality. Given the fluid nature of living tissues, these transitions have been experimentally studied and theoretically modelled in terms of the physics of wetting phenomena, which describes how a fluid droplet spreads on a solid surface. However, physical forces, the effective determinants of tissue spreading, have never been measured in the context of tissue wetting. Here we perform a systematic study of tissue mechanics during epithelial wetting/dewetting. We induce a progressive expression of E-cadherin in a confined monolayer of MDA-MB-231 cells and, simultaneously, we measure tissue forces using Traction Force Microscopy and Monolayer Stress Microscopy. The gradual formation of intercellular junctions produces a continuous increase in tissue contractility (pMLC), triggering a two-fold increase in tissue forces that ends up in a spontaneous wetting-dewetting transition. To understand how this transition arises from tissue active properties, we develop a wetting model based on active gels theory. Combining theory and experiments, we find that wetting-dewetting transition results from a competition between contractility and traction forces, which introduces a new length scale, defining a critical size for tissue wetting. Strikingly, this implies that the critical tissue contractility driving the transition is dependent on tissue size, a phenomenon that has no counterpart in passive wetting/dewetting physics. Furthermore, we find that the critical tractions, which depend linearly on substrate ligand density, are the mechanical threshold for tissue spreading. Finally, we show that long-wavelength morphological instabilities in our fluid interface, together with active fluctuations, explain tissue shape dynamics during dewetting. We conclude that tissue spreading can be understood as an active wetting transition of a viscous polar fluid.

Developing Tunable Bioink for Versatile 3D Bioprinting.
K. Elawad1, W. Jung2, S.H. Kang3, Y. Chen2;
1Materials Science and Engineering, Johns Hopkins University, Baltimore, MD, 2Mechanical Engineering, Johns Hopkins University, Baltimore, MD

With the advances in instrumentation, 3D bioprinting technology has matured over the years for potential applications that require high precision in cell placement and geometry. For instance, in order to study cell migration, tissue repair, and tumor progression at physiological conditions, it is desirable to print organoids in mimicry of the in vivo tissue conditions. However, currently available bioinks lack the tenability in adjusting mechanical properties such as stiffness and porosity to represent in vivo conditions. We have developed biocompatible and tunable alginate-based bioink for in vitro tissue printing. By adjusting the concentration, gelling, and crosslinking conditions of the alginate/gelatin composite bioink, it can be used for direct ink writing to produce printed tissues at a 500 micron scale. The bioink is extruded from the printing head to form 3D geometries as supportive scaffolds for 3D cell culture. Gelatin is used as a rheological modifier to enhance the printability of the alginate ink. Complex, tissue-like 3D architectures can be achieved by embedding multiple cell types in our bioink. We also verified that fibroblasts were able to stay viable and replicate during a 7-day incubation period. In summary, our bioink is biocompatible, mechanically tunable and can form stable structures for 3D bioprinting. It is suitable to be used in organoid fabrication where physiological biophysical microenvironments can be recreated faithfully.

Tumor metastasis is limited by the ability of cells to survive varying microenvironmental stresses. Metastatic cancer cells encounter heterogeneous two dimensional (2D) or three dimensional (3D) extracellular matrix (ECM) landscapes with variable biophysical properties. Here, we interrogated the role of ECM dimensionality in cell behavior. We employed compliant polyacrylamide gels conjugated with defined ECMs to recapitulate ECM landscapes and interrogated the cellular biophysical and biochemical response to these parameters. We found that non-spread premalignant mammary epithelial cells (MECs) plated on compliant 2D polyacrylamide gels underwent apoptosis, whereas non-spread cells survive when overlaid with laminin. Traction force microscopy, atomic force microscopy
indentation, and laser ablation studies revealed that MECs encountering a 3D ECM have reduced cortical tension. Computational modeling predicted that such drop in cortical tension should lead to an increase in the number and/or residence time of actin protrusions. To test the prediction, we ectopically expressed F-actin and plasma membrane markers (GFP-tagged F-tractin and farnesylated mcherry, respectively) in MECs to examine the plasma membrane topography and actin protrusion dynamics. Indeed, MECs in 3D ECM had longer and more stable actin protrusions. The computational model also predicted that these protrusions should increase the area of negative curvature, which recruit proteins that induce or sense negative membrane curvature. Because non-spread MECs survive in 3D ECM and have more negative membrane curvature, we speculated that negative curvature associating proteins may lead to the activation of pro-survival pathways. Consistent with the prediction, MECs interacting with a 3D ECM had higher Arf6 activity and increased its downstream pro-survival Rac/p38 signaling. Loss and gain of function studies also revealed that Rac/p38 signaling promotes MEC survival in a 3D ECM. Moreover, knockdown of key Arf6 GEFs or reducing levels of negative curvature-inducing protein Exo70 compromised MEC survival in a 3D ECM, while loss of Arf6 GAPs enhanced the survival of non-spread MECs in 2D. Importantly, reducing cortical tension of non-spread MECs on a 2D ECM through myosin inhibition promoted negative curvature in MECs as well as cell survival. Our results provide the first evidence demonstrating that ECM dimensionality alters the biophysical properties of cells to modulate an Arf6/Rac/p38 pro-survival signaling axis.

PC3 cells deterministic immobilization on biochemically-patterned slides by micro-contact printing - Effect of the patterns shapes, size and pitch
M. Schneider1, J. Chevrier1, J. Cau1, A. Lagraulet2, E. Trévisiol3, M. Blatche3, C. Vieu4,5,6;
1INNOPSYS Inc., Chicago, IL, 2INNOPSYS, Carbonne, France, 3LAAS, CNRS, Toulouse, France, 4Université de Toulouse, Toulouse, France, 5INSA, Toulouse, France, 6LAAS, Biosoft-CNRS, Toulouse, France

Microstructured cell immobilization has been shown to be a useful tool in different areas of cell biology such as neuron motility, cell signaling responses facing physical stress, cell migration and the study of cell behavior under different extracellular matrix protein composition, etc. The micro-contact printing of extracellular matrix proteins on conventional glass slides or coverslips turned out to be an efficient method to fabricate micropatterned cell culture substrates. Automated printing by the InnoStamp40 is a powerful tool to control the stamping parameters and obtain reproducible patterns of different shapes, sizes and pitches. Here we present a dedicated study in which different pattern sizes and gaps for the deterministic immobilization of PC3 prostate cancer cells were screened. Automated microcontact printing was used to create microstructured slides with four different feature types with different sizes and gaps. The spreading of the immobilized cells on the different patterns and the selectivity of the immobilization on the adhesive patterns were monitored in comparison to the antifouling background. We found that the number of immobilized cells per pattern decreased in direct correlation with its size and independently of its shape. Patterns with a pitch larger than 50µm did not present any junction between them, while for smaller pitches, some cells immobilized between the patterns creating a junction. The optimal parameters to create microstructured cell arrays with different pattern types are presented.

Programmable viscoelastic matrices from artificial proteins.
L.J. Dooling1, D.A. Tirrell2;
1Division of Chemistry and Chemical Engineering, California Institute of Technology, Pasadena, CA

Extracellular matrix compliance influences cellular adhesion and migration, proliferation and apoptosis, and differentiation. Much of our current knowledge of the effects of substrate stiffness on cellular behavior is based on elastic substrates, in particular cross-linked polyacrylamide hydrogels. Biological tissues, however, are viscoelastic and exhibit stress relaxation and energy dissipation on physiologically relevant timescales. While emerging evidence suggests that these physical properties also influence cellular behavior, materials in which viscoelasticity can be precisely engineered are currently lacking. Here, we describe programmable hydrogel matrices assembled from artificial recombinant proteins designed to be cross-linked by covalent bonds involving cysteine residues, by association of helical domains as coiled coils, or by both mechanisms. Using these proteins, we construct chemical, physical, and chemical-physical hydrogel networks that deform elastically or viscoelastically depending on the type of cross-linking (Dooling et al., Adv. Mater., 2016, 28, 4651–4657). In viscoelastic networks, the amount of stress relaxation is tuned by controlling the ratio of physical cross-linking to chemical cross-linking, and the timescale for stress relaxation is tuned over five orders of magnitude by single point mutations to the coiled-coil physical cross-linking domain (Dooling and Tirrell, ACS Cent. Sci., 2016, 2, 812–819). The genetic engineering approach also allows biological activity to be encoded directly within the protein sequence in the form of cell-adhesive domains and proteolytic cleavage sites. The capacity to program the viscoelasticity and biological activity of hydrogel matrices is anticipated to have applications in studying and engineering cell-matrix interactions.

Subcellular localization, uptake and dynamics of inorganic polyphosphate in mammalian cells.
L. Xie1, U. Jakob1;
1Molecular, Cellular and Developmental Biology, University of Michigan, Ann Arbor, MI

Inorganic polyphosphate (polyP), a linear chain of 3 to over 100 orthophosphates, is a highly conserved and universal molecule found in all species tested. Yet, unlike in bacteria where its biosynthetic pathway has been well characterized, little is known about polyP metabolism in mammals. This is largely due to a lack of feasible tools for detection and manipulation. Here we utilize a specific probe called MBP- EcPPXc (a fusion protein of maltose binding protein and the polyP binding domain of E. coli exopolyphosphatase) to monitor subcellular localization and dynamics of polyP by immunofluorescence. In several cell culture models including HeLa cells and primary human fibroblasts, we observed endogenous polyP in the nucleus (with enrichment in the nucleolus), plasma membrane and distinct foci in the cytoplasm. By using exogenously applied polyP300 chains labeled with Alexa Fluor 647 (polyP300 - AF647), we furthermore discovered that cells are able to rapidly take up polyP from the environment through endocytosis. This finding enables us to increase cellular polyP level under normal culture condition, and offers the unique opportunity to reveal the physiological function of polyP in mammalian cells. Finally, we observed a massive increase of polyP in response to hypochlorous acid (HOCl) treatment, the first known induction of polyP synthesis in mammalian cells. Taken together, we have
now established the tools that will finally allow us to uncover the physiological roles of this enigmatic polymer in mammalian systems.

**Exploring compartment-specific protein disaggregases to combat neurodegenerative diseases.**
R.R. Cupó1, J. Shorter2;
1Pharmacology Graduate Group, University of Pennsylvania, Philadelphia, PA, 2Department of Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA

Protein aggregates accumulate in several neurodegenerative diseases. Protein disaggregases have great therapeutic potential as they can reverse toxicity caused by protein aggregates and soluble oligomers by disassembling these structures and recovering natively-folded proteins. The yeast protein disaggregate, Hsp104, disassembles disease-associated protein aggregates and soluble oligomers to suppress toxicity. Hsp104 has a yeast mitochondrial homologue, namely Hsp78. I targeted mitochondrial (mt) Hsp78 (mtHsp78) to the cytoplasm (cHsp78) and potentiated its activity via homologous mutations that nonselectively potentiated Hsp104. Three cHsp78 variants selectively rescue α-synuclein (αSyn), FUS, or TDP-43 toxicity in yeast. Three different mtHsp78 variants rescue αSyn toxicity in yeast without affecting cytoplasmic αSyn aggregation. We are exploring the mechanism of rescue for each of these variants. The results presented here will help to further our understanding of the demands of compartment- and substrate-specific protein disaggregate activity.

**Small HSP αB-Crystallin is a hydrolyzed eggshell membrane-response chaperone and keeps hydration of epidermis keratinocyte through the interaction of lipid membrane regulator-acid sphingomyelinase.**
Y. Atomi1, M. Shimizu1, E. Fujita1, A. Atomi1, T. Mizutani2, J. Masaki2, Y. Hasebe3;
1material health science, Tokyo university of agriculture and technology, Tokyo, Japan, 2bioscience and biotechnology, Tokyo university of Technology, Tokyo, Japan, 3Almado inc., Tokyo, Japan

Small Heat Shock Protein alphaB-crystallin (αB) has various essential biological roles not only to protect cells from apoptosis but also improve function of differentiated tissues that constitutively receive stresses like mechanical stress on slow-twitch muscle (Atomi et al., 1991) and heart (Pereira et al., 2014), and light on lens. Present study is intended to address interesting and important relation of molecular chaperone αB and solubilized eggshell membrane (ESM) and was succeeded in adding ESM beneficial effect of increased hydration on epidermal keratinocytes as well as dermal fibroblasts previously reported (Ohoto-Fujita et al., 2011). Recently we show that αB, chaperone for tubulin/microtubule controls shape and adhesion of glioma and myoblast cells in the absence of stress (Shimizu et al., 2016) through its chaperone-like activity (Ohoto-Fujita 2007). Both significant increased hydration of the arm skin and decreased wrinkles of the face after ESM-2-weeks-topical applications for women were associated with significant increased SMPD-1 gene expression encoding acid sphingomyelinase that produces ceramide by hydrolyzing sphingomyelin after 10 days-application on hairless mice skin. To know the mechanism of epidermis hydration by ESM, 1 to 10 (w/v) % of ESM was applied to a dispase II separated epidermis from dermis and human embryonic keratinocyte, and fixed after various time points, and the localization of αB, ceramide, and acidic SMase (aSMase) were analyzed. αB colocalized with membrane associated aSMase that produces ceramide. Co-

*POSTER PRESENTATIONS-TUESDAY*

*Tuesday-461*
immunoprecipitation of αB and aSMase was observed in mouse epidermis homogenate. αB highly expresses in muscle and lens, whereas the expression level is different depending on activity properties like long-lasting contraction and reception of stresses. Cells in such tissues are required “endurance”, which results in long-lasting higher calcium level, which needs special endoplasmic/sarcoplasmic reticulum calcium channel (shown in slow skeletal and heart muscles), and also long-lasting suppliable energy source lipid, of which metabolism needs mitochondria. Although exact reason is not known, recently sHSPs was found to be the most important protein for keeping proteostasis linked to longevity. αB has been thought to be a cytosolic chaperone supporting structural regulation of cytoskeleton, however now considered as chaperone for ER and also mitochondrial stresses, both are the matter of lipid membrane. The present study offers another role of αB, regulating membrane dynamics probably related to tubulin/microtubule cytoskeleton dynamics, contributing to anti-apoptosis effect against constitutively receiving stresses like gravity, light and dehydration and convert them to beneficial stimuli for adaptation.

Endoplasmic reticulum morphology serves as predictor for stress severity.
L. Wünsche1, A.R. Nair1, K.C. Sadler1;
1Biology Department, New York University Abu Dhabi, Abu Dhabi, United Arab Emirates

The Unfolded Protein Response (UPR) serves to counteract the accumulation of proteins in the Endoplasmic Reticulum (ER) during stress. The initial phases of the UPR adapt cells to ER stress, but chronic UPR activation can lead to cell dysfunction and pathology. Our work using gene expression analysis uncovered a distinct UPR, activated in the liver of zebrafish and humans, that correlates with the accumulation of lipid in hepatocytes (fatty liver). We reasoned that ER morphology alterations would occur during an adaptive phase of the UPR, prior to gene expression changes in response to disease, and asked whether it could indicate an early stress response. We tested this utilizing intravital confocal imaging of 5 days post fertilization (dpf) old transgenic zebrafish expressing an ER-marker in hepatocytes (Tg(fabp10:ER-tdTomato)). Tunicamycin, a well-established ER-stressor causing fatty liver, induced dramatic changes in the ER marker from a reticular pattern to motile punctae first observable by 12 hours of tunicamycin treatment. At 24 hours exposure 80% of the livers contained punctae. To identify the nature and origin of these structures, we tested their co-localization with the trans Golgi apparatus using a transgenic marker (Tg(bact2:Galt-GFP)) and with acidic compartments using Lysotracker. We found no co-localization with the Golgi-marker, but Lysotracker co-stained and was present in 63% of the larvae by 12 hours of tunicamycin treatment compared to 6% of livers in untreated controls. We hypothesize that this represents the activation of ER-phagy to mitigate severe ER stress and suggests that markers of ER-phagy indicate the organisms most prone to disease. Our preliminary data shows that UPR target genes are upregulated in livers from tunicamycin treated larvae with multiple punctae per hepatocyte, compared to those with milder phenotypes. These findings suggest that ER morphology may be prognostic for identifying stressed and disease prone cells.

Suppressing Aβ toxicity with potentiated Hsp104 variants in a yeast model of Alzheimer’s disease.
S. Sudesh1, K.L. Mack1, J. Stillman1, E. Griffin7, K.A. Caldwell2, G.A. Caldwell2, J. Shorter3;
1Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA, 2Biological Sciences, University of Alabama, Tuscaloosa, AL

As the sixth leading cause of death, Alzheimer’s disease (AD) continues to be an intractable public health issue. 5.3 million Americans suffer from the declines in memory, cognition, and behavior characteristic of the disease. AD is currently incurable and unpreventable. Research has shown AD is linked to the formation of cytoplasmic neurofibrillary tangles (NFTs) and extracellular senile plaques (SPs) in the brain1. NFTs are comprised of tau protein2 and SPs are comprised predominantly of amyloid beta peptides (Aβ) of amino-acid length 40 (Aβ40), 42 (Aβ42) and 43 (Aβ43)3. The amyloid cascade hypothesis proposes that AD is fundamentally caused by the accumulation of misfolded Aβ oligomers, which can form highly ordered plaques in brain regions with severe neurodegeneration. One therapeutic strategy is to target amyloid fibrils and toxic oligomers for disaggregation. Hsp104, a protein disaggregase found in yeast, has been previously engineered to display potentiated activity against other proteins such as α-synuclein, TDP-43, and FUS4, aggregates of which underpin Parkinson’s disease, amyotrophic lateral sclerosis, and frontotemporal dementia. Here, we show that some of these engineered Hsp104 variants rescue the toxicity of Aβ42 and Aβ43 in a powerful yeast model of AD5, which has revealed important risk factors for AD in humans. Remarkably, several enhanced Hsp104 variants also rescue Aβ42 toxicity in the context of the metazoan nervous system in C. elegans6. We further assessed the activity of these Hsp104 variants in yeast when they are targeted through the secretory pathway alongside Aβ42. Curiously, we found that the enhanced Hsp104 variants exhibit off-target toxicity when they are targeted to the secretory pathway and fail to rescue Aβ42 toxicity.

Engineering Potentiated Hsp70 Variants to Combat Neurodegeneration.
I. Subudhi1, J. Ramirez1, J. Shorter1;
1Biochemistry and Biophysics, University of Pennsylvania, Philadelphia, PA

When proteins become misfolded, they can form prions, amyloids, amorphous aggregates, and toxic oligomers, which have been implicated in aging and neurodegenerative diseases such as Parkinson’s
disease (PD), Alzheimer's disease (AD), and amyotrophic lateral sclerosis (ALS). Protein-misfolding processes are remediated by the metazoan disaggregase system (MDS), which may become overwhelmed under these disease states. Here, we present our work on engineering Heat Shock Protein 70 (Hsp70), a component of the MDS, to counter toxic protein-misfolding events. We utilize yeast as a high-throughput and facile proteinopathy model to study the mechanism of these engineered Hsp70 variants against the PD-linked protein, alpha synuclein, and the ALS-linked proteins, TDP-43 and FUS. Through this model, several Hsp70 variants have been identified with the capacity to selectively rescue PD- and ALS-linked proteotoxicity. This work will contribute to our understanding of how we can therapeutically engineer human Hsp70s to combat protein misfolding implicated in neurodegenerative diseases.

The Ribosome-Associated Complex Suppresses [PSI+] Prion Formation in Yeast.
C. Kelly1, T. Tessitore1, J. Taddeo1, D.M. Cameron1;
1Department of Biology, Ursinus College, Collegeville, PA

Prions are self-propagating infectious protein conformations. In mammals, prions underlie the transmissible spongiform encephalopathies, a set of invariably fatal neurodegenerative disorders associated with misfolding of the mammalian prion protein, PrP. In recent years, increasing numbers of fungal proteins capable of infectiously propagating altered conformations have been discovered. Multiple yeast prions can produce beneficial phenotypes resulting in increased fitness in the presence of stressors, possibly by serving as epigenetic switches that can rapidly confer beneficial heritable phenotypes. To gain critical insight into the mechanisms by which cells regulate prion formation, propagation and toxicity, we examined the role of the ribosome-associated complex (RAC) chaperones in the formation and toxicity of the [PSI+] prion in yeast. The [PSI+] prion results from a self-propagating amyloid form of the essential translation termination factor Sup35, and is manifested phenotypically as elevated levels of nonsense suppression. The RAC consists of the Hsp70 chaperone Ssz1 and the Hsp40 chaperone Zuo1, which anchors the complex onto ribosomes and stimulates the ATPase activity of the Hsp70 chaperone Ssb. Previous work in the lab has shown that yeast cells lacking Zuo1, and thus lacking RAC function on ribosomes, exhibit higher frequencies of spontaneous and induced [PSI+] formation. Cells expressing variants of Zuo1 that are unable to associate with ribosomes, or that are unable to stimulate Ssb ATPase activity, exhibit similarly high levels of prion formation. These findings are consistent with a role for the RAC in chaperoning nascent Sup35 to prevent misfolding of the N-terminal prion domain as it emerges from the ribosome. An alternative role for Zuo1 is its ability to function as a transcriptional co-activator for the pleiotropic drug resistance pathway, which enhances resistance to various drugs and environmental toxins. Its role in this pathway requires unfolding of the C-terminal domain of Zuo1, which prevents its association with ribosomes. Since a variety of environmental stress conditions are known to induce prion formation, RAC dissociation from ribosomes under these conditions may facilitate prion formation. Our current work aims to understand the mechanism by which Zuo1 dissociation from ribosomes is triggered in response to environmental stress.
The nucleus of a eukaryotic cell is enclosed by a double-membrane structure, the nuclear envelope, which separates the nucleoplasm from the cytoplasm. The outer nuclear membrane is continuous with the endoplasmic reticulum (ER), whereas the inner nuclear membrane (INM) acts as the intermediate connecting the outer nuclear membrane to the nucleoplasm. As with most cellular compartments, the proteome of the INM is highly specific. Proteins targeted to the INM can be associated with the membrane through peripheral interactions or integrally embedded within the INM. The sorting of integral INM proteins after synthesis at the ER is achieved through either an energy dependent transport or by simple diffusion-retention. Due to the extremely high rate of protein synthesis and subsequent misfolding present at the ER, a mechanism for protein quality control is present to ensure dysfunctional or unwanted proteins are removed. A large majority of membrane associated proteins are degraded by the ubiquitin proteasome through the endoplasmic reticulum associated protein degradation (ERAD) pathway. ERAD functions in a step wise manner which involves the target protein being ubiquitylated by the joint actions of a ubiquitin conjugating enzyme and ubiquitin ligase. There are two redundant ubiquitin conjugating enzymes, Ubc6 and Ubc7, known to function with one of the three independent ubiquitin ligases (Doa10, Hrd1 and the Asi complex) in budding yeast, creating three separate branches for ERAD mediated degradation. The Asi pathway is thought to be a major ERAD pathway specific for degrading INM associated proteins. The conserved SUN-domain protein, Mps3, which resembles a type II single-pass transmembrane protein, is localized to the inner nuclear membrane. Its N-terminus is in the nucleoplasm, whereas the characteristic SUN-domain of Mps3 is in the lumen of the nuclear envelope. We have found that Mps3 has a half life of 45 minutes, and its degradation is regulated by Ubc7. However, there is no discernable change in Mps3 stability when any of the known ERAD ubiquitin ligases, including the Asi complex, are inactivated. Our findings suggest another ubiquitin ligase that is specific for the degradation of Mps3 is present at the INM, providing further evidence for an inner nuclear membrane associated degradation pathway (INMAD) that functions independently of ERAD.

The Golgi apparatus, a complex multi-layered endomembrane compartment, is the major site of protein modification and sorting within a cell. Additionally, it serves as an important platform for spatially-regulated signaling. Golgi homeostasis mechanisms that ensure precise processing and proper localization of protein substrates and signaling complexes remain poorly understood, due in large part to the lack of strategies capable of specifically inducing Golgi stress. Current tools used to perturb the Golgi, such as the ionophore nigericin or the glycosylation inhibitor xyloside, induce numerous off-target effects that confound studies on Golgi homeostasis. To overcome this limitation, we developed a novel
methodology to establish a Golgi-specific stress model that involves the expression of an artificial Golgi-localized protein and its targeted destabilization by small molecule hydrophobic tagging. The present study establishes for the first time that protein unfolding perturbs the Golgi, leading to a specific Golgi stress response that is distinct from the ER stress response. Using RNA sequencing, we transcriptionally profile our stress inducer and compare it to the current state-of-the-art Golgi stressors nigericin and xyloside. We find that stress induced by protein unfolding in the Golgi is specific to the Golgi apparatus, while nigericin and xyloside affect a broad range of cellular processes. Furthermore, from the obtained dataset, we uncovered a group of previously uncharacterized proteins involved in Golgi structural maintenance, knockdown of which leads to Golgi fragmentation. Together, these findings establish important new aspects of Golgi auto-regulation.

Unfolding of a Golgi-localized Protein Identifies Important Protein Quality Control Mechanisms in the Early Secretory Pathway.
D. Hellerschmied¹, Y.V. Serebrenik¹, C.M. Crews¹,²,³;
¹Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT,
²Department of Chemistry, Yale University, New Haven, CT, ³Department of Pharmacology, Yale University, New Haven, CT

Eukaryotic cells have evolved to utilize distinct reaction environments by employing a complex endomembrane system enclosing specialized organelles. Each of these organelles needs to maintain a quality control system to ensure the fidelity of its specific proteome and prevent toxic protein aggregation. The endoplasmic reticulum (ER) employs chaperones and the ER-associated degradation (ERAD) pathway to ensure the proper folding of proteins and to mark misfolded proteins for degradation. Proteins evading the ER quality control system or becoming damaged at later stages of their life cycle encounter downstream surveillance mechanisms. The Golgi apparatus is a major component of the secretory pathway which sorts and modifies incoming proteins from the ER. How the Golgi maintains proteostasis and exerts quality control measures is very poorly understood. To enable studying post-ER proteostasis mechanisms we have developed a tool that involves the expression of a Golgi-resident HaloTag2 fusion protein and its subsequent induced unfolding by covalent attachment of a small molecule hydrophobic tag. A similar approach in the ER has established that unfolded HaloTag2 is recognized and degraded by the ERAD machinery, validating the construct as a quality control substrate. Conversely, HaloTag2 unfolding in the Golgi does not lead to its degradation. Confocal imaging studies show that distinct carriers selectively export the unfolded protein from the Golgi. Three hours after inducing protein destabilization, the unfolded protein is localized to the ER, where it associates with molecular chaperones of the ER quality control machinery. The small-molecule induced protein unfolding approach serves as an important tool for identifying key features of organelle-specific proteostasis mechanisms. Together, our data demonstrate that the Golgi apparatus maintains a quality control system that is able to recognize unfolded proteins and induce their selective export, thus demonstrating the existence of a novel quality control mechanism in the early secretory pathway.

Modulation of calreticulin expression reveals a novel mechanism of Z variant alpha-1 Antitrypsin disposal.
N. Khodayari¹, Y. Lu¹, K. Krotova¹, M. Brantly¹;
¹Medicine, University of Florida, Gainesville, FL

Introduction

Alpha-1-antitrypsin deficiency (AATD) is an inherited disease characterized by emphysema and liver disease. AATD is most often caused by a single amino acid substitution at amino acid 342 in the mature protein, results in Z mutation of the AAT gene (ZAAT). This substitution is associated with misfolding and the accumulation of ZAAT in the Endoplasmic reticulum (ER) of hepatocytes and monocytes, causing a toxic gain of function. It has been shown that retained ZAAT is eliminated by ER-associated degradation (ERAD). ERdj3, one of the soluble ER luminal DnaJ homologue along with calreticulin directly interact with misfolded ZAAT. We hypothesize that depletion of each of these chaperones will change the fate of ZAAT polymers. Our study demonstrates that calreticulin modulation reveals a novel ZAAT degradation mechanism mediated by exosomes.

Methods

Human PiZZ hepatocytes and K42 mouse fibroblast cell line were grown in DMEM/F12 containing 10% FBS and transfected with or without calreticulin siRNA. To confirm interaction between EC ERdj3 and ZAAT and calreticulin regulatory role in ZAAT-ERdj3 secretion, quantitative RT-PCR, immune blotting, immunofluorescence, co-immunoprecipitation and flow cytometry were performed in PiZZ cell line.

Results

ERdj3 and calreticulin directly interact with ZAAT in PiZZ hepatocytes. Silencing calreticulin or preventing its interaction with ZAAT, induces calcium independent ZAAT-ERdj3 secretion through exosome pathway. This co-secretion decreases ZAAT aggregates within the ER of hepatocytes.

Conclusion

We demonstrate that calreticulin has an inhibitory effect on exosome mediated ZAAT-ERdj3 secretion. This is a novel ZAAT degradation process that involves DnaJ homologue chaperone bound to ZAAT. In this context, calreticulin modulation may eliminate the toxic gain of function associated with aggregation of ZAAT in lung and liver, thus providing a potential new therapeutic approach to the treatment of AATD related liver disease.

Redox modification of the Hsp70 nucleotide exchange factor Fes1.
E.E. Nicklow¹, C.S. Sevier¹;
¹Molecular Medicine, Cornell University, Ithaca, NY

Elevated levels of reactive oxygen species (ROS) are associated with many degenerative disorders. Increased cellular ROS levels correlate with accumulation of irreversibly oxidized proteins, which are prone to misfolding and aggregation. 70-kDa heat shock proteins (Hsp70s) are a conserved family of ATPases that serve as molecular chaperones to refold misfolded and aggregated proteins, such as those damaged by ROS. As such, Hsp70s play a critical role in protein quality control under oxidative stress. To examine the role of cytosolic Hsp70s in coping with oxidative stress, we screened S. cerevisiae strains mutated for each of the chaperones and their cofactors for peroxide sensitivity. Notably, we found that the nucleotide exchange factor Fes1 is required for cell survival during oxidative stress, and that when
cells are grown in medium containing oxidant, Fes1 is modified directly by ROS at three methionine residues. Preliminary data demonstrate that this oxidative modification of Fes1 reversibly alters its nucleotide exchange activity. We hypothesize this modification confers a protective role during stress conditions allowing cells to sense and respond to elevated ROS levels. Altered Hsp70 activity, as a consequence of Fes1 modification, may help cells cope with elevated ROS by limiting protein aggregation, targeting misfolded polypeptides for degradation, and/or activating the heat shock response. We are currently focused on characterizing these events to determine how Fes1 modification affects cell physiology and Fes1’s protein quality control activities in the cell.

The ASNA-1/ENPL-1 redox sensitive complex modulates C.elegans insulin secretion.
A. Podraza1, B. Natarajan1, D. Robakowska7, G. Kao1, P. Naredi1;
1Sahlgrenska Cancer Center, Gothenburg University, Gothenburg, Sweden

ASNA-1 is a positive regulator of insulin secretion in C.elegans and mice. To understand its biochemical role, we are studying candidate interacting proteins that may promote its activity. We have analyzed the function of C.elegans ASNA-1 candidate gene GRP94/ENPL-1. enpl-1 mutants have growth and reproductive defect. ASNA-1 gene positively regulates the secretion of the C.elegans insulin DAF-28. Phenotypes of enpl-1 mutants overlap with asna-1 mutants. We have identified a role for the chaperone ENPL-1 as a new positive regulator of insulin signaling that acts at the level of insulin availability similar to ASNA-1. We hypothesized that they might physically interact. Using Y2H and GST pulldown analysis we showed that ENPL-1 binds to ASNA-1 through defined subdomains and in vivo interactions were revealed by IHC in embryos. In worms these two proteins interact in neurons which are also one of the sites for insulin secretion. Moreover, in DAF-28/insulin mutants the level of binding decreases significantly. This finding suggest that an ASNA-1/ENPL-1/DAF-28 complex is needed for proper processing of insulins in C.elegans. ASNA-1 and ENPL-1 show increased binding under oxidative stress conditions. The S.cerevisiae homolog of ASNA-1 acts as a dimer to promote targeting of tail-anchored proteins to the ER membrane and upon oxidation, converts to a tetrameric state in which it acts as a general chaperone. Worm ASNA-1 as well is present in both states: oxidized and non-oxidized and conversion is controlled via two cysteines. Under oxidative stress conditions ASNA-1 changes its shape which allows increased binding to ENPL-1, without changing its total level. Our aim is to further investigate conditions which favor or inhibit structural changes of ASNA-1 to be able to specifically control these processes. We hypothesize that insulin secretion in C.elegans needs the interaction between ASNA-1 and ENPL-1 in order to happen. In the ER, ENPL-1 promotes the proper cysteine bond formation in insulin molecules via a molecular complex. Only then, the complex of the properly folded insulin together with ENPL-1 leaves the ER and translocates to Golgi apparatus where can meet the tetrameric ASNA-1 chaperone. ASNA-1 and ENPL-1 creates a complex, which allows ENPL-1 to release insulins which can be secreted through dense core vesicles outside the cell. Discovering the mechanism of insulin folding and secretion and the relation to two chaperones will lead to a better understanding of insulin maturation/secretion and better design of diabetes targeting drugs.

Amyloids as the natural protein storage reservoirs.
1Proteomics of Supra-Organismal Systems, All-Russia Institute for Agricultural Microbiology, St. Petersburg, Russia, 2Genetics and Biotechnology, St. Petersburg State University, St. Petersburg, Russia

Amyloids represent protein fibrils with highly ordered spatial structure that makes them one of the most stable biogenic particles. Amyloids are resistant to treatment with ionic detergents, proteinases and other protein denaturants, and can survive in the environment for years. For a long time, amyloids were mainly perceived as the lethal pathogens causing about 40 incurable disorders in humans and animals. During last decades, amyloid became clear to be not only pathogenic but also functionally important variant of the quaternary protein structure. A wide variety of functional amyloids was identified in different species of prokaryotes and eukaryotes. Among various functions of amyloids, protein storage takes an important place. Different toxins in bacteria and hormones in humans are stored in the amyloid state. Plants are poorly studied group in the field of amyloid biology. Several plant proteins or peptides were shown to have amyloid properties only in vitro or in heterological systems in vivo. The main functions of these plant proteins are defense from the pathogens as well as regulation of flowering [for a review, see 1]. We performed large-scale bioinformatic analysis of the amyloidogenic properties of 2.9 million proteins in 75 plant species using SARP and WALTZ algorithms. We identified protein families and functional groups, in which potentially amyloidogenic proteins are overrepresented. We found that seed storage proteins are highly enriched with amyloidogenic regions, and this feature is evolutionary conservative among land plants [2]. Experimental analysis performed with recently developed PSIA approach [3] revealed several candidates for novel amyloid-forming proteins among storage proteins. Taking together, our data suggest that amyloid formation is likely to represent an important mechanism of protein storage in seeds. Broader perspectives of secretory pathway quality control revealed through the study of misfolded GPI-anchored proteins.
B.S. Park, C. Bi, K. Budharaju, P. Satpute-Krishnan;
1Biochemistry and Molecular Biology, Uniformed Services University, Bethesda, MD, 2Thomas Jefferson High School for Science and Technology, Alexandria, VA

Secretion of misfolded proteins can result in disruptive and toxic molecular interactions, such as those associated with prion and Alzheimer’s diseases. Accordingly, cells have evolved multiple coordinated protein quality control (QC) pathways to target and retain misfolded secretory pathway proteins in the endoplasmic reticulum (ER) for refolding or degradation via ER associated degradation (ERAD) or autophagy. Yet, we now appreciate that some misfolded secretory pathway proteins escape degradation at the ER and traverse the secretory pathway before being secreted and/or destroyed in
lysosomes. For example, misfolding mutants of a prevalent class of membrane proteins called glycosylphosphatidylinositol-anchored proteins (GPI-APs), which includes prion disease-associated mutants of PrP, are selectively cleared out of the ER by a stress-enhanced, Tmp21-dependent pathway. We named this ER export pathway RESET (for Rapid ER Stress-induced Export). Upon release from the ER, the misfolded GPI-APs move through the Golgi and transiently reside on the plasma membrane before being internalized for lysosomal degradation. Recently, we discovered that a subset of misfolded transmembrane proteins, including human disease mutants of LDLR, also associate with Tmp21 and are cleared from the ER by RESET. We are now dissecting the precise role of Tmp21 and associated factors in the ER export of misfolded GPI-APs and transmembrane proteins. Additionally, we are characterizing the currently unknown QC system(s) that target and send misfolded GPI-APs on the cell surface to lysosomes for degradation.

Prions may act as the gain-of-function mutations.
A.A. Nizhnikov\textsuperscript{1,2}, K.S. Antonets\textsuperscript{1,2}, S.F. Kliver\textsuperscript{1,2}, D.E. Polev\textsuperscript{2}, A.R. Shuvalova\textsuperscript{2}, E.A. Andreeva\textsuperscript{2}, S.G. Inge-Vechtomov\textsuperscript{2};
\textsuperscript{1}Proteomics of Supra-Organismal Systems, All-Russia Research Institute for Agricultural Microbiology, St. Petersburg, Russia, \textsuperscript{2}Genetics and Biotechnology, St. Petersburg State University, St. Petersburg, Russia

Prions are proteins that can form in the same conditions two or more structurally distinct states, at least one of which is infectious. Prions were initially described as the proteinaceous infectious agents that cause neurodegenerative pathologies in humans and animals. However, it soon became clear that prions are also implicated in different biological processes in a wide range of species. The most common point of view postulates that prion formation leads to functional inactivation of prion-forming protein similarly to the deletion of corresponding structural gene or loss-of-function mutation. Certainly, in contrast to mutations, prion formation is not caused by changes in genetic material, but is determined by conformational change of the prion-forming protein. Here we used [SWI\textsuperscript{1}] prion of yeast \textit{Saccharomyces cerevisiae} as a model to compare the effects of prion formation and deletion of prion-encoding gene at the transcriptome-wide level. [SWI\textsuperscript{1}] is a prion of Swi1 protein, which is a component of evolutionary conservative chromatin remodelling complex SWI/SNF. We analyzed transcriptomes of the [SWI\textsuperscript{1}], [swi\textsuperscript{1}], and swi1Δ strains. We found that both, prion formation and deletion of Swi1, lead to changes in the expression of hundreds of genes. Nevertheless, 20 genes that are downregulated in the swi1Δ strain are upregulated in the [SWI\textsuperscript{1}] strain. Thus, formation of [SWI\textsuperscript{1}] prion affects expression of several genes in a manner similar to the gain-of-function mutation. Taking together, our data show that the effect of prion formation are not equal and may be even opposite to the effects of the deletion of prion-encoding gene. This work was supported by the grants of the Russian Foundation for Basic Research (17-04-00816) and the President of the Russian Federation (MK-3240.2017.4). The authors acknowledge Research Park of SPbSU for the opportunity to use equipment of “Biobank” and “RRCMCT”.
During heat shock, single-celled organisms must be able to dynamically sense and respond to changes in the protein-folding environment, such as temperature, to ensure proteostasis and survival. The budding yeast S. cerevisiae grows best in acidic (low-pH) conditions, yet during logarithmic growth maintains a resting cytosolic pH just above neutral, expending a considerable portion of cellular ATP resources to do so. When cells experience acute stresses such as high temperatures or energy depletion, intracellular pH drops. Although changes in intracellular pH have been shown to influence the cellular response to starvation, in the case of heat shock little is known about the interplay between changes in pH and other, more well-studied processes such as the transcription and translation of the heat shock genes, and the behavior of the protein homeostasis machinery. In order to understand how changes in intracellular pH might influence the heat shock response, we dictate intracellular pH with an ionophore, use a pH-sensitive GFP derivative to measure intracellular pH, and simultaneously measure the production of heat shock proteins using quantitative, multicolor flow cytometry.

We find that cells that are held at the pre-shock pH during heat shock almost completely fail to synthesize certain heat shock proteins in an interval where acidified cells do so robustly. We measure relative growth rates and demonstrate that the intracellular pH profile during stress also alters cellular fitness during recovery. Finally, we correlate production of molecular chaperones to intracellular pH during recovery at the single-cell level. These findings implicate pH regulation as a key aspect of the cellular stress response.

Translation of heat shock proteins is regulated by poly(A)-binding protein assembly. How do cells sense and respond to changes in the environment? During heat stress, numerous eukaryotic RNA and protein species assemble into macromolecular bodies - stress granules - the function of which is largely unknown. Simultaneously, cells increase transcription of genes encoding heat shock proteins, many of which are molecular chaperones. In addition to increased transcription, the mRNA for these genes is also translated more efficiently. Thus, heat shock protein production is regulated by both transcription and translation. These heat-induced mRNAs have exceptionally A-rich 5′ untranslated regions (UTRs), which have long been known to mediate cap-independent translation. We observe that poly(A)-binding protein (PABP, Pab1 in S. cerevisiae) is bound to these A-rich UTRs during exponential growth. Pab1 is able to repress translation of its own mRNA by binding a similar A-rich UTR. We find that Pab1 represses translation of mRNA by binding A-rich UTRs of heat shock proteins. Further, we propose that during heat-shock, as Pab1 assembles into heat-induced RNA-protein granules, Pab1 releases bound 5′ UTRs, and relieves repression. We have recapitulated Pab1-mediated repression and heat-induced relief with an in vitro translation system. Moreover, yeast expressing assembly-impaired Pab1 are not able to grow at elevated temperature; this result is consistent with disruption of an
assembly-mediated regulatory mechanism. Viewed through this lens, formation of RNA-protein granules is a regulatory response, whose functions include translational regulation.

**Differential impact of several PD-associated genes on the toxicity associated with wild-type and familial mutant forms of α-synuclein in a yeast model.**  
P. Jones1, E. Ong1, A. Balaram1, A. Biel1, C. Mwale1, M. Tembo1, S. DebBurman1;  
1Neuroscience Program and Biology Department, Lake Forest College, Lake Forest, IL

Parkinson’s disease (PD) is a neurodegenerative disease characterized by motor impairment. The aggregation of the α-synuclein in the midbrain dopaminergic neurons and the corresponding death of these cells underlie these symptoms. PD can be both genetic and sporadic. Familial PD is directly caused by a mutation in one of at least 10 genes, including SNCA, DJ1, VPS35, and ATP13A2. SNCA encodes α-synuclein and has six identified missense mutations (A30P, E46K, H50Q, G51D, A53E, and A53T) that each cause early-onset PD. Sporadic PD is linked with several risk genes, including VPS13, Sac1, and Swa2. In our budding yeast model system, we first find wild-type, E46K, A53T, H50Q, and A53E α-synuclein to be toxic to yeast and they show varying degrees of membrane binding and aggregation, while A30P and G51D α-synuclein are relatively non-toxic and show cytoplasmic diffuse localization. What is still not well understood is whether the PD-causing and PD-risk genes mentioned above can influence the toxicity properties of this six familial mutants of α-synuclein. To explore this connection, wild-type and familial forms α-synuclein were studied in yeast strains that were singly deleted for these six PD-linked genes. Results indicate that some gene deletions increased α-synuclein toxicity (DJ1, VPS13), others reduced toxicity (ATP13A2, VPS35), while some had no effect (Swa2, Sac1). In each case, those genes that altered α-synuclein toxicity did so in a familial mutation-specific way. Our findings suggest that each familial mutant creates cellular toxicity in a unique way regulated by different subsets of genes/cellular processes, offering doors for additional mechanistic insight into the mode of toxicity with each mutant.

**The Saccharomyces cerevisiae SUMO-targeted ubiquitin ligase subunit Slx5 reduces the toxicity and transcriptional activity of poly-Q expanded huntingtin.**  
J.L. Peek1, N. Pasupala2, G. Driessnack-Sclar2, R. Levy-Myers2, K. Ohkuni3, M.A. Basrai2, O. Kerscher1;  
1Biology, The College of William & Mary, Williamsburg, VA, 2Biophysics and Biophysical Chemistry, The Johns Hopkins School of Medicine, Baltimore, MD, 3Genetics Branch, NCI/CCR, Bethesda, MD

Cell viability and gene expression profiles are altered in cellular models of neurodegenerative disorders such as Huntington’s Disease (HD). Using the yeast model system, we show that the SUMO-targeted ubiquitin ligase (STUbl) Slx5 reduces the toxicity and abnormal transcriptional activity associated with a mutant, aggregation-prone fragment of huntingtin (htt), the causative agent of HD. We demonstrate that expression of an aggregation-prone htt construct with 103 glutamine residues (103Q), but not the non-expanded form (25Q), results in severe growth defects in slx5Δ and slx8Δ cells. Concomitantly, an extra copy of SLX5 reduces the accumulation of 103Q aggregates in the cytosol of wild type cells while overexpression of SUMO led to diffuse nuclear staining of htt. This prompted us to assess the effect of STUbls on the transcriptional properties of aggregation-prone htt. Expression of 25Q, 55Q and 97Q fused to the Gal4 activation domain (AD) resulted in reporter gene auto-activation. Remarkably, the

*POSTER PRESENTATIONS-TUESDAY*
auto-activation of htt constructs was abolished by expression of Slx5 fused to the Gal4 DNA-binding domain (BD-Slx5) but not an Slx5 mutant (BD-Slx5ΔSIM) that fails to interact non-covalently with SUMO. In support of this observation we find that chromatin-associated poly-Q expanded htt is reduced when Slx5 levels are elevated. Finally, we show that RNF4, the human orthologue of Slx5, curbs the aberrant transcriptional activity of aggregation-prone htt in a tissue culture model of Huntington’s disease. This research indicates that STUB1s are functionally required to counteract the reduced cell viability and abnormal transcriptional profiles observed in protein aggregation disorders such as HD.

Functions of TPR Containing Proteins in the Endoplasmic Reticulum.
J. Bradley-Graham1, J. Sunryd1, D.N. Hebert1;
1Biochemistry and Molecular Biology, University of Massachusetts, Amherst, Amherst, MA

The endoplasmic reticulum (ER) is a complex, multi-functional organelle, comprised of a continuous membrane and lumen that is organized into several functional regions with various roles including protein translocation, folding, quality control, secretion and the unfolded protein stress response. Total cellular protein homeostasis is maintained by a complicated chaperone network and when the various factors are categorized into functional families, the largest family consists of proteins containing tetra-trico peptide repeats (TPR). TPRs are well-studied structural motifs that support intermolecular protein-protein interactions in various organelles and organisms, consisting of 34 amino acids with a degenerate consensus sequence, making them highly acceptable and capable of interacting with a wide range of ligands. Since TPR motifs are ubiquitous and adaptable scaffolds, we hypothesized that additional TPR domain-containing proteins could contribute to complex formation and ER compartmentalization. Putative TPR containing proteins, identified from database searches and an in silico library (Regan, Yale University), were subjected to SignalP 4.0 and TargetP1.1 to identify those targeted to the secretory pathway. This analysis identified 10 TPR containing proteins. While some of these proteins have been confirmed to be ER localized and currently determined to be involved in chaperone function/modification and ERAD, a clear understanding of the remaining 7 is currently absent. Confocal microscopy and carbohydrate analysis revealed that TMTC1-4 reside in the ER. TMTC1-4 were determined to be integral membrane proteins by alkaline extraction and trypsin protection assays on isolated ER microsomes showed that their C-terminal ends are in the ER lumen. Recent data has implicated TMTC1-4 in O-mannosylation. We seek to determine the role they may play in O-mannosylation and resulting disease states characterizing previously determined mutations.

Molecular insights into life span through changes in tRNA export and transcription activation.
C.L. Lord1, S.R. Wente1;
1Cell and Developmental Biology, Vanderbilt University School of Medicine, Nashville, TN

Aging is significant risk factor for a variety of serious diseases, and is regulated by several cellular and molecular signaling pathways. One such pathway involves tRNA nucleocytoplasmic transport. tRNAs are transcribed in the nucleus and must be exported through nuclear pore complexes (NPCs) to mediate...
protein translation in the cytoplasm. We and others discovered that inhibition of tRNA export in *S. cerevisiae* increases replicative life span (RLS), which is defined as the number of daughters an individual yeast cell produces prior to senescence or death. RLS is a robust system to model the aging process due to the conservation of several longevity factors in metazoans and the short time frames required for analysis. Our prior studies showed that deletion of the nucleoporin Nup100 or its GLFG domain, an intrinsically disordered region consisting of glycine-leucine-phenylalanine-glycine repeats that regulates passive diffusion and active transport through NPCs, is sufficient to increase RLS. Since *nup100Δ* and tRNA export mutants both display increased life spans, we tested whether tRNA transport is affected by Nup100. Fluorescence in situ hybridization experiments reveal isoleucine, tyrosine, and tryptophan tRNAs, but not serine or methionine tRNAs, accumulate in the nuclei of *nup100Δ* cells. In addition, protein levels of the transcription factor Gcn4 are elevated in *nup100Δ* mutants, and *GCN4* is necessary for the increased life spans of *nup100Δ* cells. In *S. cerevisiae* cells, intron-containing and mature tRNAs are exported from nuclei; however, the majority of tRNAs present in *nup100Δ* cells are spliced, suggesting re-export of mature tRNAs is inhibited. Functional assays indicate that transport of the tRNA-binding nuclear transport receptors Los1 and Msn5 are unaffected in *nup100Δ* cells. Together, these results suggest a model whereby Nup100 is required for the re-export of specific mature tRNAs. Nuclear accumulation of these tRNAs in *nup100Δ* cells then extends life span through a Gcn4-dependent signaling pathway. Since the GLFG domain of Nup100 is critical for regulating longevity, we speculate Nup100 is required for an unidentified nuclear transport event, independent of Los1 or Msn5, that is necessary for tRNA export. We are currently investigating how Nup100 influences tRNA export, and whether Gcn4 overexpression is sufficient to increase RLS. Through these studies, we mechanistically define several important signaling events that modulate longevity.

**IRBIT links nucleotide metabolism to aging in the gut.**

A. Arnaoutov¹, K. Plevock Haase¹, M. Serpe², M. Dasso¹;

¹Division of Molecular and Cellular Biology, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD, ²Section on Cellular Communication, National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD

Within the gut, there are age-related changes in the microbiota, immune signaling and inflammation response. At the cellular level, aging in the gut is coupled with decreased epithelial integrity. Using the genetically tractable model organism Drosophila melanogaster, we have identified IRBIT as a key protein in maintaining gut homeostasis and epithelial integrity in aging.

We recently reported a conserved role for IRBIT in inhibiting ribonucleotide reductase (RNR), an enzyme that produces dNTPs within the cell for DNA synthesis. During embryogenesis, in situ hybridization reveals localization of IRBIT to regions that will become the midgut, and it is expressed highly in the adult midgut. WT flies show a marked decrease in IRBIT protein level as they age, hinting at a function for IRBIT in aging. Therefore, we probed IRBIT’s potential role in regulating gut aging by generating an IRBIT null fly (IRBIT/-). One day old WT and IRBIT/- flies are indistinguishable at the tissue architecture level. However, rapid progressive aging occurs in the IRBIT/- flies, whereby one week old flies resemble dramatically older WT flies. IRBIT/- flies show an increase in undifferentiated enteroblast progenitor cells, that are RNR positive. This increase in RNR positive progenitor cells contributes to the tissue dysplasia. IRBIT/- flies also show decreased cell-cell contacts when stained for junctional proteins in the posterior midgut epithelium. These phenotypes are fully rescued with full length IRBIT; suppressing RNR by hydroxyurea treatment also rescues the IRBIT/- phenotype, which reveals IRBIT’s role in aging is
through RNR inhibition. Finally, artificial elevation of dNTP levels extensively phenocopies the IRBIT deletion. Altogether, these data suggest that IRBIT plays a key role in aging and tissue homeostasis in the fly gut via its role antagonizing RNR in nucleotide metabolism. We are currently examining the interplay of IRBIT with inflammatory pathways and microbiota changes that are characteristic features of aging in flies.

Jaboticaba extract prevents inflammation and hormonal imbalance in the prostatic microenvironment of high-fat-fed aging mice.
C.A. Lamas¹, L.A. Kido ¹, E. Nogueira-Pangrazi², C. Collares-Buzato², M. Maróstica Jr², V.H. Cagnon¹;
¹Department of Structural ans Functional Biology, University of Campinas, Campinas, Brazil,
²Department of Biochemistry and Tissue Biology, University of Campinas, Campinas, Brazil

Jaboticaba is a Brazilian fruit rich in phenolic compounds, such as anthocyanin, which display antioxidants and anti-inflammatory effects. Aging and obesity are involved in prostatic lesions, due to their association with cellular proliferation, inflammation, and hormonal imbalance. Thus, the aim of this study was to evaluate the effect of jaboticaba extract (JE) in molecular pathways related to inflammation and hormonal metabolism, during aging and/or high-fat diet ingestion in mice prostate. Seventy FVB mice was distributed in the following experimental groups: YG(young-3 months old), SE(senile-11 months old), HfSE(senile+high-fat diet), JSEI(senile+0.003mL/gJE), JSEII(senile+0.006mL/gJE), HfJSEI(senile+high-fat diet+0.003mL/gJE) and HfJSEII(senile+high-fat diet+0.006mL/gJE). After 60 days, animals were anesthetized, ventral prostates were collected and submitted to morphological analysis and AR, ERα, COX-2, NFkB immunohistochemical and/or Western Blotting evaluation. Aging itself increased prostate cellular proliferation, well-differentiated adenocarcinoma, microacini and inflammatory infiltrate frequency as well as the COX-2, NFkB and ERα levels, and reduced AR level in relation to JV group. The high-fat diet intensified the senescence alterations. HfSE group presented significantly higher cellular proliferation, well-differentiated adenocarcinoma, microacini and fibromuscular layer frequency, besides increasing AR, ERα, COX-2 and NFkB levels compared to SE group. The treatment with JE at both doses reversed most of the alterations seen during aging by lessening the cellular proliferation, the well-differentiated adenocarcinoma and inflammatory infiltrates frequency as well as the COX-2 level in senile mice. Only JSEII group showed lower fibromuscular layer frequency and reduced AR, ERα and NFkB levels compared to SE group. Moreover, both JE doses in HfJSEI and HfJSEII groups reduced cellular proliferation, microacini, well-differentiated adenocarcinoma, inflammatory infiltrates and fibromuscular layer frequency as well as AR, ERα, COX-2 and NFkB levels in relation to HfSE group. HfJSEII group showed even lower frequency of cellular proliferation and atrophy in relation to HfJSEI group. Thus, JE exerted a dose-dependent positive effect, probably acting on the ERα pathway, which led to prostate microenvironment recovery and hormonal and inflammation balance, as well as to the maintenance of prostate typical morphology, impaired by aging process and/or high-fat diet ingestion. Therefore, JE can be indicated as an alternative therapy for the prevention of prostatic damage during aging and/or overweight.
Proteopathic proteins have characteristic phase behaviors.
J. Wu1,2, R. Halfmann1,2;
1Stowers Institute for Medical Research, Kansas city, MO, 2Molecular and Integrative Physiology, University of Kansas Medical Center, Kansas City, KS

Protein self-assembly regulates the function of many proteins. Under certain conditions or stimuli, the same protein can form different assemblies that correspond to different cellular activities. For example, ASC, an inflammasome adaptor protein, is an inactive monomer in mammalian cells, however, in response to a pathogen or cellular danger signal, ASC undergoes prion-like polymerization which then leads to caspase-1 activation and subsequent programmed cell death. In contrast, for many neurodegenerative disease-related proteins, the formation of a high-order assembly underlies pathology. For example, oligomeric forms of Aβ42 are believed to be toxic and a precursor of the amyloid aggregates that characterize Alzheimer’s disease. However, the mechanistic differences between functional and dysfunctional assembly are unclear. Thus, distinguishing distinct assembled forms of the proteins is a pivotal step to reveal their inter-relationships and roles in disease. Here, I applied Distributed Amphifluoric FRET (DAmFRET), a FRET- and imaging flow cytometry-based approach developed in our laboratory to study protein self-assembly, to show that ectopically expressed disease-associated proteins, including Aβ42, -synuclein (Parkinson’s Disease), and amylin (type II diabetes), each accumulate in yeast cells as diffuse oligomers that are metastable with respect to higher order assemblies. We also found that cell size was negatively affected only in cells that harbored these oligomeric forms of -synuclein or Aβ42, but not in cells that contained -synuclein in an exclusively monomeric form, or Aβ42 in high order assemblies. The oligomers of -synuclein or Aβ42 also inhibited the proliferation of their host cells. Moreover, among several -synuclein mutants examined, only the A30P mutant disrupted oligomerization. It likewise alleviated toxicity. Our results suggest that a propensity to form soluble oligomers (that are metastable with respect to higher order assemblies) commonly underlies proteotoxicity. This ongoing study is aimed to explore the connection between the different assemblies and the underlying pathology of the disease-associated proteins.

Increasing glucose uptake suppresses age-dependent reductions in ATP levels in brain neurons and behavioral deficits in Drosophila.
M. Oka1, E. Suzuki2,3, H. Imamura4, S. Hisanaga1, K.M. Iijima5,6, K. Ando1;
1Department of Biological Sciences, Tokyo Metropolitan University, Tokyo, Japan, 2Structural Biology Center, National Institute of Genetics, Shizuoka, Japan, 3Department of Genetics, The Graduate University for Advanced Studies (SOKENDAI), Mishima, Japan, 4Department of Functional Biology, Kyoto University, Kyoto, Japan, 5Department of Alzheimer's Disease Research, National Center for Geriatrics and Gerontology, Obu, Japan, 6Department of Experimental Gerontology, Nagoya City University, Nagoya, Japan

Aging has been associated with changes in metabolism at system and cellular levels. Brain neurons are highly energy demanding cells and require local energy supply due to their polarized structures. Disruption in energy metabolism in neurons is thought to cause age-related functional declines as well as neurological and neurodegenerative diseases. However, temporal and special information regarding age-dependent changes in ATP levels in brain neurons is limited. Using Drosophila as a model system,
here we analyzed the age-dependent changes in ATP levels in the cell bodies and axons in brain neurons using FRET-based ATP biosensor. We focused on the mushroom body structure, in which the cell body region and the axonal region are easily distinguished. ATP levels in the axon were similar between young and aged flies. In contrast, we found that ATP levels in the cell body were significantly reduced during aging. To gain insight into the mechanisms underlying age-dependent reduction in ATP levels in the cell bodies, we first compared the numbers and quality of mitochondria between young and aged flies via ultrastructural analyses. While the number of mitochondria was similar between young and aged fly brains, mitochondria with abnormal cristae were more often observed in aged brain neurons, suggesting that ratio of damaged mitochondria was increased during aging. Thus, increased ratio of damaged mitochondria was correlated with age-dependent reductions in ATP levels in the cell bodies. We next compared mRNA levels of glycolytic enzymes in young and aged fly brains. We found that mRNA levels of several rate-limiting enzymes in the glycolytic pathway were reduced during aging. Interestingly, flies with knockdown of pfk, one of the key glycolytic enzymes, did not show age-dependent reductions in ATP levels in the cell body, suggesting that reduced glycolysis also contributed to age-dependent reduction in ATP levels. Interestingly, we also found that enhancement of glucose uptake by neuronal overexpression of glucose transporter (GLUT) can suppress age-dependent declines in ATP levels in the cell body. Moreover, neuronal overexpression of GLUT suppressed the age-dependent decline in locomotor functions in flies. Taken together, these results suggest that age-dependent reductions in ATP levels are due to mitochondrial damage and reduced glycolysis, while reduction in ATP levels as well as decline in neuronal functions can be suppressed by increasing GLUT into neurons. Further study of regulatory mechanisms underlying glucose uptake in brain neurons may lead to novel therapeutics against normal aging and age-related neurodegenerative diseases.

Role of sphingolipid enzymes in the regulation of stress response and aging through detoxification protein pathways.

C.I. Meyer1, A. Nolan1, J. Brown1, J.P. Chan1;

1Biology, Juniata College, Huntingdon, PA

Sphingolipids play an important role in different regulatory processes including those for structural support and cell signaling. Sphingosine is a sphingolipid involved in regulating cell death, whereas sphingosine-1-phosphate (S1P) is a sphingolipid that induces cell proliferation and inhibits apoptosis. Thus, the enzymes that control cellular levels of sphingolipids, such as sphingosine kinases ceramide synthases, and acid sphingomyelinases, are critical to cell survival decisions. When cells face stress, such elevations of reactive oxidative species (ROS) that damage proteins and lipids, they must respond to counteract stress. Cellular responses to ROS include the upregulation of detoxifying proteins such as glutathione S-transferases (GSTs) and superoxide-dismutases (SODs). Recently, it has also been shown that sphingolipids are important for stress responses in animals. We show here that C. elegans mutants lacking sphingosine kinase (sphk-1) have poor heat and oxidative stress responses, whereas animals lacking certain ceramide synthases exhibit greater stress response. In particular, the stress resistance phenotype of ceramide synthase mutants is dependent on sphk-1, suggesting that conversion of sphingosine to S1P may be critical to maintaining stress responses. However, it is not known whether sphingolipids directly influence stress response through detoxification protein pathways. To examine this, we further analyzed a panel of C. elegans sphingolipid metabolism mutants; sphingosine kinase (sphk-1), ceramide synthase (hyl-1, hyl-2), and acid sphingomyelinase (asm-3) in oxidative stress assays. We found that H2O2 treatment induced the the expression of sod-3/SOD, using GFP transcriptional

Tuesday-477
Sphingolipids are cellular signaling molecules known to play vital roles in locomotion and neuromuscular function in organisms. In particular, sphingosine-1-phosphate (S1P), promotes neurotransmitter and neuropeptide release, is produced by the activity of the enzyme sphingosine kinase. Sphingolipids are interconverted through enzymatic activity that mediates lipid content within a cell. However, S1P levels change with age, but it is not known how loss of S1P and changes in sphingosine kinase activity mediate changes in neuronal aging. Using the model organism C. elegans, we aimed to determine the effects of loss of sphingolipid metabolism enzymes on the maintenance of locomotion and neuromuscular function in age. Using movement, we aim to measure how sphingolipid metabolism affects health span, defined as the amount of time an organism lives until the onset of morbidity, or serious or chronic illness. To do this, we examined thrashing and body bending behavior in aging animals at multiple time points; we used C. elegans knockouts of the sphingolipid pathway enzymes including sphingosine kinase (sphk-1), ceramide synthases (hyl-1, hyl-2), and an acid sphingomyelinase (asm-3). We found that the loss of sphk-1 leads to decreased thrashing behavior and declined neuromuscular function with age in comparison to wildtype animals. However, loss of hyl-1 results in increased thrashing behavior in age. Furthermore, we wanted to determine the role of sphingolipids during development and adulthood. To do this, we assessed the role of sphingolipid metabolism enzymes during different windows of age through the use of RNAi-mediated knockdown, which also allowed us to assess combinations of enzymes.

Poly(ADP-ribose) (PAR) promotes TDP-43 liquid droplet formation but reduces TDP-43 aggregation.
E. Gomes¹, L. McGurk¹, L. Guo², N. M. Bonini², J. Shorter¹;
¹Biochemistry and Molecular Biophysics, University of Pennsylvania, Philadelphia, PA, ²Biology, University of Pennsylvania, Philadelphia, PA

TAR DNA-binding protein 43 (TDP-43) is a nuclear RNA-binding protein (RBP) that contains a C-terminal prion-like domain (PrLD). Approximately 97% of cases of amyotrophic lateral sclerosis (ALS) show mislocalization and cytoplasmic aggregation of TDP-43. Interestingly, several other RBPs with PrLD, including Fused in Sarcoma (FUS) and heterogeneous nuclear ribonucleoprotein A1 and A2 (hnRNP A1 and hnRNP A2), also mislocalize and aggregate in ALS. These RBPs are components of stress granules,
which are membrane-less organelles that form via liquid-liquid phase separation in cells experiencing stress. Research has been done on FUS and hnRNP A1 and A2 showing that these proteins are capable of liquid-liquid phase separation in vitro, so we thus hypothesized that purified TDP-43 will similarly undergo liquid-liquid phase separation. Furthermore, it is thought that aberrant phase transition of these RBPs leads to misregulation of stress granule dynamics, which then induce toxicity and disease. Therefore, understanding the basis of TDP-43 recruitment to stress granules may provide potential avenues for ALS therapies. Previous research indicated that Poly (ADP-ribose) (PAR) is required for stress granule assembly. Interestingly, TDP-43 contains a putative PAR binding motif and localizes to stress granules that are Poly (ADP-ribosylated) (PARylated). This suggested that poly (ADP-ribose) (PAR) may recruit TDP-43 into stress granules, and so we further hypothesized that PAR may promote TDP-43 phase separation by binding TDP-43. We purified SUMO tagged TDP43 and here show that SUMO-TDP-43 is indeed capable of phase separating into liquid droplets in vitro. Moreover, the addition of PAR promotes TDP-43 liquid droplet formation while mutating the putative PAR-binding motif dramatically reduces TDP-43 phase separation. Additionally, TDP-43 is an inherently aggregation prone protein that also forms solid aggregates upon cleavage of the SUMO tag. We used turbidity measurements to monitor this aggregation kinetics and found that addition of PAR reduced the formation of solid aggregates. Together our results suggest that poly (ADP-ribose) promotes liquid-liquid phase separation of TDP-43 while also preventing TDP-43 from forming solid aggregates.

Young blood serum increased cellular response associated to wound healing in old rats.
M. Caceres Lluch¹, M. Saldias¹, C. Fernandez², V. Folli², O. Cerda³;
¹Molecular and cellular program, Universidad de Chile, Santiago, Chile

Aging is a natural process which is associated with the appearance of a number of diseases that contribute to progressive deterioration in the quality of life. Aging affect negatively wound healing. However, the mechanisms underlying this phenomenon remain unclear. Here, we studied the in vivo wound healing process during aging using a rat skin repair model in young and old rats and an in vitro model using primary skin fibroblast from young and old rats and human gingival fibroblast. To do that, we evaluated histologically using Masson Trichrome the in vivo effect of young and old rat blood serum in skin wound healing in young (2 months old) and old rats (18 months old). We next evaluated in vivo and in vitro myofibroblast differentiation. To do that we used rat blood serum applied topically in skin wound form young and old rats, rat skin fibroblast obtained from young and old rats and human blood serum classified into 3 groups: “young” from 18 to 22 years old, “middle-aged” from 30 to 48 years old and “aged” over 50 years old. Myofibroblastic differentiation, measured through alpha-smooth muscle actin (α-SMA) was decreased in the presence of middle-aged and aged serum compared to young serum. Moreover, the topical use of young blood serum in skin wound repair improves wound healing and myofibroblast differentiation in old rats. The present study suggests that serum factors present in middle-aged and aged individuals may be responsible, at least in part, for the altered responses observed during wound healing in aging.

Alcohol causes a defect in telomere homeostasis.
Q. Zhu1, J. Park1, W. Belden1;
1Department of Animal Sciences, Rutgers, The State University of New Jersey, New Brunswick, NJ

Telomeres are repeated DNA sequences at the distal tips of eukaryotic chromosomes. The linear nature of chromosomes causes a dual problem for telomeres; the end replication problem and the end-protection problem. The end-replication problem is solved by telomerase, which is a ribonucleoprotein composed of telomerase RNA component (TERC) and telomerase reverse transcriptase (TERT). Telomerase adds the TTAGGG repeat to chromosome ends using TERC as a template. Shortened telomeres are observed in chronic drinkers and shorten telomeres are a factor in pathology of many diseases. Despite all that is known about the adverse effect of alcohol, the molecular mechanism of alcohol-induced telomere shortening is still unclear. To address this question, we establish a zebrafish model of alcohol consumption to ascertain how alcohol impacts telomere homeostasis. We find that TERRA, a long noncoding RNA that originates from telomeres and is needed for telomere heterochromatin, was phase-shift relative to the normal TERRA rhythm. In addition, it also appears that alcohol intake disrupts the diurnal rhythm of TERT and TERC. Our data suggest that alcohol intake alters normal telomere homeostasis on multiple levels, including TERRA expression, heterochromatin formation, TERT and TERC expression. These findings reveal multifarious mechanisms involved in alcohol-induced telomere shortening.

Functions of CLIC proteins in heat stress in C. elegans.
J. Liang1, C. Guerrero1, H. Wang1;
1Science, Borough of Manhattan Community College, New York, NY

Chloride intracellular channel proteins (CLIC) are multifunctional proteins. Mammalian CLIC family, which has seven members, varies in subcellular localization and cellular functions. Cellular stress molecules induce endogenous CLIC4 to translocate from the cytoplasm into the nucleus. Mammalian Schnurri-2 is required for CLIC4 nuclear translocation in response to Transforming Growth Factor – beta (TGF-beta) but not required for CLIC4 nuclear function. Schnurri-2 is a transcription cofactor in the BMP pathway. However, the physiological functions of CLIC in whole animals level are not well understood, in particular how the genes regulate thermostolerance is largely unknown. To address these issues, we took advantage of viable CLIC mutants in C. elegans and characterized its functions in heat stress and aging. Schnurri-2 is homologous to C. elegans SMA-9 which functions in the DBL-1/TGF-beta pathway. There are two CLIC homologs in C. elegans: EXL-1 and EXC-4. exc-4 mutants develop cysts in the excretory canal, while abnormal phenotypes of exl-1 mutants have not been identified. We analyzed integrated EXL-1::GFP lines in wild type background and observed strong fluorescence in intestinal cells, which is consistent with previous study. EXL-1::GFP indeed is translocated into the nucleus under various heat shock conditions. Supporting functional importance of this, exl-1 loss-of-function mutants are thermosensitive, in compare with wild type animals. Meanwhile, we found that EXL-1, not EXC-4, bears a non-classic Nuclear Localization Signal (NLS). This may explain why exl-1 translocates into the nucleus upon heat stress, while exc-4 still remains in the cytoplasm. Our phylogenetic analysis across evolutionary species shows that duplication of CLICs in protostomes and deuterostomes occurred independently. We also observe that EXL-1 nuclear translocation occurs in a timely ordered manner in the intestine, from

Tuesday-480
posterior to anterior regions. Furthermore, we also generated double mutants of exl-1 and DBL-1/TGF-beta pathway components and will dissect the genetic interactions between exl-1 and the DBL-1 pathway in the future.

**Human Dermal Stem/Progenitor Cell-derived Conditioned Medium Ameliorates Ultraviolet A-induced Damage of Normal Human Epidermal Keratinocytes.**
J. SHIM;
1Faculty of cosmetics and biotechnology, Semyung Univ., Jecheon, South Korea

Purpose: The present study aimed to define the epidermal moisturizing effects of human dermal stem/progenitor cell-derived conditioned medium (hDSPC-CM) on normal human epidermal keratinocytes (NHEKs). Methods: To investigate the epidermal moisturizing effects of hDSPC-CM on NHEKs, I measured 2,2-diphenyl-1-picrylhydrazyl (DPPH) radical-scavenging activity and gene expression and performed cell viability assay and hyaluronic acid (HA)—enzyme-linked immunosorbent assay (ELISA). Results: In the present study, I elucidated the effects of hDSPC-CM on the mRNA expression of hyaluronan synthase 2 (HAS2), aquaporin 3 (AQP3), keratin 1 (KRT1), and keratin 10 (KRT10) and HA production. Real-time polymerase chain reaction (real-time PCR) revealed that hDSPC-CM increased HAS2 and AQP3 expression in NHEKs, and HA-ELISA revealed that hDSPC-CM increased HA production in NHEKs. On the other hand, hDSPC-CM decreased KRT1 and KRT10 expression in NHEKs. Conclusions: The results revealed that hDSPC-CM is a potent moisturizing cosmetic ingredient for epidermal moisturization. Based on this study, I anticipate further studies on mechanisms underlying the effects of hDSPC-CM on epidermal keratinocytes to develop not only cosmetics but also healthcare medicines.

**Crataegus pinnatifida extract increases lifespan of Drosophila melanogaster.**
D. Jung; J. Shim;
1Korea Food Research Institute, Jeongju, Korea, South

*Crataegus pinnatifida* is known to possess various medicinal properties. In this study, we investigated the lifespan-prolonging effects of *Crataegus pinnatifida* extract (CPE) on in vivo using *drosophila melanogaster* and explored its underlying mechanism. We found that CPE significantly extended the lifespan of drosophila melanogaster in both male and female. To elucidate the efficacy of CPE to the longevity, we evaluated the expression of aging related genes, such as atg5, atg8, TRF, and Hep. In addition, CPE improved the antioxidant ability in drosophila by regulating the antioxidant enzymes of superoxide dismutase (SOD), catalase, Thioredoxin (Trx) and hemeoxygenase (HO) in RNA level as well as in protein level. The progress of antioxidant ability was confirmed by prolonged survival time of drosophila melanogaster treated with CPE in H2O2 challenge test. Furthermore, we found that increased lifespan by CPE was associated with increased lipid level and locomotion activity. Therefore, our data suggest that CPE extended the lifespan in *drosophila melanogaster* attributing to exerts upregulating endogenous antioxidant response and at least partially associated with its interaction with increasing lipid level.

Probing mitochondrial dynamics and heterogeneity during cell state switching using multiplexed, environment-sensitive fluorescent dyes.  
S.O. Raja¹, G. Sivaraman², A. Mukherjee³, S. Kataria⁴, C. Jamora⁵, A. Gulyani¹;  
¹Technology for Advancement of Science, Institute for Stem Cell Biology Regenerative Medicine, Bengaluru, India

Mitochondria are known as power house of the cell as they efficiently produce ATP through Oxidative Phosphorylation (OxPhos). Apart from this, mitochondria also play significant role in regulating cellular metabolism, calcium and ROS signaling as well as in programmed cell death. Despite decades on research, precise and real-time information on mitochondrial dynamics and functionality, is still limiting. For example, recently it has been shown that cellular migration during metastasis relies, in part, on mitochondrial motility and precise positioning within the cell. Similarly, morphology and activity of mitochondria are linked with maintenance of stemness as well as triggering of differentiation event. Therefore, unraveling the spatio-temporal localization as well as functional heterogeneity of mitochondria during various cellular states appears to be crucial for understanding the coherent behavior of cell. To better visualize the functional dynamics of mitochondrion, we have developed red-emitting, multi-functional, novel mitochondrial probes that are sensitive to local environment, specifically parameters like viscosity, pH, ROS, etc. The developed dyes have low toxicity and very high photo-stability, allowing their use in long term imaging. In this presentation, we will show these dyes have yielded new insights into mitochondrial dynamics in embryonic stem cells as well as onset of differentiation. In a different example, we have also used our new dyes to probe mitochondrial heterogeneity within primary ‘activated’ cells during cell migration. These results would be placed in the context of our larger efforts to build new ways of probing ‘cellular dynamics’ with a focus on physico-chemical changes in the cell.

Discovery and development of novel antifungal compounds from marine endophytic fungal sources.  
E.J. BLESSIE¹, P.K. ARTHUR²;  
¹West African Center for Cell Biology of Infectious Pathogens, Department of Biochemistry, Cell and Molecular Biology, P.O BOX LG 54 Legon, UNIVERSITY OF GHAHA, ACCRA, Ghana, ²West African center for Cell Biology of infectious Pathogens, Department of Biochemistry, Cell and Molecular Biology, P.O Box LG 54 Legon, UNIVERSITY OF GHANA, ACCRA, Ghana

Discovery of new drugs have shifted from plants to microorganisms due to the enormous diversity. Marine endophytic fungi (MEF) have not been explored as compared to their terrestrial counterparts in the treatment of diseases. We set out to identify and develop novel antifungal compounds from marine endophytic fungi sources using yeast genomics guided approach. To achieve this, isolated marine endophytic fungi (Top 6) were fermented (1-2 litres) and extracted with ethyl acetate after 4 weeks. Crude extracts were tested against S. cerevisiae and C. albicans with majority of the extracts showing activity above 10mm zone of inhibition. Characterization of the crude extracts and fractions were performed against C. albicans, S. cerevisiae and mutant S. cerevisiae. The activities of the crude extracts
were tested under various chemical conditions against S. cerevisiae and C. albicans with most of the extracts maintaining their activities across the chemical conditions. Crude extracts from the selected 6 MEF were fractionated by Kupchan’s solvent partitioning and preparative thin layer chromatography (TLC). The data obtained from this study showed that the extracts possessed distinct activities and were able to maintain their activities even when the cells were under different chemical conditions. A total of 59 active fractions were obtained from the 3 selected MEF after the preparative TLC. It is estimated that 148 active fractions will be obtained after the analysis of all 6 selected MEF. Two of the fractions from MEF 134 were highly active. An HPLC-HRMS full scan was performed on fractions 134FDV5V7 and 134FDV5V9. Both fractions (V7 and V9) had 2 peaks that were similar, all others were different. Preliminary structural elucidation of the compounds identified based on ms/ms showed all structures to be novel. Hence 100 Litre cultures of MEF 134 have been prepared for large scale product isolation.

Remodeling and Visualizing Bacterial Peptidoglycan to Understand Crohn’s Disease.
C.L. Grimes1,2, K. DeMeester1, H. Liang1, Z. Jones1;
1Chemistry and Biochemistry, University of Delaware, Newark, DE, 2Biological Sciences, University of Delaware, Newark, DE

Bacterial cells surround themselves with a peptidoglycan cell wall, an essential structure that resists changes in osmotic pressure and other environmental insults. To a certain degree, the peptidoglycan is also essential to humans as antibiotics target its destruction and fragments activate immune responses. Crohn's disease is believed to arise from a misrecognition of the commensal bacteria that inhabit the human body. Normally, the body recognizes fragments of bacterial cell wall; however in CD this pathway is disabled. Chemical tools to investigate the problem of misrecognition are needed to understand why the innate immune system fails in CD. We have developed novel syntheses of bacterial cell wall fragments, expression systems for mutated innate immune receptors and a series of assays to measure and map binding events. Here we present two independent methods to metabolically label the glycan backbone of the bacterial peptidoglycan and track its breakdown. We have developed the methodology to label and visualize the glycan backbone. As chemists, we are passionate about working with other cell biologists to incorporate this methodology into their projects.

Exploration of a novel cyclic peptide that senses lipid-packing defects.
H. Hirose1; H. Suga1;
1Department of Chemistry, Graduate School of Science, The University of Tokyo, Tokyo, Japan

Regulation of dynamics of cellular membrane is vital for cell functions such as membrane trafficking. Development of the tools to observe or artificially regulate membrane dynamics including membrane curvature and tension will gain novel insights into cellular events. In this study, we have explored a new cyclic peptide to sense membrane curvature, or lipid-packing defects, using a random non-standard peptide integrated discovery (RaPID) system in which cyclic peptides (\(~ 10^{13}\)) can be produced by in vitro translation of mRNA libraries. We used 0.03 μm-filtered DOPC liposomes containing biotin-labeled DOPE as high curvature membrane immobilized on Streptavidin magnetic beads. We selected the peptides that bound to the small liposomes by excluding the peptides that strongly bound to the beads. After several selection cycles, the obtained peptide sequences were analyzed and then the 4 peptides
labeled with nitrobenzoxadiazole (NBD) were chemically synthesized as candidates to sense lipid-packing defects. We carried out NBD fluorescence assay to examine the binding affinity of each peptide to various liposomes with different compositions and sizes. We have found one of the peptides can sense lipid-packing defects. This peptide was consisted of cyclic peptide and tail peptide. The linear peptide without cyclization was less sensitive to lipid-packing defects than the original one. This suggests that cyclic structure could enhance the ability to sense lipid-packing defects. We expect that our findings lead to the development of a novel peptide sensor for membrane curvature in living cells or for small vesicles such as exosomes.

Study of the purinosome in HeLa cells and Caenorhabditis elegans model systems.
O. Souckova¹, V. Bařesová¹, V. Skopova¹, M. Krijt¹, M. Zikanova¹;
¹Institute of Inherited Metabolic Disorders, First Faculty of Medicine, Charles University, Prague, Czech Republic

Objectives: Defects of ADSL and ATIC enzymes of de novo purine synthesis (DNPS) cause two known metabolic disorders – ADSL deficiency and AICAr ibosiduria. This malfunction leads to accumulations of substrates of the affected enzyme and afterwards to unspecific neurological symptoms. Moreover, there is clear disruption of multienzyme complex, purinosome. We decided to prepare human cellular model (HeLa cells) and multicellular model (Caenorhabditis elegans) to study intracellular compartmentalization and formation of purinosome.

Methods: CRISPR-Cas9 method was used to prepare HeLa cells deficient for specific steps of DNPS. The DNPS proteins in HeLa cells were immunofluorescently labeled. The DNPS proteins in C. elegans were fused with fluorescent protein GFP or mCherry. The intracellular compartmentalization of purinosome was observed by fluorescence confocal microscopy.

Results: Deficient HeLa cells for GART, ADSL and ATIC enzymes showed no signal overlap, which suggest the disruption of purinosome formation. HeLa cells deficient for PFAS and PAICS enzymes showed fine granular staining and reduced formation of purinosome compared with control HeLa cells grown in the same conditions. These findings correspond with previous studies, that the structurally intact proteins are important for purinosome assembly. The organism C. elegans with translational reporters of human homologues PPAT::GFP and GART::mCherry appears to be valuable model for study of purinosome formation in vivo. It showed us that the purinosome complex is dynamic structure. Its localization differs in different developmental stages and it is represented in different types of tissues.

Conclusions: We prepared CRISPR-Cas9 genome-edited model HeLa cells and multicellular model organism C. elegans with translational reporters. Both models gave us interesting insights into purinosome assembly and offer us opportunity to furthermore investigate the physiological and pathogenic mechanisms of purinosome formation and regulation.

Bioorthogonal fluorescent probe for molecular imaging of cancer aggressiveness.
H. Erkan1, D. Telci1, O. Dilek2;
1Biotechnology, Yeditepe University, Istanbul, Turkey, 2Biochemistry, Husson University, Bangor, ME

While early stage cancers that were hard to detect can now be analyzed by high content imaging screening and many of these early detected cancers are not life threatening. Although it is possible to detect early stage cancers with appropriate screening methods, some typical lesions are cancer and still cannot always distinguish from the cancers which are not life threatening. Some certain biomarkers are frequently used to detect early stage of some cancer types. However, we still do need better specific markers such as small fluorescent molecules that can tag some of the certain proteins in cancer cells to monitor aggressiveness of the cancer at a molecular level. Likewise, fluorescence imaging is referred to as a “tool” used to detect spatially or temporally resolved cancer cells, tissues and their surroundings. We therefore aim to develop new bioorthogonal imaging agents (fluorophores) using fluorescence spectroscopy for monitoring aggressive cancers and the less aggressive ones. The design of suitable imaging agents for biological labeling requires consideration of both the reactivity of the nucleophilic functional group and good spectroscopic features of the fluorophore. Although newly designed fluorophores do react with carbonyls at neutral pH to form a hydrazone product, the reaction is very challenging. In this work, confocal microscopy was here used to be an effective approach to distinguish two cancer cell lines with different metastatic ability, based on the changes in their fluorophore compositions due to their oxidative stress levels. A moderately metastatic (A498), and an advanced metastatic (ACHN) prostate cancer cell lines were monitored with the newly synthesized fluorophore using confocal microscopy after treatment with certain amount of hydrogen peroxide. The experimental and the analyzed results indicate that confocal microscopy can be used to monitor the changes of the key fluorophores response to carbonylation of various cell lines with different cancer risk levels. The method introduced here may also form the basis of a synthetic small molecule based diagnostics approach to give a new insight in molecular cancer staging.

Structure-activity relationship study for α-dystroglycan binding peptide A2G80 derived from mouse laminin α2 chain sequence.
F. Katagiri1, Y. Fukasawa1, J. Kumai1, K. Hozumi1, Y. Kikkawa1, M. Nomizu1;
1Department of Clinical Biochemistry, Tokyo University of Pharmacy and Life Sciences, Hachioji, Japan

Dystroglycan (DG) is a component of the dystrophin-glycoprotein complex (DGC) in skeletal muscle. DGC is a molecular complex composed of dystrophin and membrane glycoprotein group and forms a structure linking the basement membrane and the actin skeleton. The association of basement membrane-cytoskeleton mediated by DGC is thought to be important for maintaining the strength of the muscle cell membrane which can withstand mechanical stress such as elongation and contraction of the muscle. DG binds with dystrophin directly under the cell membrane, it is bound extracellularly to basement membrane molecules such as laminin and play a role as a molecular axis linking the cytoskeleton and basement membrane. DG consists of two subunits α and β, αDG, which is an extracellular subunit, binds ligands. βDG is a transmembrane subunit, which binds αDG to the cell surface extracellularly, and binds dystrophin within the cell. Laminin is known as a ligand molecule of αDG. Laminins are major components of basement membrane, consists of three different subunits, α, β,
and γ chains, and so far, five α, three β, and three γ chains have been identified. We have constructed the synthetic peptide library derived from the laminin sequences, and identified functional peptides. We have reported that A2G78 (GLLFYMARINHA, mouse laminin α2 chain, 2796-2807) and A2G80 (VQLRNGFPYFSY, mouse laminin α2 chain, 2812-2823) peptides bind αDG [1]. In this study, we investigated the structure-activity relationship of A2G80 to identify the specific residues for binding to αDG. The αDG was rough purified from mouse muscle myoblast cell line C2C12. The A2G80 and its derivative peptides substituted each amino acid residue to alanine were synthesized by Fmoc-solid phase methods, furthermore, the biotinylated peptides of A2G80 and its Ala substituted peptides were prepared. The circular dichroism (CD) spectra of the peptides were measured. The peptides substituted Asn5, Phe7, Pro8, Tyr9, Phe10, and Ser11 for Ala were different spectra to A2G80 peptide. The binding activity was evaluated by enzyme immunoassay using biotinylated peptides and crude αDG. The A2G80 peptide bound crude αDG with dose-dependent manner. The peptides substituted Val1, Gln2, Arg4, Gly6, Phe8, Tyr9, and Tyr12 to Ala lost the αDG-binding activity. From the result of X-ray crystallographic analysis, it is reported that the Gln2 and Arg4 were critical residue for binding to αDG. **Inhibition of osteoclast formation and function by EW33.**

J. LEE¹, G. LEE¹, Y. JO¹, S. HONG¹, H. Lee¹, N. Kim¹, M. Kwon¹, H. Son¹, E. Seo², W. Jeong¹;

¹Life science and the Research Center for Cellular Homeostasis, EWHA womans university, SEOUL, Korea, South, ²College of pharmacy, EWHA womans university, SEOUL, Korea, South

Many bone diseases such as osteoporosis and rheumatoid arthritis are due to an increase in osteoclast number or activity, of which control thus has significant clinical implications. Here, we show that EW33, a natural compound having anti-inflammatory activity, inhibited osteoclast differentiation and function. It inhibited osteoclast differentiation with decreased activation of NFATc1, mitogen-activated protein kinases (MAPKs), Src and CREB. Such effects of EW33 were reversed by co-treatment of hydrogen peroxide, and it also reduced reactive oxygen species by scavenging them or activating Nrf2. In addition, it significantly attenuated the survival, migration and bone resorption of differentiated osteoclasts with decreased expression of RANK, c-Fms, caveolin-1 and p130Cas. Furthermore, it inhibited inflammation-induced bone erosion in the calvaria of mice. These results suggest that EW33 may inhibit osteoclast formation through the redox-dependent regulation of MAPKs, Src and CREB during RANKL-induced osteoclastogenesis, and attenuate osteoclast function by regulating caveolin-1 and p130Cas expression.

**Board Number: B778**

**EW17 inhibits osteoclastogenesis and attenuates the migration and resorption of osteoclasts.**

H. Lee¹, G. LEE¹, Y. JO¹, S. HONG¹, J. LEE¹, N. Kim¹, M. Kwon¹, H. Son¹, E. Seo², W. Jeong¹;

¹Life Science and the Research Center for Cellular Homeostasis, Ewha Womans University, seoul, Korea, South, ²College of Pharmacy, Ewha Womans University, seoul, Korea, South

Excessive number and activity of osteoclast cause many bone disease such as osteoporosis and rheumatoid arthritis. Thus, the control of osteoclast formation and function has significant clinical
implications. EW17 was identified from the screening of phytochemicals inhibiting RANKL-induced osteoclast differentiation. EW17 inhibited the activation of NFATc1 with decreased activation of NF-kB, JNK and Src, and c-Fos expression during osteoclastogenesis. It decreased intracellular reactive oxygen species by scavenging them or activating Nrf2. In addition, it inhibited the migration and bone resorption of osteoclasts with decreased expression of Src, p130Cas and caveolin-1. Moreover, it inhibited inflammation-induced bone erosion in mouse calvariae and ovariectomy-induced bone loss in mice. These results suggest that EW17 may inhibit osteoclast differentiation by regulating NF-kB, JNK and Src through the control of redox status and attenuate osteoclast function by regulating Src, p130Cas and caveolin-1 expression, and support its therapeutic potential for treating bone diseases caused by moderate osteoclast activity.

The study reports biological derived synthesis of gold nanoparticles using marine bacterial isolates of Arabian Sea, Karachi. The isolates were identified as Vibrio alginolyticus, V. natrigens, V. campbelli and Bacillus aquimaris using 16S rRNA gene sequence similarity. The synthesized nanoparticles showed a prominent peak at 550 nm; with SEM image result analysis showing particles within the range of 85-200 nm. Particles of diverse shapes were visible from the SEM image analysis. Most of the particles generated were elliptical or oval with abundance of spherical shaped nanostructures however, a few triangular shaped particles were also visible from SEM images of B.aquimaris with maximum size of 118 nm and smallest particle of 85 nm. The EDX further confirms the particles to be of gold with one prominent peak visible at 2 KeV while three to four smaller peaks are also visible around 8 and 9 KeV. The in vitro cytotoxicity studies of biosynthesized gold nanoparticles against leukemia cell line show the particles to be of non toxic nature with no effect on cell morphology or cell viability making them ideal targets for delivery of genes or drugs as well as bioimaging tools.

Purification of an exceptionally resilient and long-lived orange fluorescent protein from the Gulf anemone Calliactis tricolor.
K.M. Hart1, R. Lawson1, D. Boggio1, H. Flurry1, K. Helbert1, A.G. Moss1;
1Biological Sciences, Auburn University, Auburn, AL

Green fluorescent protein (GFP) was one of the most useful discoveries of the 20th Century, due to its subsequent use in cell and molecular tagging applications, resulting in three Nobel Prizes in 2008 (Noble Media AB 2014). GFP and similar proteins, including anthozoan fluorescent proteins, have been used in numerous research efforts to probe cellular structure and function since its introduction. We have discovered a similar protein in a variant of the common anemone, Calliactis tricolor, from the Alabama Gulf Coast, which, unlike other anthozoan fluorescent proteins (Curr. Opin. Chem. Biol. 20:92; Curr. Opin. Biol. 12:505), is extraordinarily long-lived and resilient. In February 2014 and 2015, anemones were collected by trawling at a depth of 8 to 20 m south of the Mobile Bay Entrance. The anemone’s mouth and mesenteries produce intense orange fluorescence, peak emission at 510 nm and 570 nm when illuminated by blue light at 500 nm and 540 nm. Illumination at 490 nm gives the perception of
brilliant orange fluorescence. The protein appears to be freely associated with the cytoplasmic space of mesentery cells; purification of the protein from a cleared cytosolic homogenate by 5-20% sucrose gradient rate-zonal centrifugation yields a ~10S trimeric quaternary complex with three bands at 31, 25 and 10 kDa as revealed by SDS-PAGE. LC-MS/MS reveals that the fluorescence moiety is novel and has effectively no homology to any previously known fluorescent protein; moreover the fluorescent group is found only in the largest subunit. Ongoing whole genome analysis and differential transcriptomic analyses seek to reveal genome organization and appropriate regulatory elements and should provide data for future incorporation of this group into cellular probes. Our work reveals that this is a very easy to purify, resilient and easily handled protein, albeit limited currently by availability of the host, which has been impacted by heavy rainfall in the collection area. Funded by the Office of the Provost and the Office of the Vice President for Research and Economic Development, Auburn University.

A chemical-genetic toggle switch for phosphorylation events applied to Plk1 signaling.
J.M. Johnson1,2, Q. Drane1,2, M.E. Burkard1,2;
1Department of Medicine, Hematology/Oncology Division, University of Wisconsin-Madison, Madison, WI, 2University of Wisconsin Carbone Cancer Center, University of Wisconsin-Madison, Madison, WI

Protein kinases are a large family of enzymes that regulate pathways through phosphorylation of threonine, serine, or tyrosine phosphoacceptors. Yet, untangling these signaling networks proves challenging as most kinases are pleiotropic, with large numbers of molecular targets and functions. It is not currently possible to chemically control a single phosphorylation with tight temporal control. Here we describe a chemical-genetic toggle switch for serine/threonine kinases that allows for control of a particular phosphorylation event. This is accomplished by regulating phosphoacceptor preference, allowing threonines to be chemically controlled while serines remain phosphorylated. We demonstrate this system in RPE1 cells using polo-like kinase 1, a pleiotropic and essential mitotic kinase. We first generated Plk1S and Plk1T alleles, selective for serine or threonine phosphoacceptors, respectively, by mutating sites in the phosphopeptide interface that engage the substrate. We verified Plk1S (L197F) and Plk1T (L197S/L211A) as phosphoacceptor-specific mutants through in vitro kinase assays with purified substrates containing S, T, or both S/T as phosphoacceptors. To evaluate phenotypic effects, these constructs were used to complement a cell line driven by Plk1as, which can be chemically controlled by 3-MBPP1 without affecting Plk1S or Plk1T. Neither Plk1S nor Plk1T were sufficient to restore all essential mitotic functions of Plk1, as cells failed to proliferate by comparison with either phosphospecific allele. Surprisingly, however, Plk1T is sufficient to restore mitotic progression to anaphase, but is unable to restore essential roles of Plk1 in cytokinesis. By contrast, Plk1S was unable to restore any kinase functions surveyed, suggesting that threonine phosphorylations have less functional significance. To demonstrate the ability to toggle phosphorylations from always on (S) to chemically controlled (T), we expressed the motor protein Kif2b47, in which 4 serine phosphoacceptors are mutated to threonines. As predicted, expression of Kif2b47 with Plk1S yields a chemical-genetic toggle switch where Kif2b can now be chemically controlled. When switched off, there is a sharp increase in the frequency of misaligned chromosomes, attributable solely to this particular phosphorylation event. These findings demonstrate a method whereby specific phosphorylations are designated to specific functions in a temporally controlled manner, eliminating confounding factors associated with overexpression of non-phosphorylatable mutants. While we have applied this technique to Plk1, it can in principle be used to chemically control any desired S/T phosphorylation event to more clearly define kinase-signaling networks.
Development of protein tools to study receptor clustering on cell membrane.

D. Song\textsuperscript{1}, Y. JUNG\textsuperscript{1};
\textsuperscript{1}Chemistry, KAIST(Korea Advanced Institute of Science and Technology), DAEJEON, South Korea

Receptor proteins freely move membrane and convert extracellular stimuli into intracellular responses by spatial arrangement that brings receptor clusters. Receptor clustering on cell membrane is one of the key mechanisms underlying cellular signal transduction, so understanding it is crucial to illuminating the function of biological systems. Despite of the significance, visualizing receptor clusters in detail have been obscure because it requires the use of methods that reveal both molecular and supramolecular in sub-nanometer level. We engineered protein tools, ‘Membrane (M) -BiFC’, based on BiFC (Bimolecular Fluorescence complementation) to visualize and control the receptor clustering. BiFC is one of the most widely used tools for direct visualization of protein-protein interactions in living cells. The strategy of BiFC is to split a fluorescent protein into two non-fluorescent fragments at the proper site. A fluorescent complex is formed when two proteins (that are fused to fragments of a fluorescent protein) interact with each other. The interaction between the fusion proteins leads the association of the fluorescent protein fragments. However, the main limitation of current BiFC assays is a low signal to noise ratio caused by self-assembly between the two non-fluorescent fragments. It contributes to false-positive fluorescence, which makes data interpretation difficult. Here, we developed new BiFC systems, ‘M-BiFC’, which have low self-assembled properties for studying receptor clustering on cell membrane. Charged superfolder GFP and Venus (mutation form of YFP) proteins were engineered to form M-BiFC fragment pairs. SpyCatcher-Spytag and Calmodulin-M13 binding pairs were used for specific protein-protein interactions of fused proteins. Various Split pairs of charged sGFP as well as Venus proteins were tested for reduced false-positive fluorescence during overexpression in bacterial cytosols. After then we applied M-BiFC to membrane system of mammalian cell. We demonstrate M-BiFC offers new scaffold to enable visualization of the clustering of diverse transmembrane receptors including Death receptor, GPCR(G protein coupled receptor) and integrins in multiple cell types.
ions are observed, which indicate a bidentate NO3- coordination [2]. The molar conductivity (65 S-cm2-mol-1) of the cobalt chloride complex with IQ-1 gives an evidence for the presence of one chloride ion in the outer sphere. The other complexes showed low values of molar conductivity, indicating the absence of an outer sphere. Cu(II) complexes demonstrated the highest superoxide dismutase (SOD)-like activity in a murine bone marrow leukocytes, generated superoxide anion, with IC(50) values in the nanomolar range.

Oxidative stress is the result of an imbalance between pro-oxidant and anti-oxidant species inside the body. An excess of reactive oxygen species (ROS) introduces covalent modifications in proteins, lipids and DNA altering their structure and function. These covalent modifications are a result of oxidation and introduce an aldehyde or ketone functional group on the biomolecule, which is referred to as carbonylation. We have shown previously that a coumarin fluorophore, containing a hydrazine functional group, may be used to probe these carbonylated biomolecules in live cells. This fluorophore, however, has limited versatility such as high excitation energy, photobleaching, and low brightness. In order to improve upon these, a novel hydrazide containing fluorophore has been synthesized that is able to conjugate to the carbonylated biomolecules in live mammalian cells. This probe can be excited in the lower energy green fluorescent protein (GFP) channel, which is common to many fluorescence microscopes. Furthermore, the quantum yield of the molecule undergoes a large increase upon covalent conjugation with aldehydes and ketones. The fluorophore is resistant to photobleaching and is therefore a promising probe for observing the fate of carbonylated biomolecules in live cells and for use in high-throughput and high-content cellular assays for the detection of protein and lipid carbonylation.

Polymeric Particles for the Control Release of Bioactive Molecules to PC12 Cells.
P.M. Gehret¹, R. Hoff¹, L.P. Kelly¹, W.H. Suh¹;
¹Bioengineering, Temple University, Philadelphia, PA

The demonstration of a molecular delivery system that consistently releases a protein to mammalian cells is of special interest for the elimination of experimental errors. Researchers could use protein loaded microspheres instead of retreating the cells with solubilized protein solutions every or every other day. PC12 cells, derived from rat pheochromocytoma, are a common cell type used to model neuronal differentiation [1] and we specifically tested our microspheres using PC12 cells. This cell line will grow neurite-like outgrowths when exposed to NGF (nerve growth factor) [2]. Prior to protein encapsulation, we tested the encapsulation methodology on two model small molecules. Ibuprofen, a household anti-inflammatory drug, and retinoic acid, a bioactive lipid, were encapsulated in polylactic acid (PLA) microspheres. The release profiles of these molecules and their biocompatibility details were acquired and quantified. Next, we prepared PLA microspheres incorporating a dye-labeled protein via the double emulsion synthesis method to demonstrate the encapsulation proteins in PLA microspheres. We envision expanding our work to further include other non-fluorescent but bioactive proteins such as NGF. This presentation will focus on microsphere synthesis and characterization with and without PC12 cells and with and without encapsulated molecules. Quantitative and statistical analysis results will include live-cell microscopy data.

Cholic Acid Conjugation as a Tool for Enhancing Intracellular Delivery of Linker-Extended Constructs.
R. Bhadoria¹, K. Ping¹, P. Starkov¹;
¹Dept of Chemistry Biotechnology, Tallinn University of Technology, 12618, Estonia

Chemical tagging of biologically active entities is instrumental to the research at the interface of chemistry, biology and biomedicine. Such tools deliver reliable ways to study existing, discover novel and molecularly engineer new variants of mechanisms of action for a plethora of chemical probes, including small molecules, gene products and conjugates thereof. A major challenge when designing probes that bear additional functionality is their decreased cellular uptake, which is essential for probes aimed at intracellular targets. The extension of a given probe by a polyethyleneglycol (PEG) or other linker often results in strongly diminished or no intrinsic biological activity. To address this challenge, we report that direct conjugation to cholic acid derivatives serves as a useful tool in overcoming decreased biological activity of the linker-extended constructs. Moreover, we systematically explore structure–activity relationships of cholic acid conjugation using cell biological assessment of the constructs targeting three unrelated targets to demonstrate the potential utility of this approach.

Identification of natural compounds that alter myoblast cell cycle kinetics.
J.N. Kidrick1, S.E. Johnson2;
1Animal and Poultry Sciences, Virginia Polytechnic Institute and State University, Blacksburg, VA

It is common in the elderly to experience sarcopenia, a loss in muscle mass. There are many different possibilities of treatment; many of which are currently on the market, but none of the pharmaceuticals are completely efficient. Increasing muscle mass is perceived as the main therapeutic route to remediate this disorder. To increase muscle mass, there is a requirement for proliferation, differentiation, and fusion of muscle stem cells, also known as satellite cells, allowing for the formation of new muscle. The objective of this study was to identify nutraceuticals that can promote proliferation in satellite cells. We used a mouse satellite cell line, C2C12, to screen 133 natural compounds to observe any potential increase in proliferation. A thymidine analog, EdU, was used to monitor progression into S phase of the cell cycle and MTT, a tetrazolium dye, was used to report cell number. The usage of both EdU and MTT allows for an overall view of cell proliferation in high-serum media (growth media; HSM) or low-serum media (arrest media; LSM). Andrographisolide is one of a few compounds that decreased (P = 0.02) C2C12 proliferation when cultured in HSM. Morphological assessment coupled with EdU incorporation and MTT mitochondrial activity suggest the cells suffered from growth arrest at either G1 or S phase. By contrast, indole-3-carbinol inhibited (P = 0.01) proliferation of the C2C12 cells in LSM but had no effect on cells cultured in HSM. Additional compounds, such as berberine chloride, were identified to have the ability to alter mitochondrial activity independent of the cell cycle indicating a metabolic effect. Overall, our data demonstrate that natural compounds can inhibit or stimulate proliferation of C2C12 cells and affect metabolic function. Ongoing studies are examining the direct effect of the compounds on satellite cell bioactivity in vivo with the goal of increasing muscle in mice suffering sarcopenia or muscular dystrophy.

Research in the molecular mechanism of coagulation activity of sulfur-containing monoterpenoids of pinane series.
Z.R. Azizova1, S.V. Kiselev2, L.E. Nikitina2, V.A. Srartseva2, V.V. Klochkov3;
1General Pathology Department, Kazan State Medical University, Kazan, Russia, 2General and Organic Chemistry Department, Kazan State Medical University, Kazan, Russia, 3Institute of Physics, Kazan Federal University, Kazan, Russia

Currently we have synthesized a series of sulfur-containing terpenoids of varied structure with the large set of the functional groups. Previously we have already revealed antifungal, anti-inflammatory, anti-helicobacter, antimicrobial and other types of activity of sulfur-containing monoterpenoids. Sulfoxide synthesized on the basis of naturally occurring monoterpene (-)-β-pinene was investigated for its coagulation properties. The possibility of using sulfoxide for correction of hemostasis was determined in vitro on human blood plasma obtained from healthy donors not taking antiplatelet and anticoagulant medications. The anticoagulant activity of sulfoxide was measured by activated partial thrombosis time, thrombin time and prothrombin time. As a result of a study it was shown that the sulfoxide of pinane series in contrast to acetylsalicylic acid and clopidogrel completely inhibited activation of platelets induced by adrenaline, collagen and arachidonic acid and also reduced the effect of ADP and ristomycin. Arachidonic acid, in contrast to other inducers, is known to activate platelets directly penetrating into

Tuesday-492
the cell and reducing cyclic adenosine monophosphate concentration. The loss of this property in the presence of sulfoxide is explained by changes in permeability of platelet membranes associated with formation of additional intermolecular interactions between hydrophobic parts of the thieterpenoid molecules and the phospholipids of the membrane. Integration of the hydrophobic part of sulfoxide molecule into the cell membrane stabilized it and prevented using the molecules of phosphatidylcholine from the external layer of membrane as a formation source of lipid peroxidation products, which would lead to initiation of platelet aggregation mechanisms. Detailed NMR studies and molecular dynamics simulations using SDS membrane models indicated that the bicyclic fragment of sulfoxide was embedded in the SDS micelle whereas the -SO(CH2)2OH fragment remained on the surface of the micelle contacted with the solvent. It was demonstrated that the coagulation activity of sulfoxide was due to its ability to inhibit platelet activation and suppress the catalytic activity of phospholipid surface. The cell membrane was stabilized by van-der-Waals interactions of sulfoxide with phospholipids of the external layer which was involved in formation of coagulation clotting factor complexes. Considering the low toxicity, the ability to block induced and spontaneous aggregation, sulfur-containing terpene compounds are promising agents with possible use for platelet blood products stabilization, treatment and prevention of thrombophilia.

**Src oxidation directs cell polarity to promote rapid embryonic wound healing.**

M.V. Hunter¹, J. Woszczyk³, P. Laprise³, R. Fernandez-Gonzalez¹,²,⁵,⁶,

¹Cell and Systems Biology, University of Toronto, Toronto, ON, ²Ted Rogers Centre for Heart Research, University of Toronto, Toronto, ON, ³Centre de Recherche sur le Cancer, Université Laval, Quebec, QC, ⁴Oncologie, Centre de Recherche du CHU de Québec - Université Laval, Quebec, QC, ⁵Biomedical Engineering, University of Toronto, Toronto, ON, ⁶Developmental and Stem Cell Biology Program, Hospital for Sick Children, Toronto, ON

Embryos exhibit a striking ability to rapidly repair wounds without inflammation or scarring. Embryonic wound healing is a conserved process, driven by redistribution of the cytoskeleton and cell-cell junctions around the wound. Immediately after wounding, both actin and the molecular motor myosin become polarized in the cells around the wound, accumulating at the wound margin to form a supracellular cable. The rapid contraction of this cable draws the surrounding cells together to close the wound. We recently showed that polarized endocytosis of the junctional protein E-cadherin from the wound margin is a prerequisite for actomyosin cable assembly and wound closure. However, the upstream signal that triggers redistribution of junctions and the cytoskeleton around wounds is unknown. Using quantitative time-lapse microscopy in *Drosophila* embryos, we measured a burst of reactive oxygen species (ROS) production immediately after wounding, exclusively in the cells that are eventually enclosed by the actomyosin cable. Blocking ROS production significantly inhibited wound healing, and severely impaired junctional trafficking and actomyosin accumulation around the wound. Together, our results suggest that ROS production drives wound healing by promoting E-cadherin trafficking and subsequent polarized actomyosin assembly. ROS can post-translationally modify proteins by oxidizing electron-rich cysteine residues. The *Drosophila* ortholog of Src kinase, Src42A, contains several putative redox-sensitive cysteines, and has been implicated in E-cadherin trafficking during morphogenesis. Src42A⁴⁷¹ is a conserved cysteine that is oxidized in zebrafish leukocytes upon wounding. We mutated Src42A⁴⁷¹ to generate an oxidation-resistant form of Src42A (Src42A⁴⁷¹). Src42A⁴⁷¹ exhibited reduced kinase activity in
vitro, and, importantly, embryos expressing Src42A	extsuperscript{OR} displayed impaired wound healing. We are currently investigating the phosphorylation targets of Src42A and how Src activation promotes wound healing. We propose that ROS act as a critical wound signal, orchestrating the polarity of junctions and the cytoskeleton through Src to drive rapid wound healing.

Actomyosin-based basal protrusions drive long range lateral inhibition via dynamic cell-cell contacts during epithelial tissue patterning.

G.L. Hunter	extsuperscript{1,2,3}, L. He	extsuperscript{4}, N. Perrimon	extsuperscript{4}, G. Charras	extsuperscript{5}, B. Baum	extsuperscript{2,3}, E. Giniger	extsuperscript{1};

\textsuperscript{1}National Institute of Neurological Disorders and Stroke, Bethesda, MD, \textsuperscript{2}MRC-LMFB, University College London, London, United Kingdom, \textsuperscript{3}Institute for the Physics of Living Systems, University College London, London, United Kingdom, \textsuperscript{4}HHMI, Dept of Genetics, Harvard Medical School, Boston, MA, \textsuperscript{5}Dept of Cell Dev Biology, University College London, London, United Kingdom

Here we investigate (1) the nature of cell-cell contacts mediated by basal cellular protrusions, and (2) whether the retraction of cellular protrusions and cortical tension generated by the actomyosin cytoskeleton contributes to the mechanical forces required for Notch signaling. Dynamic, actin-based cellular protrusions (e.g., cytonemes) mediate cell-cell signaling across several species and signaling paradigms, including Notch signaling, a conserved mechanism that drives cell fate determination. Activation of Notch receptor by Delta ligand requires a pulling force in ligand expressing cells. The pulling force required for Notch activation between neighboring cells is proposed to be generated through ligand endocytosis, but it is unclear how activation occurs via protrusions. (1) We use bristle patterning in the Drosophila notum as a model system for studying protrusion-mediated signaling. Notum epithelial cells radially extend long, actin-rich protrusions from their basal surface that contact cells > 10 microns away (i.e., distant neighbors). At the level of individual protrusions, we quantify cycles of extension/retraction in these dynamic, unbranched structures. Using GRASP and EM, we observe that contact between protrusions extends along their entire length, and that both Notch receptor and Delta ligand localize to areas of contact. We show that protrusions interact in dynamic ‘foci’, making complex contacts between several neighboring cells, which contribute to a gradient of cell response in the tissue. (2) Next we address the role of actomyosin contractility in Notch signaling. Using a genetic approach, we find that contractility is required in ligand and receptor expressing cells for bristle patterning. Expression of constructs aimed to decrease myosin activity lead to defects in bristle precursor cell spacing, indicative of defective protrusion-based Notch signaling. Expression of a transcriptional reporter of Notch signaling shows that loss of contractility in ligand expressing cells is sufficient to decrease Notch response in adjacent and distant cells compared to controls. Epistasis experiments in vivo and in cell culture suggest contractility drives Notch signaling in parallel with endocytosis. We find that moderate loss of myosin activity decreases tissue tension but does not affect protrusion morphology or ligand endocytosis, whereas strong loss of activity leads to irregularly shaped protrusions. Treatment of notum explants with Rho kinase inhibitor to decrease contractility similarly did not affect protrusion formation, but inhibited movement of contractile foci of interacting protrusions. Our results support a model in which actomyosin contractility in protrusions and at the cell cortex is required for Notch activation in vivo.

Erk-dependent control of epithelial morphogenesis.
H.E. Johnson, S.Y. Shvartsman, J.E. Toettcher; 1Molecular Biology, Princeton University, Princeton, NJ, 2Chemical and Biological Engineering, Princeton University, Princeton, NJ, 3Lewis–Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ

The role of Ras/Erk signaling in cancer, growth, and differentiation has long been appreciated. In contrast, the roles of Erk signaling in cell motility, collective cell migration, and tissue-level morphogenesis are complex and remain poorly defined. Here, we set out to define the Ras/Erk pathway’s role in orchestrating collective cell movement during gastrulation in the early Drosophila embryo. Using an optogenetic input to Ras, we found that Erk activity is sufficient to induce cells to adopt a contractile cell fate at nearly any illuminated location within the embryo. This tissue mimics gene expression and physical organization of the posterior midgut (PMG), a tissue normally patterned by the Torso receptor tyrosine kinase. We define the transcriptional network by which Erk programs PMG cell fate, leading to the accumulation of apical myosin and tissue contraction at gastrulation. By systematically varying the timing and duration of Erk activity, we define the spatiotemporal features of the Erk signal that is required to program these fates. We find that the early embryo responds to the cumulative load of Erk activity delivered over a two hour window in early embryogenesis, revealing a previously unknown long-term memory of signaling that spans multiple nuclear division cycles. Our work mechanistically defines an Erk-dependent cell fate choice and establishes a model system for interrogating how signaling pathway activity can program morphogenesis in vivo.

Unraveling multiciliated ependymal cell identity: Ubiquitin-proteasome and IKK2 control Foxj1 stability.
K.M. Abdi, J. Pyun, C.T. Kuo; 1Department of Cell Biology, Duke University, Durham, NC

Cellular differentiation and identity is often coupled to the presence of specific organelles and typically driven through genetic programming. For instance, proper multiciliated cell function requires a highly differentiated state that includes numerous motile cilia and polarized epithelial-like morphology. Multiciliated ependymal cells line brain ventricles, promote cerebrospinal fluid (CSF) flow, and form a barrier between CSF and the brain parenchyma. Foxj1 is an evolutionarily conserved transcription factor required for the development of multiciliated cells from Xenopus to mammals. Here we show that continued Foxj1 expression is required to maintain differentiation of mature multiciliated ependymal cells. Upon tissue-specific deletion of Foxj1 from mature animals, ependymal cells undergo multicilia loss, develop radial-glial-like basal projects that contact blood vessels, and re-enter the cell cycle. Environmental insult such as growth factors and viruses induce Foxj1 protein loss, dedifferentiation, and hydrocephalus. Live imaging combined with lineage tracing captures stages of ependymal transformation and cell division, while recovery experiments reveal a capacity for ependymal cell self-renewal. Surprisingly, we find that Foxj1 protein is inherently unstable and continually degraded by the ubiquitin-proteasome through activity of cullin-RING E3 ligases. Foxj1 stability is regulated by a highly conserved and protein stabilizing IKK2 phospho-site. Thus we uncover opposing IKK2 and cullin-RING
ligase pathways that regulate FoxJ1 and ependymal stability. These results have important implications for hydrocephalus research and post-translational control of cellular differentiation.

Nopo, the Drosophila ortholog of the microcephalic primordial dwarfism gene TRAIP, encodes a centrosomal E3 ubiquitin ligase specifically required for mushroom body development. R.S. O'Neill, B.J. Galletta, C.J. Fagerstrom, N.M. Rusan;

1Cell Biology and Physiology Center, National Heart, Lung, and Blood Institute, Bethesda, MD

Primary microcephaly and microcephalic primordial dwarfism (MPD) are a spectrum of genetic disorders characterized by reduced brain size and, in MPD, reduced body size. Most known primary microcephaly and MPD genes function at centrosomes or in DNA damage response (DDR). While some functional connections between centrosomes and DDR have been established, it is likely that a deeper and more direct link is at play. We believe that primary microcephaly and MPD genes are opportune candidates for uncovering functional connections between centrosomes and DDR pathways and, more generally, how these functions impact neurodevelopment. As part of a large screen for neurodevelopmental defects, we homed in on TRAIP, an MPD gene encoding an E3 ubiquitin ligase known to regulate DDR and apoptosis. Interestingly, the Drosophila melanogaster ortholog nopo (no poles) was named for its loss-of-function phenotype of acentrosomal spindles, suggesting that this DDR gene might function at centrosomes. We performed yeast two-hybrid analysis to reveal extensive interactions between Nopo and several core centrosome proteins, including Sas4, Ana2 and Plk4. Thus, we have established another potential link between a DDR gene and the centrosome. To explore the role of nopo in neurodevelopment, we analyzed both larval and adult brains from nopo mutant animals. We discovered that loss of nopo leads to defects in the mushroom body (MB), a brain region critical for memory formation. Nopo mutant α and β MB lobes are thin, fused, and are often missing. Axon guidance is also abnormal in nopo mutants as we find many misguided MB axons. Our studies of mutants for bendless, which encodes an E2 conjugating enzyme previously shown to interact with Nopo, reveal that 100% of MBs are fused, suggesting that Nopo functions with Bendless to ensure proper brain development and prevent MPD. We are currently focused on identifying the ubiquitination substrates of Nopo required for MB development; candidates include Nopo direct binding partners at the centrosome. Together, this work reveals an exciting new link between the DDR and the centrosome bridged by nopo. Furthermore, we have established D. melanogaster as a new model for understanding the role of TRAIP in neurodevelopment.

Negative feedback loops protect stem cell progenitors’ identity and architecture during embryonic skin development.

I. Matos, A. Asare, J. Levorse, E. Fuchs;

1The Rockefeller University, New York, NY

Adult stem cells (SCs) are long-lived and can self-renew and differentiate to replenish the tissues where they reside. They exist in specialized niches, where they often remain quiescent until they are needed for homeostasis and wound repair. Their precise spatial organization and tight regulation of proliferation are essential to generate and maintain the complex architecture of adult tissues. The formation of SC niches and regulation of SC behavior by local signals are essential for the proper functioning of organs
and fundamental to the organism’s health. However, despite intensive investigation, it remains obscure how SC progenitors are embryonically specified in space and time, how they occupy their position, and how they dynamically interact with their neighbors while maintaining their own identity. We successfully developed innovative ex-utero live imaging, and together with immunofluorescence and in utero lentiviral transduction we showed that in developing hair buds, SCs are born from asymmetric divisions that differentially display WNT and SHH signaling. Displaced WNT low suprabasal daughters become SCs that respond to paracrine SHH and symmetrically expand. By contrast, basal daughters remain WNT high. Here we show that basal daughters use negative feedback loops to keep their number and identity. This is fundamental to distinguishing them from their immediate neighbors, preserving their identity, promoting hair follicle morphogenesis and surveilling epithelial architecture.

The interaction between calreticulin and Wnt/β-catenin signaling induces hair follicle neogenesis.
A. Tellechea¹, S. Levental¹, U.M. Pandya¹, C. Egbuta¹, L.I. Gold¹;
¹Medicine and Pathology, New York University School of Medicine-Langone Medical Center, New York, NY

Topical application of calreticulin (CRT), an endoplasmic reticulum stress response chaperone protein, to wounds in pig and diabetic mouse models profoundly enhances the rate and quality of cutaneous wound healing. Interestingly, wounds treated with CRT are repopulated with dermal appendages, including neogenic hair follicles; this has not been observed in adult mammals following full-thickness wound injury. In mice, we show evidence of hair follicle neogenesis in the neodermis as early as 3 days post-injury. Notably, hair follicle neogenesis has been shown to be dependent on the Wnt pathway. In addition, genetic deletion of CRT results in disruption of canonical Wnt signaling and thus, decreased downstream β-catenin transcriptional activity. Therefore, we hypothesized that CRT is critical for inducing stem cell differentiation for hair follicle neogenesis. However, a direct and/or indirect relationship between Wnt/β-catenin and CRT signaling has not been investigated. Our studies show that CRT treatment increases nuclear localization of β-catenin, and induces Wnt/β-catenin signaling in Human Foreskin Fibroblasts (HFFs) transfected with a vector containing β-catenin/Tcf/Lef binding sites linked to a Luciferase reporter gene. Moreover, inhibition of glycogen synthase kinase 3 beta (GSK3β), which targets β-catenin for proteasomal degradation, with lithium chloride enhances CRT-mediated increase in nuclear β-catenin by 3-fold. Furthermore, CRT dose-dependently induces Wnt5a, 10a, 10b, and FGF9 mRNA expression, as well as Wnt3a protein expression, all of which have been shown to be involved in hair follicle neogenesis. Accordingly, in CRT-treated mouse wounds, Wnt5a, β-catenin, and LRP-1 (CRT receptor) were expressed by day 7 post-wounding. Interestingly, treatment of CRT-null mouse embryo fibroblasts (MEFs) with exogenous CRT failed to upregulate mouse Wnt ligand (WLS/GRP177) mRNA whereas wild-type MEFs were responsive, suggesting that intracellular CRT is required for Wnt induction by exogenous CRT. Additionally, the treatment of HFFs with a Wnt agonist dose-dependently increased both CRT mRNA and protein levels indicating a reciprocal feedback effect between CRT and Wnt signaling. Whereas we show that CRT treatment induces hair follicle neogenesis via the Wnt pathway, transgenic mice expressing constitutively active β-catenin in the dermis have less hair follicles, increased dermal thickening and fibrosis post-wounding. Taken together, these findings suggest a complex mechanism by which CRT interacts with the Wnt/β-catenin pathway to modulate wound regeneration and hair follicle neogenesis. Revealing this mechanistic interaction may lead to the development of potential therapies for wounds, degenerative skin conditions, and hair loss.

Zebrafish models of RASopathies: the impact of PTPN11 mutations on early embryogenesis.
V.L. Patterson1, S.Y. Shvartsman2,3, R.D. Burdine1;
1Molecular Biology, Princeton University, Princeton, NJ, 2Chemical and Biological Engineering, Princeton University, Princeton, NJ, 3Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ

Mutations that activate the RAS/ERK signaling pathway contribute to human disease; de novo somatic mutations in pathway components cause cancer, while mutations transmitted through the germline cause a spectrum of developmental disorders, collectively termed RASopathies. PTPN11 missense mutations cause either Noonan Syndrome (NS) or Noonan Syndrome with Multiple Lentigines (NSML). NS patients exhibit congenital heart defects, craniofacial malformation, neurocognitive delay and an increased predisposition to cancer. NSML patients display the same symptoms, with the addition of lentigines – freckle-like lesions – and sensorineural deafness. While NS mutations increase the phosphatase activity of PTPN11 by destabilizing the inactive conformation, NSML mutations decrease phosphatase activity but cause sustained pathway activation. Modeling the comparative impact of these mutations could be informative for predicting symptom risk in patients. Using transient overexpression of variant PTPN11, we have compared the strength of patient mutations as measured by the effect upon early embryogenesis in zebrafish. The aspect ratio of the 11 hpf-old embryo provides a convenient readout of pathway activity, with stronger mutations presenting an increasingly oval morphology due to defects in convergence and extension. Injected embryos are also shorter at 3 dpf, display craniofacial malformations at 5 dpf and exhibit heart defects, reduced heart rate and cardiac edema, phenocopying many of the characteristic symptoms of NS and NSML. We have performed quantitative analysis and generated a rank of mutation impact for each phenotype. Intriguingly, preliminary data suggest that the rank of mutation strength generated at 11 hpf is not predictive for phenotype severity at later stages, indicating that mutations may differentially impact the development of distinct structures.

Interplay of ubiquitination and palmitoylation in trafficking of Fat-Hippo signaling pathway components.
J.R. Misra1, K.D. Irvine1;
1Waksman Institute, Rutgers University, Piscataway, NJ

Proper coordination of growth and morphogenesis during development is critical to formation of appropriately proportioned organs. The evolutionarily conserved protocadherins, Dachsous (Ds) and Fat constitute a signaling pathway that coordinates growth and morphogenesis by regulating the Hippo pathway and planar cell polarity (PCP) respectively. The atypical myosin Dachs is a key downstream effector of Fat signaling that mediates both of these effects and apical localization is critical for Dachs function. Fat regulates growth and PCP by modulating the levels and polarity of Dachs at the apical membrane. However, how Dachs localization is regulated is not well understood. A palmitoyl transferase, Approximated (App) is required for proper Dachs localization. But the exact mechanism by which it regulates Dachs is unknown. Recently, I have identified a novel gene, Vamana (Vam), which encodes an SH3 domain containing adapter protein that plays a critical role in apical membrane localization of Dachs. Further, Vam functions as an adapter by physically connecting Dachs to Ds and Fat. In order to identify additional regulators of this signaling pathway, I conducted a genetic screen using
RNAi targeted against the ubiquitin ligases encoded by the Drosophila genome and isolated a novel RING domain E3 ligase, Elgi, which when depleted results in tissue overgrowth and PCP defects, phenotypes reminiscent of mutations in Fat signaling. At the cellular level, depletion of Elgi results in significant increase in Dachs and Vam levels. Interestingly expression of a dominant negative Elgi results in failure of Dachs and Vam to localize to the apical cortex and their accumulation in the cytoplasm in punctate structures. Similar accumulations are observed when Elgi and App are depleted simultaneously. These accumulations are reversible in nature and do not arise from concentration dependent phase separation of misfolded proteins. Further localization analysis revealed that they arise from trafficking defect in Dachs, where it is observed to traffic in random directions instead of trafficking apically. Taken together these results indicate that Elgi and app coordinately regulate the trafficking of Dachs and Vam to the apical membrane. Our current efforts are aimed at elucidating the mechanism by which loss of Elgi and App disrupt the vectorial trafficking of these key effectors of Fat-Hippo signaling.

**Fish scales dictate the pattern of adult skin innervation.**  
J.P. Rasmussen1, N. Vo1, A. Sagasti1;  
1Molecular, Cellular and Developmental Biology, University of California, Los Angeles, Los Angeles, CA

The skin is profusely innervated by axon endings of touch-sensing neurons. As animals mature from embryonic to adult stages, the skin grows and adds epithelial strata, specialized cells, and dermal appendages, like hairs, feathers and scales. How cutaneous sensory axons adapt to these dramatic changes is poorly understood. By characterizing remodeling of skin innervation in zebrafish, we discovered that sensory axons are delivered to the adult epidermis in strikingly organized nerves patterned by features in bony scales. These sensory axons associate with Schwann cells, blood vessels and osteoblasts. Osteoblasts create paths that independently guide nerves and blood vessels, during both development and regeneration. By preventing scale regeneration and examining mutants lacking scales, we found that scales dictate the pattern of axon distribution in the epidermis, suggesting a new mechanism for achieving comprehensive innervation of the adult skin. Thus, scales coordinate a metamorphosis-like transformation of the skin with sensory axon remodeling. We speculate that regularly spaced dermal appendages in other animal classes may also pattern skin innervation.

**Building a barrier: survival of the fittest in the developing skin.**  
S. Ellis1, E. Fuchs1;  
1Laboratory of Cell Biology and Genetics, The Rockefeller University, New York, NY

A key feature of animal embryogenesis is the creation of a permeability barrier that protects internal organs and tissues from physical damage, dehydration, pathogen invasion, and other harmful environmental stresses. In mammals, this function is fulfilled by the epidermis, a tissue comprised of stratified layers of specialized epithelial cells. During embryonic development, the epidermis expands dramatically to accommodate the growth and increase in surface area of the organism. Concomitantly, the skin undergoes a differentiation program from a monolayer of progenitors to become a functionally specialized, multi-layered permeability barrier at birth. This rapid process of patterning and growth is vulnerable to deleterious genetic errors and epigenetic and/or post-translational misregulation that could be propagated throughout the tissue and thus compromise both barrier function and the fitness
of the organism. Therefore, we sought to understand the quality control mechanisms that operate during the complex process of skin development. Cell competition is a phenomenon by which less fit “loser” cells are eliminated by more fit “winner” cells. Could such a mechanism exist in embryonic skin to ensure that only the fittest progenitor cells persist to establish and maintain a functional epidermal barrier? Using a combination of functional genetics and time-lapse imaging, we establish a model for cell competition in the mouse embryonic epidermis. Early in epidermal development, loser cells are eliminated from the growing epithelium via apoptosis and engulfment by surrounding winner cells. Strikingly, we observe a developmental switch in loser cell elimination mechanisms; upon the emergence of stratified tissue layers, loser cells are eliminated via hastened differentiation rather than apoptosis. Abrogating the function of factors required for loser cell clearance leads to compromised barrier integrity and differentiation defects. Altogether, our studies raise the intriguing possibility that cell competition acts as a selective force during epidermal development to maximize tissue fitness. Moreover, our data illuminates how the strategy a tissue uses to preserve fitness can evolve as architectural complexity increases during morphogenesis.

Examining Carmil3’s role in Kupffer's vesicle morphogenesis and function.
B.C. Stark1, L. Solnica-Krezel2, J.A. Cooper1;
1Biochemistry Molecular Biophysics, Washington University School of Medicine, St. Louis, MO,
2Developmental Biology, Washington University School of Medicine, St. Louis, MO

CARMIL family proteins have traditionally been thought of as regulators of actin capping protein; recent work has also begun to examine their role as scaffolds within signaling networks. Vertebrates express three CARMIL isoforms, and CARMIL3 is the least well studied. Zebrafish have three genes and express the three isoforms throughout development. Fish homozygous for loss-of-function alleles of Carmil3, generated via genome editing or ENU mutagenesis, exhibit a delay in development and an increase in dextrocardia. The nodal-related gene southpaw, required for left-right patterning, was no longer strictly expressed in the left lateral plate mesoderm; instead, it was frequently expressed in the right lateral plate mesoderm or bilaterally. Preliminary data suggests that this phenotype is a result of a decrease in Kupffer’s vesicle formation and lumen inflation; and a loss of primary cilia in the Kupffer’s. Overexpression of Carmil3, induced by microinjection of RNA, leads to different defects in embryo patterning, and these gain-of-function phenotypes require Carmil3’s ability to bind capping protein. These results demonstrate a critical role for CARMIL3 in regulation of the Nodal signaling pathway establishing left-right asymmetry in the developing animal.

Distinct Signaling Roles for Type I Receptors Bmpr1 and Acvr1l, and the Type II Receptors Bmpr2 and Acvr2 within the BMP Receptor Complex.
B. Tajer1, M.C. Mullins1;
1Cell and Developmental Biology, University of Pennsylvania, Philadelphia, PA

The Bone Morphogenetic Protein (BMP) pathway patterns dorsal-ventral (DV) axial tissues during gastrulation. The zebrafish embryo is an excellent system to investigate the mechanism of BMP signal transduction during DV patterning, as many BMP pathway mutants are available and, unlike in
mammals, these mutants survive to show DV patterning defects. When signaling, a dimeric BMP ligand assembles a receptor complex composed of two type I and two type II receptors. Type II receptors phosphorylate and activate type I receptors, which in turn phosphorylate Smad proteins. Phosphorylated Smad then regulates gene expression. This model, however, is overly simplistic as there are two conserved classes of type I receptor, Bmpr1 and Acvr1l, and two conserved classes of type II receptor Bmpr2 and Acvr2, all of which are necessary for vertebrate development. Our previous findings demonstrate that BMP2/7 heterodimers are the only ligands that signal in DV patterning. This sufficiency arises from the heterodimer’s unique ability to integrate both type one receptors into the BMP receptor complex, as Bmpr1 preferentially binds the BMP2 ligand, and Acvr1l exclusively binds BMP7. We have also found that kinase dead Acvr1l cannot rescue acvr1l knockdown, while, surprisingly, kinase dead Bmpr1 can rescue bmp1 knockdown. Additionally, Bmpr1’s intracellular domain (ICD) cannot function in the place of Acvr1l’s. These results suggest Acvr1l and Bmpr1’s ICDs play separate functional roles in BMP signaling. I aim to determine the location and nature of the motifs within Bmpr1 and Acvr1l that impart these specific functions through a series of domain swap experiments. We do not currently know the contribution of the two BMP type II receptor classes, Bmpr2 and Acvr2, to the signaling complex acting in DV patterning. While experiments in mice suggest that both classes are necessary for early embryonic development, these embryos die before DV patterning begins. I aim to create zebrafish mutants null for each entire type II receptor class, allowing us to determine whether both classes have independent, necessary signaling functions in DV patterning.

Caenorhabditis elegans BMP Signaling Determines Body Size Via Transcriptional Regulation of Collagen Genes.
U. Madaan1, E. Yzeiraj1, M. Meade1, C. Rushlow2, C. Savage-Dunn1; 1Biology, Queens College and the Graduate Center, Flushing, NY, 2Biology, New York University, New York, NY

Body size is a tightly regulated phenotype in metazoans that depends on both intrinsic and extrinsic factors. While signaling pathways are known to control organ and body size, the downstream effectors that mediate their effects remain poorly understood. In the nematode C. elegans, a Bone Morphogenetic Protein (BMP)-related signaling pathway is the major regulator of growth and body size. We investigated the transcriptional network through which the BMP pathway regulates body size and identified cuticle collagen genes as major effectors of growth control. We demonstrate that cuticle collagens can act as positive regulators (col-41), negative regulators (col-141, col-142), or dose-sensitive regulators (rol-6) of body size. Moreover, we find a requirement of BMP signaling for stage-specific expression of cuticle collagen genes. We show that the Smad signal transducers directly bind conserved Smad binding elements in regulatory regions of col 141 and col-142, but not of col-41. Hence, cuticle collagen genes are directly and indirectly regulated via the BMP pathway. Our work thus connects a conserved signaling pathway with its critical downstream effectors, advancing insight into how body size is specified. Since collagen mutations and misregulation are implicated in numerous human genetic disorders and injury sequelae, understanding how collagen gene expression is regulated has broad implications.

Determination of Novel BMP-Smad1/5 Signaling Interactions in Fibrodysplasia Ossificans Progressiva.
R. Allen¹, M.C. Mullins¹, E. Shore¹;
¹Developmental Stem cell and Regenerative Biology, University of Pennsylvania, Philadelphia, PA

Fibrodysplasia ossificans progressiva (FOP) is a rare and debilitating human genetic disorder that perturbs skeletal development and induces heterotopic ossification. Classical FOP is caused by a single nucleotide substitution in the BMP/TGFβ cell surface receptor, ACVR1 (617G>A, R206H). This mutation results in over-activation of receptor signaling through the Phospho-Smad1/5 (pSmad1/5) pathway. However, the mechanism through which the mutant receptor confers enhanced signaling activity remains uncertain. To assay for mutant ACVR1 activity, we used zebrafish embryonic dorsoventral (DV) patterning, which is established by a gradient of BMP signaling activity that specifies ventrolateral cell fates. We confirmed that ACVR1-R206H misexpression causes over-activation of pSmad1/5 activity and ventralization of zebrafish embryos. We tested several rare ACVR1 mutations of FOP for signaling activity in the zebrafish embryo assay and found similar results. Recent studies suggest that ACVR1-R206H and other FOP variant mutant receptors may have altered ligand affinity compared to WT ACVR1. We confirmed that BMP ligand enhances pSmad1/5 signaling through ACVR1-R206H. Surprisingly, Activin A, a ligand that normally binds ActR1 and signals through pSmad2/3, also enhances pSmad1/5 signaling by ACVR1-R206H. In addition to testing ligand enhancement, we examined if other receptors are required with ACVR1 to induce signaling. We found that BMPR1, a receptor normally required for pSmad1/5 signaling and DV patterning in the zebrafish, is not required for pSmad1/5 over-activation by ACVR1-R206H or the variant mutant ACVR1-G328R. These data suggest that BMPR1 is not required for the pathogenesis of FOP. These and further studies of the signaling interactions of ACVR1-R206H will allow for identification of novel therapeutic targets to treat FOP and give us unique insight into how this fundamental cell signaling pathway functions in development.

Expression pattern and potential role of placental Psg genes in sex-specific immune response during pregnancy.
D. Jeong¹, J. Lee¹, M. Kim¹;
¹Anatomy Embryology, Yonsei University College of Medicine, Seoul, South Korea

Placenta is essential organ for sustaining survival and growth of fetus during gestation. It mediates maternal-fetal exchange and produces hormones that alter maternal physiology and protect the fetus against the maternal immune system during pregnancy. These placental roles are necessary for normal pregnancy outcomes, and defects in its functions lead to adverse pregnancy outcomes including intrauterine growth restriction (IUGR) and pre-eclampsia (PE), spontaneous preterm delivery, and abortion as well as long-term effects on health and behavior of adult offspring in sex-specific manners. The pregnancy-specific glycoproteins (PSGs), members of the immunoglobulin (Ig) superfamily, are the most abundant fetal proteins produced by placenta during pregnancy and play pivotal roles in anti-platelet, pro-angiogenesis and anti-inflammation. There is accumulating evidence that prenatal maternal stress or infection show differential effects on immune activation and inflammation depending on fetal sex. Especially, our previous work demonstrated that administration of synthetic glucocorticoid, dexamethasone, on pregnant mice induces sex-specific activation of immune-related genes including...
many Psg genes. Therefore, we hypothesized that the placental Psg genes are regulated differently in a sex-dependent manner, contributing to immune response during pregnancy. Here we first examined differential Psg gene expression patterns at different gestational days by RT-PCR and further determined the possible roles of Psg genes in sex-specific immunoregulatory responses during pregnancy.

*Role of HAND1 in collagen expression and post-translational modifications in the long bone.*

Y. Taga¹, L.E. Laurie°, H. Kokubo³⁴, Y. Saga⁵⁶, M. Kusubata¹, K. Ogawa-Goto¹, S. Hattori¹, N. Funato³⁶; ¹Nippi Research Institute of Biomatrix, Ibaraki, Japan, ²Department of Signal Gene Regulation, Tokyo Medical and Dental University (TMDU), Tokyo, Japan, ³Division of Mammalian Development, National Institute of Genetics, Shizuoka, Japan, ⁴Department of Cardiovascular Physiology and Medicine, Hiroshima University, Hiroshima, Japan, ⁵Department of Genetics, Graduate University for Advanced Studies, Shizuoka, Japan, ⁶Research Core, Tokyo Medical and Dental University (TMDU), Tokyo, Japan

Temporal and/or spatial modifications in gene regulation result in a multitude of long bone defects. The long bone develops through endochondral ossification from the ossification center of the diaphysis. The basic helix-loop-helix transcription factor HAND1, which is expressed in the developing long bone, is involved in morphogenesis and mineralization of the bone collar. To understand the underlying mechanism of HAND1 in bone development, we characterized and examined the expression of fibril-forming collagens from *Hand1*-overexpressing mice. Overexpression of *Hand1* in osteochondral progenitors resulted in hypoplastic ossification in the diaphyses of long bones. In *Hand1*-overexpressing mice, expression of *Runx2*, a master molecule for osteoblast differentiation, was significantly decreased. Mass spectrometric analysis revealed that the expression of types V and XI collagens was down-regulated in the diaphyses of *Hand1* mutants. In addition, *Hand1* overexpression led to an increase in collagen-specific post-translational modifications for type I collagen. Our results demonstrate that HAND1 plays a role in the temporal expression and post-translational modifications of collagens involved in endochondral ossification, which may result in the development of long bone defects.

*Tbx1* knockout mice exhibit dysregulated expression of genes associated with cleft palate in humans.

N. Funato¹², D. Srivastava³, H. Yanagisawa⁴; ¹Department of Signal Gene Regulation, Tokyo Medical and Dental University (TMDU), Tokyo, Japan, ²Research Core, Tokyo Medical and Dental University (TMDU), Tokyo, Japan, ³Gladstone Institute of Cardiovascular Disease, University of California, San Francisco, CA, ⁴Life Science Center of Tsukuba Advanced Research Alliance, University of Tsukuba, Tsukuba, Japan

*TBX1*, the T-box transcription factor gene, is considered the causative gene for 22q11.2 deletion syndrome, which manifests as velocardiofacial syndrome, DiGeorge syndrome, or conotruncal anomaly face. 22q11.2 deletion syndrome is characterized by craniofacial anomalies including facial muscle hypotonia, velopharyngeal insufficiency, and various subtypes of cleft palate, namely, complete cleft palate, incomplete cleft palate, soft palate cleft, and submucosal cleft palate. Ablation of *Tbx1* in mice results in different subtypes of cleft palate similar to those observed in humans. To examine the function of TBX1 in palatal development, we performed gene profiling of developing palatal shelves from wild type and *Tbx1* knockout embryos. Gene ontology analysis indicated that genes associated with...
development of muscle and the nervous system were dysregulated in Tbx1 knockout palatal shelves. Furthermore, in Tbx1 knockout palatal shelves, genes associated with human cleft palate, specifically, gamma-aminobutyric acid (GABA) A receptor subunit beta 3 (Gabra3), collagen type IX alpha 2 (Col9a2), myosin heavy chain 3 (Myh3), andnebulin (Neb) were downregulated. These results demonstrate that TBX1 maintains normal palatogenesis, mediated at least partly through the regulation of genes involved in the GABAergic system, development of muscle and the nervous system, and collagen synthesis. We conclude that multiple factors in Tbx1 knockout mice lead to different subtypes of cleft palate.

Delineation of neuro-ontogenic mechanisms of schizophrenia using induced Pluripotent Stem Cells (iPSCs).
L. Bayona Chuye1, A. Dimitri1, S.T. Narla1, C. Benson1, S. Dhiman1, P. Sarder1, E.K. Stachowiak1, M.K. Stachowiak1;
1Pathology and Anatomical Sciences, State University of New York at Buffalo, Buffalo, NY

Schizophrenia is a neurodevelopmental disorder featuring complex aberrations in the structure, wiring, and chemistry of multiple neuronal systems. The abnormal developmental trajectory of the brain appears to be established during gestation, long before clinical symptoms of the disease appear in early adult life. In order to understand the effect of schizophrenia on neuronal differentiation, we utilized induced Pluripotent stem cells (iPSCs) derived from both schizophrenia disease (SCZD) patients (n=3) and normal patients (n=4). iPSCs were differentiated into neuronal progenitor cells. In order to elucidate the effects of schizophrenia on NPCs we preformed global RNA-sequencing to quantify differences in RNA expression. RNA-seq analysis shows 1375 dis-regulated genes in all SCZD iPSCs compared to control. Many of these genes are involved in important developmental pathways such as WNT/B-Catherin signaling, or in neuronal pathways, such as axonal guidance and glutamate receptor signaling. The majority of the deregulated genes are targeted by nuclear form of FGFR1, supporting the role of the Integrative Nuclear FGFR1 Signaling in schizophrenia. Experiments utilizing iPSC-derived cerebral organoids support an early (preneuronal) developmental-genomic etiology of schizophrenia. Supported by NYSTEM (C026415, C026714), National Science Foundation (CBET-1555720), Clinical and Translational Science Institute NIH (2T35AI089693-06), and Patrick P. Lee Foundation.

The Formin, DIAPH1, Contributes to Epidermal Structure and Differentiation By Enabling Basal Keratinocyte Crowding.
R.M. Harmon1, M.L. Gardel1;
1Institute of Biophysical Dynamics, University of Chicago, Chicago, IL

To maintain a stratified, epidermal barrier, basal layer keratinocytes proliferate, stratify and differentiate to replace cells shed from the skin surface. Basal cell morphology impacts the production of differentiated, suprabasal layers, with prior cell crowding and micropattern studies suggesting that minimization of cell-matrix contact enables differentiation. While these studies implicated Rho-dependent, cortical actin accumulation upstream of serum-response factor (SRF), it remains unclear what actin nucleators partake. Identifying specific nucleators which participate in differentiation may aid in resolving the conundrum that arises in determining whether, in a physiological setting, the production of cortical actin represents a response to confinement/crowding or enables it by driving the columnar
shape associated with basal keratinocytes in vivo. Towards addressing these issues, we investigated the canonical formin, DIAPH1, a Rho-activated actin nucleator/elongator, known to support SRF signaling, but little studied with regard to epidermal architecture. Our results suggest that DIAPH1-deficient 2D and 3D cultures stratify but fail to differentiate. Depletion of DIAPH1 disrupted basal layer morphology, yielding large, heterogeneously shaped cells defective with respect to accumulation of E-cadherin along the apical surface. In 2D, knockdown cells also failed to induce differentiation markers and SRF targets in response to increasing cell density. We hypothesize that DIAPH1 supports epidermal differentiation by driving basal cells into a columnar morphology, thereby, increasing basal cell density, minimizing matrix contact and enabling differentiation. Potential effects on cell-matrix adhesion, cell-cell adhesion and cortical mechanics are being evaluated as possible contributors to the DIAPH1-phenotype.

Role of ROOT UVB SENSITIVE 1 in Vitamin B6 Homeostasis Modulation.
N. O’Neil¹, H. Tong¹, C. Leasure¹, S. Reveles Jr.¹, Z. He¹;
¹Department of Biology, San Francisco State University, San Francisco, CA

Vitamin B6 (vitB6) is essential for all life. In plants, vitB6 can be either synthesized via a highly conserved biosynthesis pathway or regenerated by salvage pathways. VitB6 is consumed in a number of physical and physiological processes. VitB6 in its bioactive form, pyridoxal 5'-phosphate (PLP), can be photolytically destroyed by ultraviolet-B (UVB) light. As a potent antioxidant, PLP is utilized to quench out reactive oxygen species. A good portion of cellular PLP is expected to be conjugated at the active site serving as a cofactor for more than 140 enzymes. How cellular vitB6 homeostasis is maintained to regulate development is not understood. An Arabidopsis protein called ROOT UVB SENSITIVE 1 (RUS1) was shown to play a key role in modulating vitB6 homeostasis. When mutated, rus1 displays a vitB6 deficient phenotype that can be partially rescued by either supplying vitB6 or by specific mutations in Aspartate Aminotransferase 2 (ASP2), a vitB6 using enzyme. The endogenous vitB6 level is comparable with that in the WT but any physiological conditions that perturb vitB6 homeostasis greatly enhance rus1 phenotype. Here we report mutations in genes that are required in vitB6 salvage pathways result in severe developmental arrest in rus1. Loss-of-function of the pyridoxal kinase gene called SOS4 (SALT OVERLY SENSITIVE 4) gives minor phenotype as the de novo vitB6 biosynthesis pathway is expected to supply vitB6 and maintain vitB6 homeostasis. Surprisingly, our genetic analyses show that the rus1 sos4 double mutant is embryonic lethal, suggesting that RUS1 is required to maintain vitB6 homeostasis that is directly linked vitB6 biosynthesis pathway. Our study strongly suggest that RUS plays a critical role in regulating development via modulating vitB6 homeostasis in Arabidopsis.

Tuesday-505
France

The proper development of both human and murine lungs relies on a precise temporal-spatial expression of growth factors including WNT, FGF, and TGF-beta family of ligands. Among these, Tgf-beta family is well known for its functions in relation to cell proliferation, differentiation, apoptosis, and epithelial-mesenchymal transition, which play key roles not only during development but also during tumor growth. Sex is a risk factor in several human lung diseases. Male infants have higher risk of developing bronchopulmonary dysplasia (BPD) as compared to females and idiopathic pulmonary fibrosis has higher incidence and worse outcome in male patients than in female patients. Sex hormones have been shown to modulated the severity of lung disease in animal models. For instance, the male hormone androgen exacerbates the bleomycin-induced lung fibrosis in female mice. Herein, we have induced the activation of the TGF-beta signaling pathway specifically in embryonic lung epithelium by crossing Ca-Tgf-beta-r1-Stopfl/fl (Constitutively active Tgf-beta-receptor-1) female mice with Ttf1-Cre male mice which produced a complex and lethal phenotype only in male fetuses. The phenotype displayed by the mutant male resembles the bronchopulmonary dysplasia disease displayed by human preterm infants and was not compatible with life. In contrast, mutant females were viable and showed either a weak phenotype or no phenotype at all. The lung epithelium of the mutant males showed increased number of progenitor Sox9 positive cells and genetic deletion of one allele of the Sox9 gene significantly reduced the severity of the phenotype in mutant male mice. Transcriptome profiling delivered important insights on the mechanism responsible for the lung phenotype in mutant male animals. Among the genes deregulated in the mutant male lung we recognized genes already known to be critical for the lung physiopathology such as Spock2 and Amantsl2 which are implicated to the pathogenesis of BPD in human and bronchial dysplasia in mice, respectively, Adams18 which is a critical regulator of murine lung development and Adam1s2 which is over-expressed in patients with sarcoidosis. Finally, we showed that injection of estrogen in pregnant female mice was able to reverse the phenotype in the male lungs which suggests a hormonal dependency of the phenotype in the lung of the transgenic male mice. In conclusion, we have established a novel male sex-specific model of the TGF-beta signaling pathway that will be useful in studying how male sex can adversely affects lung development as well as neonatal pulmonary diseases in humans and to identify the sex-specific signaling pathways that give to male patients bearing lung diseases a prognostic disadvantage compared to female patients.

Sox2 inhibits lef1 expression in the trailing zone to facilitate FGF-dependent neuromast formation.

G.R. Palardy1, K. Yoo2, A.B. Chitnis1;
1Aquatic Models of Human Development, National Institute of Child Health and Human Development, Bethesda, MD, 2Department of Biology, Chungnam National University, Daeyeon, Korea, South

The posterior Lateral Line (pLL) primordium, a group of approximately 100 cell, migrates under the skin, periodically depositing sensory organs called neuromasts, to pioneer formation of the zebrafish posterior Lateral Line system. During its migration, primordium cells sequentially reorganize themselves to form nascent neuromasts. Previous studies have shown that establishment of polarized signaling systems, Wnt in a leading zone and FGF in the trailing zone, coordinate systematic changes in cell organization and migratory potential within the migrating primordium. Wnt signaling inhibits FGF signaling in cells of the leading zone preventing them from reorganizing to form epithelial rosettes. On
the other hand, FGF signaling promotes morphogenesis of epithelial rosettes to form nascent neuromasts in the trailing zone. Sox2 is expressed in maturing protoneuromasts in the trailing zone. We now show that Sox2 whose expression is inhibited by Lef1-mediated Wnt signaling in the leading zone, contributes to the stability of maturing neuromasts in the trailing zone by inhibiting expression of the Wnt effector, Lef1. Knock-down of Sox2 with morpholinos results in a consistent loss or delay in the formation of the first deposited neuromast. However, the loss of the first neuromast is much more variable in sox2 loss-of-function mutants. We show that this weaker phenotype, is likely to be related to compensation by sox1a, another sox homologue, whose expression is normally restricted to the leading zone of the primordium. In sox2 mutants, sox1a expression expands from the leading zone into the trailing zone, where sox2 is normally expressed. When sox1a is knocked down in a sox2 mutant background, there is consistent loss of the first neuromast, as observed in sox2 morphants. This observation supports a compensatory role for sox1a in a sox2 mutant background. However, it remains unclear why sox1a does not adequately compensate for loss of sox2 function in a sox2 morphant, where, surprisingly, its expression also expands into the trailing zone.

Low-level copper exposure causes neurodevelopmental and cardiac defects in the embryonic zebrafish.
A. Shields\textsuperscript{1}, K. Figueroa\textsuperscript{1}, J. Pagnotta\textsuperscript{1}, K. Michalak\textsuperscript{1}, A.L. Dell\textsuperscript{1,2};
\textsuperscript{1}Biology, St. Francis College, Brooklyn, NY, \textsuperscript{2}Neuroscience, Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA

Neuronal and cardiac birth defects are correlated with pesticide application and water quality. Human exposure to these pollutants may occur through drinking water, or during contact with surface water, but the molecular pathways that cause these defects are not well defined. GPCR signaling pathways constitute one primary mechanism for cells to respond to their environment. Using the zebrafish retinotectal projection as a model system, we previously showed that GPCR signaling is required for axon guidance during normal development. Retinal ganglion cell (RGC) axons that express a dominant negative G-protein subunit Ga\alphaS fail to cross the midline and misproject. Our aim was to use this system to dissect cell signaling events that translate exposure to environmental pollutants into neuronal developmental defects. We measured elevated copper levels at sites along Newtown Creek, one of the most polluted waterways in New York City and designated Superfund Site validating our findings with EPA data. We report generalized developmental as well as cardiac and behavioral deficits in zebrafish embryos transiently exposed to low levels of copper ions during development. To discover the molecular and cellular basis of copper toxicity we identified potential gene targets of copper by analyzing GEO2R datasets, and refined our candidate list to targets expressed in the right time and place to direct growing retinal axons. Using Isl2b transgenic embryos, as well as lipophilic dye tracings of retinal axons, we will assess the affect of copper on axonal trajectory correlating these developmental changes with alterations in expression of canonical GPCR signaling components.

Endoderm Nitric Oxide Focally Elevated “Hotspots” at the Heart Forming Regions (HFRs) Signals in Early Cardiogenesis in Chicken Embryos.
D. Shah¹, W.F. Denetclaw¹;
¹Biology, San Francisco State University, San Francisco, CA

The chicken embryo expresses three nitric oxide synthase (NOS) isoforms: eNOS, nNOS, and iNOS, each binding L-arginine and converting it to the nitric oxide (NO) messenger gas molecule that signals through a NO canonical pathway in cardiogenesis. However, at the earliest stages of embryo cardiogenesis, NO signaling has not been well-studied for its role in signaling heart development. To investigate, gastrula staged chick embryos (HH3 – H7) were placed on agarose plates, labeled by 5 μM DAF-2DA fluorescent NO indicator, and embedded in agarose for imaging by confocal microscopy (n=23). In HH3 embryos, NO was elevated in the endoderm and early cardiogenic mesoderm (n=4) in the bilateral heart fields which are anterolateral to the cranial-most primitive streak. In HH4 and HH4+ embryos, endoderm NO signaling to subjacent cardiac splanchnic mesoderm was shown to be focal in cranial left and right bilateral Heart Forming Regions (HFRs) over an elliptical area with a diameter of 200 ± 20 μm (n=6). By HH5, endoderm and cardiac mesoderm NO signaling was observed in maturing HFRs where cardiac progenitors differentiate and cardiomyocytes migrate cranial-ward and fuse at the embryo midline to form the cardiac crescent. (n=3) Moreover, the NO signal was elevated along the cardiac crescent just prior to final heart tube formation, as well as in the HFRs in the posteriorly adjacent splanchnic mesoderm of the developing myocardium of HH6 and HH7 embryos (n=3). Focal elevated patterns of NO signal are found to be confined to anterior regions of the embryo during heart tube formation. Furthermore, HH 4-5 embryos were microinjected with NOS inhibitor, L-NAME (1 or 10 mM), into the subterminal cavity in ovo and developed to heart tube formation (HH 8 -10) stages. L-NAME embryos were observed to develop 20 ± 5% smaller heart tubes (n=4) than comparable heart tubes from control embryos. L-NAME embryos also showed noticeably reduced myosin heavy chain expressed in cardiomyocytes compared to controls (n=4). We conclude that NO is produced as dynamic focal “hotspots” in endoderm that correlate with HFRs and early cardiogenic mesoderm differentiating to cardiomyocytes, suggesting its role in early embryo heart development. These are the first studies to show in the whole chicken embryo NO signaling correlation with early heart formation and that NO is an added biomolecular regulator functioning in early heart development. Mechanical cues control alveolar epithelial cell differentiation.
J. Li¹, Z. Wang¹, Q. Chu¹, K. Jiang¹, J. Li¹, N. Tang¹;
¹National Institute of Biological Sciences, Beijing, Beijing, China

The mammalian pulmonary alveolar epithelium is essential for the gas exchange between blood and the outside environment. The pulmonary alveolar epithelium is composed of two types of epithelial cells: alveolar type I (AT1) cells and type II (AT2) cells, which both differentiate from bipotent alveolar progenitor cells. AT2 cells are cuboidal in shape, and are alveolar stem cells in adult lungs. AT1 cells, in contrast, are thin and flat in shape, and function mainly in gas exchange via their close contact with vascular endothelial cells. Despite the vital importance of alveolar epithelial cell differentiation for
essential lung function, we know very little about the cellular and molecular mechanisms that drive developmental process. Here, using mouse genetics, in vivo and ex vivo live imaging, and quantitative cell biology, we investigated the genetic programs and cellular mechanisms that control alveolar epithelial cell differentiation. We discovered that some bipotent progenitor cells are able to protrude from the basal side of the airway epithelium. The cell protrusion process is accompanied by apical constriction, which leads to myosin enrichment at the apical side of protruded progenitor cells. During fetal breathing movements, the mechanical forces in alveolar sacs are increased by inhaled amniotic fluid. All non-protruded bipotent progenitor cells were flattened by increased mechanical forces and then became AT1 cells, whereas all protruded bipotent progenitor cells were able to maintain their cuboidal cell shape and became alveolar stem cells. We show that the enriched apical myosin function to protect protruded cells from mechanical stretching. The cell protrusion process ensures the alveolar stem cell fate specification by protecting alveolar stem cells to structurally withstand the mechanical forces. Our study revealed an intricate developmental process in which cell fate choices are controlled by the levels of mechanical forces.

Metalloprotease activity shapes BMP signaling output in the developing zebrafish embryo.

F. Tuazon1, M. Mullins1;

1Cell Developmental Biology, University of Pennsylvania, Philadelphia, PA

Bone Morphogenetic Proteins (BMPs) act in an extracellular signaling gradient to specify dorsoventral (DV) axial tissues in invertebrates and vertebrates. Though the regulation of the BMP gradient across space and time is fundamental to proper tissue patterning, the molecular mechanisms that underlie this process in vivo remain unknown. The shape of the BMP gradient across the DV axis specifies distinct cell fates at precise BMP signaling levels. This critical BMP distribution is shaped by secreted modulators such as Chordin, an essential BMP antagonist. Chordin activity is extracellularly regulated by the related astacin metalloproteases Tolloid (Tld) and Bmp1a, which cleave and inactivate Chordin. Tld and Bmp1a are further regulated by Sizzled (Szl), their competitive inhibitor that prevents Chd cleavage and thus protects Chd function. We found that zebrafish embryos deficient for Tld and Bmp1a are severely defective in DV axial tissues. This indicates that Tld and Bmp1a function redundantly and reveals that astacin metalloproteases play an essential role in establishing the BMP gradient. We developed a quantitative immunofluorescence assay of nuclear phosphorylated Smad1/5 (a direct intracellular readout of BMP signaling) and used it to show that the BMP gradient in these embryos is abolished. This indicates that Chd, when unrestricted by metalloproteases, inhibits BMP embryo-wide and suggests that Tld/Bmp1a are required to spatially limit Chd activity. We also discovered, surprisingly, that the BMP signaling gradient in szl mutants is significantly altered at late blastula stages although patterning is unaffected. This underscores the importance of properly regulated metalloprotease activity in establishing the BMP gradient and suggests that Szl may play a previously unrecognized role in this process. Additionally, we discovered that the BMP gradient dramatically and rapidly steepens between mid and late gastrulation. Furthermore, tld and szl mutants display distinct alterations in BMP gradient shape at the end of gastrulation, suggesting region-specific roles for Tld and Szl. Our data indicate that Tld maintains the steepness of the late BMP gradient, while Szl restricts the highest levels of BMP signaling in lateral regions. Together, these data support fundamental, stage-specific roles for Tld/Bmp1a to differentially shape the BMP gradient, positioning astacin metalloprotease regulation as a central mechanism for modulating BMP signaling in space and time.

Loss of function of Seven-In-Absentia (SINA) E3 ligase impedes proper RAS signaling and alters peripheral nervous system (PNS) development in Drosophila.

R.E. Van Sciver1, Y. Cao1, A.U. Ahmed2, A.H. Tang1,2;
1Microbiology and Molecular Cell Biology, Eastern Virginia Medical School, Norfolk, VA, 2Department of Surgery, Mayo Clinic, Rochester, MN

The RAS signal transduction cascade is a pivotal signaling pathway that controls numerous fundamental cellular processes, such as cell proliferation, differentiation, motility, and apoptosis. Seven-IN-Absentia (SINA) is an evolutionarily conserved E3 ubiquitin ligase that is the most downstream signaling module identified in the RAS signaling pathway. Under scoring the importance of SINA is its high evolutionary conservation with over 83% amino acid identity shared between Drosophila SINA and its human SINA homologs (SIAHs). As a major signaling hub and the downstream signaling “gatekeeper” in the RAS pathway, SIAHs are uniquely positioned to inhibit “undruggable” oncogenic K-RAS activation that is prevalent in high-grade metastatic cancer. Thus, it is important to delineate the enzymatic activity, molecular regulation, and substrate targeting mechanism(s) of this highly conserved family of SINA/SIAH E3 ligases. By deploying the elegant and powerful Drosophila photoreceptor cell development system, we conducted a genetic modifier screen and identified 28 new sina mutant alleles that exhibit a range of mutant phenotypes. For example, sina complete loss of function (null alleles) is cell lethal, suggesting that SINA is an essential gene in development. All other sina mutant alleles exhibit stronger phenotypes than the previously published sina2 and sina3 alleles, providing us with an opportunity to study sina loss-of-function mutant phenotypes. Sequencing analysis of these newly identified mutant alleles reveals the critical roles of several immutable amino acid residues essential for SINA function. To demonstrate the functional conservation of SINA/SIAH proteins, we have generated a collection of transgenic fly lines that carry either wild-type (WT) or dominant negative (DN) DmSINA and human SIAH. The altered DmSINA/hSIAH expression under the control of sev-, GMR-, and dpp-GAL4 drivers revealed the biological consequences of gain of function and/or loss of function of DmSINA/hSIAH1/2 in transmitting RAS signaling in PNS development. Immunofluorescent staining of developing imaginal discs and electron micrographs of adult tissues show that ectopic expression of SINAWT/DN/SIAHWT/DN in neurons resulted in dramatic changes in neuronal cell fate in the developing eye and notum. The results from these transgenic animals suggested that Drosophila SINA and human SIAH1/SIAH2 are evolutionarily conserved and functionally interchangeable. Through this developmental neurobiology-based study, we aim to dissect the molecular action of SINA/SIAH1/2 in RAS signaling. Furthermore, we hope to translate these findings to demonstrate the anticancer efficacy of the next-generation anti-SIAH-based anti-K-RAS strategy against high-grade metastatic human cancer in the future.

Different role of YAP1 during early and late stages of mesenchymal cells differentiation.

B. Jung1, J. Kim1, D. Kim1, J. Sonn1;
1Biology, Kyungpook National University, Daegu, South Korea

Yes-associated protein 1 (YAP1), a transcriptional co-activator, regulates cell proliferation and differentiation. In this study, we sought to investigate the role of YAP1 in the differentiation of limb bud mesenchymal cells in micromass culture. As chondrogenesis proceeds, expression of YAP1 decreased while phosphorylation of YAP1 increased. YAP1 localized both in the cytosol and nucleus on 1 day of...
culture and became excluded from the nucleus on day 3 of culture. Inhibition of YAP1 with verteporfin resulted in the suppression of chondrogenesis and cell aggregation. In addition, verteporfin also inhibited the expression of N-cadherin and fibronectin. Incubating the constitutively active YAP1-overexpressing cells for 3 days had no effect on the cell aggregation and differentiation. However, Alcian blue staining decreased in 7-day cultured YAP1 overexpressing cells. When cells were cultured for 3, 6, or 8 days in normal media and treated with verteporfin for 1 or 2 more days, there was no change in Alcian blue staining. Interestingly, when cells were cultured for 8 days in normal media and incubated for 2 more days in the presence of verteporfin, Alizarin red S staining was increased. Taken together, these results suggest that YAP1 activity is essential for cell aggregation by the expression of N-cadherin and fibronectin at the early stage of chondrogenesis and that downregulation of YAP1 activity at late stage is not required for chondrogenesis but for bone formation.

A new transgenic Xenopus reporter line reveals dynamic expression of snail2 during cranial neural crest development.
A. Makhija1, M. Perfetto1,2, J. Wang1, J. Li1, A. Shah3, H. Tran4, K. Vleminckx4,5, S. Wei1,2;
1Biological Sciences, University of Delaware, Newark, DE, 2Biology, West Virginia University, Morgantown, WV, 3Biology, University of Virginia, Chalottesville, VA, 4Molecular Biomedical Research, Flanders Institute for Biotechnology, Ghent, Belgium, 5Biomedical Molecular Biology, Ghent University, Ghent, Belgium

During vertebrate embryogenesis, the cranial neural crest (CNC) is induced at the neural plate border (NPB) and subsequently migrate and differentiate into various cells and tissues. In Xenopus, the transcription factor Snail2 is induced at the NPB by canonical Wnt signaling and is required for CNC induction and migration, but the roles of Snail2 at later stages remain unclear. To monitor CNC development in live embryos, we generated a transgenic X. tropicalis line expressing Green Fluorescent protein (GFP) driven by the snail2 promoter. Using whole genome sequencing, we mapped the transgene insertion to a noncoding region. Live imaging of the transgenic embryos reveals that snail2 is expressed in pre-migratory and migrating CNC but is lost in CNC cells that have arrived at their destinations. However, snail2 is re-expressed during CNC differentiation in all CNC derivatives that were examined. Defects in CNC differentiation, in addition to induction and migration, can be readily detected using this transgenic snail2 reporter line. Comparison with a transgenic Wnt reporter line shows that Wnt signaling is consistently activated prior to snail2 expression, suggesting that the Wnt-Snail2 axis may play important roles in multiple stages of CNC development. We are also developing a new transgenic line with a photoconvertible protein instead of GFP that can be used to for lineage tracing of CNC derivatives.

Enhanced Wnt signaling in Mesenchymal stem cells can induce cell differentiation but reduce cell viability.
H. Lee1, Y. Shen1, S. Chen1, J. Lee1;
1Bioagricultural Sciences, National Chiayi University, Chiayi, Taiwan

Mesenchymal stem cells (MSCs) are multipotent adult stem cells, which are potentially applicable for cell therapy to treat various diseases, such as osteoarthritis (OA). For application, further understanding
the mechanism of MSC differentiation is necessary. MSC osteogenic differentiation and adipogenic differentiation process are controlled by many signaling pathways, and one of these is Wnt signaling pathway. We previous studies have shown that a Wnt downstream effector, Fhl1 can promote osteogenic differentiation of a pre-osteoblastic cell, MC3T3-E1. Here we present our studies in investigating the role of Wnt and Fhl1 in differentiation of the earlier cell lineage, Mesenchymal stem cells. Firstly, we mimic the Wnt signaling by LiCl treatment, and indicating that the expression of Fhl1 and the osteogenic markers, Runx2, OCN, and OPN were increased accompanying with the osteogenic induction; conversely, the adipogenic markers, PPARγ2 and FABP4 but not Fhl1 were down-regulated on the second day, of MSC adipogenesis. On the other hand, MSC cell viability was also increased in the low dose of LiCl, but was decreased in the high dose of LiCl treatment. We then questioned whether high dose but not low dose of LiCl induces Fhl1 expression, leading to the induction of differentiation and inhibition of cell growth. Examining by qRT-PCR indicated that Fhl1 expression could be induced by 25 mM LiCl but not 5 mM LiCl treatment to promote osteogenesis and to inhibit adipogenesis of MSC. The influence of Wnt signaling induced by the high dose of LiCl can be abolished by treatment of the Wnt inhibitor, Dkk. Overexpression of Wnt3a and Fhl1 gene could directly induce osteogenesis and inhibit adipogenesis. In addition to the MTT assay, cell viability was also tested by PCNA and p21 expression level. Interestingly, although each of over-gene expression could reduce cell viability, overexpressed Wnt3a increased PCNA and p21 expression, yet Fhl1 decreased PCNA gene expression. In conclusion, High Wnt signaling induces osteogenesis and to repress adipogenesis of MSC. Simultaneously, inhibition of cell viability of MSC may be because of the elevation of p21 and the down-regulation of PCNA gene expression.

Six3 suppression of R-spondin 2-Wnt signaling is required during mammalian neuroretina development.

N. Takata1, D. Abbey2,3, L. Fiore4, S. Acosta1, R. Feng5, H. Gil5, A. Lavado5, X. Geng2,4, A. Interiano2, G. Neale5, M. Eiraku6, Y. Sasai7, G. Oliver1;
1Medicine nephrology, Feinberg Cardiovascular Research Institute, Chicago, IL, 2Department of Genetics, St. Jude Children’s Research Hospital, Memphis, TN, 3Division of Translational Medicine and Human Genetics Perelman School of Medicine, Pennsylvania University, Philadelphia, PA, 4Cardiovascular Biology Research Program, Oklahoma Medical Research Foundation, Oklahoma, OK, 5Hartwell Center for Bioinformatics and Biotechnology, St. Jude Children’s Research Hospital, Memphis, TN, 6Laboratory for in vitro Histogenesis, RIKEN Center for Developmental Biology, Kobe, Japan, 7Laboratory for Organogenesis and Neurogenesis, RIKEN Center for Developmental Biology, Kobe, Japan

The mammalian neuroretina is a sensory organ that consists of multi-layered neuronal cell types. It has an important role during visual recognition where light is converted into neural signals in the visual cortex. Retinal abnormalities and retinal degenerative diseases cause severe vision loss in millions of people worldwide. Recent advances in 3-dimensional (3D) tissue cultures of embryonic stem cells (ESCs) and induced pluripotent stem cells (iPSCs) provided an additional in vitro model that recapitulates many aspects of the in vivo developmental steps. In this study we took advantage of this 3D eye organoid culture system as a faster and reliable tool to identify and characterize some of the molecular events controlling early steps of mammalian eye development. We validated these results in vivo in mouse embryos. From genome-wide microarray data, we first identified R-spondin 2 (Rspo2) as a novel candidate gene in neuroretina differentiation in vitro. Next, we determined that Six3 binds to Rspo2 regulatory elements using ChiP analysis. Using newly generated Six3−/− iPSCs and conditional Six3
knockout ESCs, we found that Six3 repression of Rspo2 is a novel required step during optic vesicle morphogenesis and neuroretina differentiation in vitro. Finally, we validated these results in vivo by showing that transient ectopic expression of Rspo2 in the anterior neural plate of transgenic mouse embryos was sufficient to arrest neuroretina differentiation. Additionally, using a chimeric eye organoid assay we determined that Six3-null cells exert a non-cell autonomous repressive effect during neuroretina differentiation. Our results further validate the organoid culture system as a reliable and fast alternative to identify and evaluate genes involved in eye morphogenesis and neuroretina differentiation in vivo.

Epithelial-mesenchymal micro-niches integrate signaling effectors to drive dynamic chromatin remodeling during stem cell lineage choices.
H. Yang1, R.C. Adam1, Y. Ge1, Z.L. Hua1, W. Lien2, P. Wang3, Y. Zhao3, L. Polak1, J. Levorse1, S.C. Baksh1, D. Zheng3, E. Fuchs1;
1Laboratory of Mammalian Development and Cell Biology, The Rockefeller University, New York, NY, 2de Duve Institute, Université Catholique de Louvain, Brussels, Belgium, 3Department of Genetics, Albert Einstein College of Medicine, Bronx, NY

Tissue regeneration relies on resident stem cells, whose activity and lineage choices are influenced by microenvironment. Once activated, stem cells typically give rise to short-lived progenitors, which then progress to differentiate into their lineages. Exploiting the synchronized, cyclical bouts of tissue regeneration in hair follicles, we investigated when and how microenvironment dynamics shape the emergence of stem cell lineages. Using temporal single-cell RNA-seq, we unearthed unexpected heterogeneity among stem cells and their progeny and found that the ability of stem cells to make lineage choices (plasticity) becomes restricted in a sequentially and spatially choreographed program. We traced the roots of lineage restriction to micro-niches located along epithelial-mesenchymal borders, each of which receive slightly different signaling inputs. Whether these signals are WNTs, BMPs or NOTCH, each has its own effector that alters the activity of a downstream transcription factor. Employing epigenetic and ChIP-seq profiling, we uncover how signal-dependent transcription factors couple spatio-temporal cues to chromatin dynamics, thereby choreographing stem cell lineages. Using enhancer-driven reporters, mutagenesis and genetics, we define the signaling inputs involved and show how stem cells establish chromatin platforms permissive for diversification, and how new signaling inputs progressively compartmentalize lineage options in vivo by modifying chromatin dynamics.

The Tumor Suppressor p53 Mediated Apoptotic Pathway Plays An Essential Role in HSF4 Regulation of Lens Fiber Cell Differentiation.
D.W. Li1;
1Zhongshan Ophthalmic Center, Sun Yat-sen University, Guangzhou, China

The Tumor suppressor p53 is a multi-functional regulator of cell proliferation, differentiation, apoptosis and transformation. Our previous studies have revealed that PP-1 directly modulates p53 functions by dephosphorylating S15 and S37 in both cell differentiation and apoptosis (Li et al., Oncogene, 2006). More recently, we have demonstrated that p53 can regulates 3 types of gene to control lens differentiation: lens major transcription factors such as c-Maf and Prox-1, lens differentiation related
genes, members of alpha, beta and gamma-crystallin genes, and apoptotic genes, Bak and Bax (Mao et al. 2001. JBC; Li et al. 1998. Eur J. Biochem., Deng et al., 2010. CMM., Liu et al. 2012; CMM., Ji et al., 2013, Hu et al., 2014. CMM. Huang et al., 2015. BBA.). The heat shock transcription factor 4 (HSF4) is a major regulator for normal lens development. Mutations in HSF4 have been associated with cataract, but the mechanisms regarding how mutations in HSF4 cause cataract are still obscure. In a recent study, we found that HSF4 can stabilize p53 to regulate cell cycle progression (Huang et al., 2015. BBA.). Here, an hsf4 knockout zebrafish line was generated. The mutant zebrafish developed an early onset cataract with multiple developmental defects in lens. Mechanistically, it was found that the lens epithelial cells were over-proliferated at the germinal zone, resulting in the overabundance of lens fiber cells in hsf4null zebrafish lens. As a result, the arrangement of the lens fiber cells became more disordered and irregular with age. More importantly, the terminal differentiation of the lens fiber cell was interrupted since the organelles including nucleus, mitochondridial, lysosome and endosome cannot be cleaved in due time. In exploring the molecular mechanisms, the cultured human lens epithelial cells were used to test HSF 4 functions. It was revealed that HSF4 could stabilize and retain p53 in the nucleus to activate its target genes Fas and Bax, members of the extrinsic and intrinsic pathways. In the hsf4null zebrafish, both p53 and activated-caspase3 were significantly decreased. Combined with the finding that the denucleation defect could be partially rescued through microinjection of p53, fas and bax mRNA into the mutant embryos, these results demonstrated that HSF4 promotes lens fiber cell differentiation by activating p53 and its downstream regulators. HSF4 functions in the upstream to activate these genes highlighted the new regulatory modes of HSF4 action in the terminal differentiation of lens fiber cell.

The Impact of Flame Retardant Exposures on Human Pregnancy.
K.A. Puckett1,2, J.F. Robinson1, H. Chen1, S.J. Fisher1, K. Ona1;
1Obstetrics Gynecology/Center for Reproductive Science, University of California, San Francisco, San Francisco, CA, 2Department of Biology, San Francisco State University, San Francisco, CA

Classes of flame retardants (FRs) such as polybrominated diphenyl ethers (PBDEs) and organophosphorus FRs (OPFRs) are used in consumer products and subsequently released into the environment. While in humans, the health consequences associated with FR exposures remain undefined, in animal models, specific FR exposures may be developmentally toxic, e.g., endocrine disruption, alter nervous system development. Recently, FRs have been identified in human placental tissues. Due to the importance of placental development during pregnancy, environmental chemicals may adversely impact prenatal development. Specialized placental cells known as cytrophoblasts (CTBs) differentiate and are responsible for uterine invasion and maternal vascular remodeling, two very important components of placentaion. In culture, primary human villous CTBs display characteristics of CTB differentiation representative of their inherent functional behaviors in vivo. Preliminary data from our laboratory suggests that PBDEs may disrupt CTB functions that are integral to normal differentiation. Here, we will test the hypothesis that FRs significantly impair CTB function, resulting in compromised placental development. In Aim 1, using cultured CTBs as a model of placentaion, we will evaluate the ability of FRs to alter CTB functions that are a proxy for their differentiation, e.g., migration and invasion. In Aim 2, we will analyze the effects of FRs on the expression of molecules that regulate these functions. In Aim 3, we will select a subset of these molecules and use an immunolocalization approach to profile their expression in placental biopsies in relationship to pre-identified FR placental levels. My project will result in the novel characterization of the effects of FRs on CTB differentiation and the molecules that regulate these processes. Proteins identified to be altered by FRs may be used as biomarkers of FR
exposure in future environmental health studies. In summary, this work will help us understand how environmentally-induced toxicity may contribute to placental pathologies during human pregnancy.

Cell fate under N-acyl dopamines control: to die or to differentiate?
M.G. Akimov1, A.M. Ashba1, N.M. Gretskaya1, V.V. Bezuglov1;
1Laboratory of Oxylinps, Shemyakin-Ovchinnikov Institute of Bioorganic Chemistry, RAS, Moscow, Russia

Bioactive lipids N-acyl dopamines (NADA) are conjugates of dopamine with fatty acids, which usually are unsaturated, and belong to the endocannabinoid/endovanilloid family. They are synthesized in mammals, as well as in some more primitive organisms. The known molecular targets of NADA are the GPCRs CB1, CB2 and several non-CB1/CB2 receptors, ion channel TRPV1 as well as some other proteins (dopamine receptors, potassium and calcium channels). The objective of the study was to evaluate the long-term effects of NADA on cell proliferation and death and to elucidate the underlying mechanisms. As far as most of the known NADA effects occur within nervous system, we used PC12 pheochromocytoma, HT22 neuroblastoma and C6 glioma cells as a model. For each cell line, the LC50 of a set of NADA was determined, and after that the cultures were incubated with various concentrations of NADA for two weeks. Cell death was assessed using MTT, LDH tests, caspase activity and annexin staining. The differentiation degree was determined by the count and length of the processes and by the mRNA expression of several stem, neural progenitor, astrocyte and “neuron markers. The molecular target of NADA and signal transduction pathways were determined using inhibitor screening, siRNA knockdown or using reporter systems. The LC50 values for NADA with arachidonic, oleic and docosahexaenoic fatty acid residues, as well as for arachidonic acid amides of tyramine and norepinephrine were in range 2-30 μM. The prolongation of cell culture treatment with NADA did not increase cell death. Instead, the concentrations below 1 μM stimulated cell proliferation, and those in range 1 μM–LC50 induced neurite outgrowth in PC12 and C6 cells with a shift towards neuronal and astrocytic marker expression, accordingly. In HT22 cells, no response other than cell death was observed for intermediate and high NADA concentrations. The molecular target of the NADA action in the PC12 cells was found to be the non-CB1/CB2 receptor GPR55, which transduced signal through PLC, IP3R and calcium to the CaMKIV, and then to the CREB transcription factor with NO synthase expression induction and a supposed IL-6 secretion; the latter is expected to induce differentiation via the JAK-STAT signaling pathway. Thus, on the model of the rat C6 glioma and the PC12 pheochromocytoma cells, we demonstrated for the first time that the low concentrations of N-acyl dopamines (below 1 μM) stimulate cell proliferation, intermediate ones (1-20 μM) induce differentiation, and higher ones lead to apoptosis after a specific receptor activation. The work is partially supported by the RFBR grant 16-04-00729a.

The tumor suppressor Lkb1 controls cell fate through pyruvate-alanine transamination.
A.G. RADU1,2, S. Torch1,2, F. Fauvelle3, P. Hainaut1, L. Larue4, C. Thibert1,5, M. Billaud5,6;
1Tumor molecular pathology and biomarkers, Institute for Advanced Biosciences, INSERM/UJF U1209, Grenoble, France, 2cofirst authors, Grenoble, France, 3MRI Facility IRMage, Grenoble Neurosciences Institut, INSERM/CEA U817, Grenoble, France, 4Normal and Pathological Development of Melanocytes, Institut Curie, CNRS UMR3347; INSERM U1021, Orsay, France, 5co-senior and co-corresponding authors, Grenoble, Lyon, France, 6Centre de Recherche en Cancerologie, Université Claude Bernard Lyon I, INSERM 1052, CNRS 5286, Lyon, France

The tumor suppressor LKB1 (also named STK11) codes for a serine/threonine kinase. Germline mutations of LKB1 are responsible for the Peutz-Jeghers syndrome, a dominantly inherited cancer disorder. Somatic mutations of this gene have been associated with various cancers including lung and cervical tumors. Lkb1 acts as a key regulator of energy metabolism through the activation of the AMP-activated protein kinase (AMPK), a sensor that adapts energy supply to the nutrient demands of cells facing situations of metabolic stress. To achieve metabolic adaptations, AMPK phosphorylates numerous substrates which inhibit anabolic processes while activating catabolic reactions. In particular, AMPK inhibits the nutrient-sensor kinase mTOR. In addition to AMPK, Lkb1 also phosphorylates 12 AMPK-related kinases that regulate cell polarization, axon branching of cortical neurons and hepatic neoglucogenesis.

To determine how Lkb1 coordinately regulates cell polarity and energy metabolism during cell fate decision, we spatio-temporally deleted the Lkb1 gene in embryonic multipotent neural crest cells (NCC). These cells originate from the neural tube and give rise to various tissues including the peripheral nerves and the enteric nervous system (ENS). We showed that Lkb1 governs several aspects of cephalic NCC development that are crucial during vertebrate head formation (Creuset et al., 2016). We also reported that mutant mice exhibited hypopigmentation, hindlimb paralysis and intestinal pseudo-obstruction. We described that Lkb1 is crucial for the differentiation and maintenance of two NCC-derivatives, Schwann cells and the ENS. Using a model of neural crest stem cell line, we demonstrated that Lkb1 is key for glial differentiation. Mechanistically, Lkb1 loss led to increased alanine levels as also observed in vivo. Interestingly, inhibition of pyruvate-alanine transamination rescued glial differentiation of Lkb1-null NCC, in a dependent manner of mTOR. Furthermore, AICAR rescued glial differentiation of Lkb1-deficient NCC and treatment of Lkb1-deficient mice with AICAR corrected the Schwann cells and ENS phenotypes (Radu et al., submitted).

Altogether, these findings highlighted the novel and crucial role of Lkb1 during neural crest cell fate and uncovered a link between Lkb1-mediated pyruvate-alanine cycling and glial differentiation. These results provide new insights to understand the metabolic regulations exerted by Lkb1 during development and tumorigenesis.
Cell fate determination is critical for cell survival and development. Importantly, cell fates are shaped by the integration of multiple signals such as external cues, intracellular nutrient storage, and the overall state of the cell. Our research is using budding yeast to study a model differentiation system: entry to meiosis/sporulation. When diploid yeast is exposed to medium without nitrogen and fermentable carbon, it can activate a specific transcriptional program that allows yeast to irreversibly commit to meiosis and sporulate. To be able to commit to meiosis, yeast has to accumulate nutrients, especially storage carbohydrates (Kane & Roth 1974). However, how upstream nutrition level regulates cell commitment remains poorly understood. Here, we investigate how storage carbohydrates affect sporulation using combinations of single cell microscopy and biochemical methods. Using fluorescently tagged enzymes that regulate the storage carbohydrates trehalose and glycogen, we can predict whether individual cells will sporulate with high (~90%) accuracy. Ongoing work aims to link such single cell measurements to the actual levels of the storage carbohydrates to verify our working hypothesis that entry to meiosis is determined by some fixed threshold of storage carbohydrates.

Background: Pulmonary fibrosis is a debilitating disease that is poorly understood. Carbon nanotubes (CNTs) have been shown to induce pulmonary fibrosis in animals, which is of concern given their widespread use in consumer products and other applications. While animal models of CNT exposure are well characterized, a robust in vitro model of particle induced fibrosis would enable testing of the fibrotic potential of these particles more quickly and efficiently. Due to the important role the extracellular matrix plays during fibrosis, an in vitro model based in a three-dimensional extracellular matrix such as collagen is necessary to best recapitulate the disease state in the body. The current study uses a 3D assay of cell contractile ability, the gel contraction assay, in conjunction with investigation of biomarkers of fibrosis to test the fibrotic potential of several CNTs of different physical dimensions.

Methods: WI38-VA13 human pulmonary fibroblasts were treated with various CNTs of differing physical properties. Exposed cells were examined for markers of myofibroblast differentiation, an important step of the fibrotic process, including α-Smooth Muscle Actin (α-SMA) expression and cellular contractile ability in a 3D in vitro model.

Results and Conclusion: Fibroblasts treated with CNTs displayed increased contractile ability compared with untreated controls. Additionally, CNT treated fibroblast expressed markers of α-SMA, a marker of myofibroblast differentiation. The fibrogenic potential of CNTs tested varied, with CNTs of more extreme physical dimensions, the largest and smallest aspect ratios in the group of CNTs tested, having a greater
effect on fibroblasts in the gel contraction assay. These results indicate that the physical dimensions of CNTs may affect their fibrogenic potential. The collagen gel contraction assay used allows for efficient measurement of the contractile ability of fibroblasts, an important component of fibrosis. Additionally, cells can be directly examined for markers of myofibroblast differentiation such as α-SMA. Finally, while not attempted in this study, the gel contraction model can be expanded to include other cell types, allowing for a more robust study of the cell interactions at play during induction and progression of fibrosis.

Understanding programming logic of motor neurons from differentiated and undifferentiated cells.

G. Garipler1, S.E. Vidal2, M. Stadtfeld2, E.O. Mazzoni3;
1Department of Biology, New York University, New York, NY, 2The Helen L. and Martin S. Kimmel Center for Biology and Medicine, Skirball Institute of Biomolecular Medicine, Department of Cell Biology, NYU School of Medicine, New York, NY

The safety concerns for transplantation of tissues derived from iPSCs/ESCs based differentiation protocols propose in vitro or in vivo transdifferentiation of somatic cells as a substitute for clinical applications. Although programming from somatic cells has the potential to be instrumental for cell replacement therapies, transdifferentiation is inefficient. The goal of this study is to understand how transcription factors (TFs) program rapidly-dividing pluripotent stem cells into post-mitotic motor neurons and then to apply this knowledge to efficiently program motor neurons from differentiated cell types.

Viral expression of 7 TFs (Ascl1, Brn2, Myt1l, Ngn2, Isl1, Lhx3 and Hb9) is able to transdifferentiate primary mouse embryonic fibroblasts (pMEFs) to spinal motor neurons (sMNs) with low efficiency (4%). Comparison of this approach to an efficient (>90%) ESC based sMN programming protocol that expresses three transcription factors (Ngn2-Isl1-Lhx3, the NIL factors) lead to an increase of efficiency (20%) in pMEF based sMN programming with maintaining 1:1 stoichiometry between Isl1 and Lhx3. NIL factors induce secondary TFs, Ebf and Onecut families during programming in ESC and colocalize with these secondary TFs at sMN specific regulatory regions. Preliminary results demonstrate that NIL factors fail to induce Ebf and Onecut TFs in pMEFs, and thus, propose a potential mechanism causing inefficient sMN programming in pMEFs. To further improve the efficiency of transdifferentiation, I will investigate if forced expression of other TFs required for sMN differentiation improves the sMN programming efficiency from pMEFs. Ration ally improving an inefficient transdifferentiation protocol by comparing to an efficient differentiation approach from ESC can lead to TF combinations that will be applicable to transdifferentiate other cell types. In the future, novel programming methods can be used to generate homogenous neuronal fates for in vitro disease modeling, drug studies and in vivo cell replacement therapies.

Molecular mechanisms of sterol transfer in intracellular coral-algal symbiosis.
E.A. Hambleton¹, I. Maegele¹, N. Bechtoldt¹, A. Guse¹;
¹Centre for Organismal Studies, Heidelberg University, Heidelberg, Germany

Many animals establish symbioses with microorganisms to gain an ecological advantage. A remarkable example is the endosymbiosis between corals and dinoflagellates (genus Symbiodinium), which provide photosynthetically fixed nutrients to enable coral survival in nutrient-poor tropical oceans. Corals are unable to endogenously synthesize cholesterol, an essential membrane component and regulator of developmental and signaling pathways, whereas coral symbionts (like their fellow dinoflagellates) synthesize cholesterol and many related sterols, but the basis and function for this breadth remains unknown. Here we use Aiptasia, a marine sea anemone, as an emerging laboratory model for coral endosymbiosis to dissect the role of the evolutionary highly-conserved cholesterol-binding proteins Niemann-Pick Type C (NPC2) in sterol transfer from the symbiont to the host. We find that the NPC2 gene family is expanded from one to six or more genes in corals and Aiptasia when compared to humans. Some NPC2 gene sequences fall outside the group of canonical NPC2s, leading to the hypothesis that these ‘non-canonical’ NPC2s are an adaptation to exploit the variety of symbiont-produced sterols for cellular use. Accordingly, gene expression of various NPC2 genes is upregulated in response to symbiosis in Aiptasia and corals and semi-quantitative GC-MS analysis reveals that indeed symbionts transfer cholesterol as well as many other sterol derivatives to their hosts. Interestingly, sterol composition in the hosts varies with different symbiont types housed. We generated polyclonal antibodies to those non-canonical NPC2 proteins and using western blotting could confirm the presence of NPC2 proteins in symbiotic animals but not in non-symbiotic ones. Currently, we are exploiting our antibodies to analyze protein localization and are establishing lipidomics techniques to directly test the binding patterns between the non-canonical NPC2 proteins and distinct sterols. Taken together, our data suggest that functional adaptation of existing molecular machineries may have contributed to forming a functional holobiont and thus the successful radiation of reef-building corals into nutrient-poor habitats.

Type III interferon signaling affects Cryptosporidium parvum infection of human intestinal epithelial cells.
A.R. Gibson¹,², B. Striepen¹,², A. Sateriale¹;
¹Center for Tropical and Emerging Global Diseases, University of Georgia, Athens, GA, ²Cellular Biology, University of Georgia, Athens, GA

Interferons are a family of cytokines that were initially discovered and named for their ability to interfere with viral replication. Type III interferons, interferon lambda subtypes 1-4, are members of the most recently discovered class. IFN lambda shares all upstream components of signaling with type I interferons, interferon alpha and beta, a well characterized relative. In contrast to IFN-a/b controlling viral replication systemically, IFN lambda specifically prevents viral replication within cells of epithelial origin. The specificity of the type III interferon response is based on the restricted expression of the IFNLR1 subunit of the receptor which is almost exclusively expressed on epithelial cells.
Cryptosporidium is an obligate intracellular protozoan parasite, and the second leading cause of severe diarrhea and diarrheal-related death in children worldwide. There are currently no vaccines and the only drug available has low efficacy in immunocompromised individuals who need it most. A lack of tools to study Cryptosporidium including continuous culture, molecular genetics, and immune competent animal models have impeded progress towards development of novel therapeutics. We conducted a genome-wide CRISPR/Cas9 knockout screen to discover host genes necessary for Cryptosporidium parvum infection. Type III interferon signaling was the most highly enriched pathway in our screen. Human intestinal epithelial cells, HCT-8s, stably expressing Cas9 were transfected with a lentiviral sgRNA library targeting every gene in the human genome. Selection for resistance to cell death was accomplished by three consecutive 72-hour C. parvum infections. After each challenge, cells were removed for gDNA extraction and sequenced to determine the abundance of each sgRNA. The top 25 enriched genes after three replicates indicate that type III interferon signaling is important for C. parvum infection. Investigation into the role of type III interferon signaling in C. parvum infection will reveal how a viral defense pathway seems to promote parasite infection.

A possible role for unconventional splicing enzymes in nonreplicative recombination of poliovirus.
A.A. Shishova1, I. Dyugay1;
1biochemistry, Institute of Poliomyelitis and Viral Encephalitis, Moscow, Russia

RNA recombination is one of the major driving forces in RNA virus evolution. Two mechanisms of this process are known to date. A recombinant RNA molecule may be formed due to the replicative template switching. Recently, there are increasing data about another, nonreplicative mechanism of viral RNA recombination. However, roles of host factors in this process remain poorly understood. We investigated the role of unconventional splicing enzymes in the process of viral RNA recombination, particularly IRE1 endonuclease. IRE1 was shown to be involved in Xbp1 mRNA intron excision in cytoplasm during UPR (unfolded protein response). A chimeric virus with a structure mimicking Xbp1 intron was inserted in a 3D-polymerase coding sequence. These mutations lead to failed viral reproduction due to the open reading frame shift. But reactivation of IRE1 endonuclease activity by chemical inducers of UPR lead to intron excision and restoring viral reproduction. A similar sequence with point mutations disrupting the IRE1 excision site was inserted into the 2A-protease coding sequence of poliovirus. Constructed virus also showed increased viability upon IRE1 activation by chemical inducers of UPR. Taken together our data shows colocalization of poliovirus RNA with IRE1 and a possible role for unconventional splicing enzymes in viral RNA recombination. We also discuss the role of cellular tRNA ligase HSPC117 in the process of non replicative poliovirus recombination. To study fundamental aspects of RNA recombination by the use of poliovirus derived RNAs, a cell culture based RNA recombination system has been established. This system allowed the generation of infectious viral RNA genomes by nonreplicative RNA recombination between two synthetic, replication incompetent transcripts. Knockdown of genes, which are essential for viral recombination will lead to failed recombinants production. Since we have in vivo system for nonreplicative recombination of poliovirus, we can observe the effect of gene knockdown on the production of recombinants. Future studies will elucidate the role of nonreplicative RNA recombination and bring new insights into the molecular mechanism of this process.

Non-silencing miRNAs promotes autophagic viral degradation by inhibiting retroviral Gag assembly.
N. Qu¹, C.J. Krueger¹², A.K. Chen¹;
¹Department of Biomedical Engineering, College of Engineering, Peking University, Beijing, China,
²Wallace H Coulter Department of Biomedical Engineering, Georgia Institute of Technology, Atlanta, GA

MiRNAs are a class of short non-coding RNAs that are recognized for their functions in silencing gene expression through base-pairing with target mRNAs. In this study, we have found that miRNAs can generally inhibit the assembly and budding of retroviruses MLV and HIV-1 through a mechanism not involving gene silencing. We showed that this blockade occurs by miRNA binding to retroviral Gag protein, the major structural protein of all retroviruses. This interaction disrupts Gag assembly at the plasma membrane, causing endocytosis of the misassembled viral complexes and ultimately their degradation in lysosomes through an intermediate pathway involving LC3, p62, ULK1 and ATG5, which are essential components of autophagy. Overall, these results support the idea that miRNAs can exert functions besides gene silencing, and that, in the context of retroviral biology, miRNAs and autophagy can work synergistically to block retroviral production. Additionally, these findings also raise the possibility of developing a universal strategy to combat retrovirus infection based on synthetic oligonucleotides. Finally, the observed pathway leading to the degradation of misassembled viral complexes could manifest in other cellular and pathological contexts where regulation of misassembled RNA-protein complexes are critical.

Fulicin-like immunoreactivity in Biomphalaria glabrata, an intermediate host for schistosomiasis.
M.W. Miller¹, A. Hernandez Vazquez¹, M.B. Rodriguez¹, S. Rolon¹, L.O. Vaasjo¹, P. Mendez de Jesus¹, M. Rosa Casillas¹;
¹Institute of Neurobiology, University of Puerto Rico Medical Sciences Campus, San Juan, PR

About 10% of the world’s population live at risk of contracting the parasitic disease schistosomiasis. Schistosoma mansoni, the digenetic trematode that causes the most widespread form of intestinal schistosomiasis, employs the freshwater snail Biomphalaria glabrata as its primary intermediate host. It has been shown that infection of B. glabrata by S. mansoni causes profound behavioral changes in the snail host, including parasitic castration, a reduction in reproductive behaviors. In this study, a neural transcriptomics approach was undertaken to identify precursor prohormones that could encode neuropeptides involved in Biomphalaria reproductive behaviors. A transcript (1616 nucleotides) was found to encode a putative precursor polypeptide (316 amino acids) that could give rise to the neuropeptide fulicin (Phe–D–Asn–Glu–Phe–Val–NH₂) and five additional related peptides. For this investigation, affinity purified polyclonal antibodies were generated against the predicted fulicin neuropeptide. Antibody specificity was confirmed with dot blots and preabsorption control experiments. Fulicin–like immunoreactivity was observed throughout the central nervous system (CNS) and in specific peripheral tissues. Double-labeling experiments (biotin backfill x fulicin immunohistochemistry) identified three groups of fulicin-like immunoreactive neurons that project to penile nerve. Immunoreactivity was present in the ovisperm duct, sperm duct and prostate gland, tissues associated with the male reproductive system. These results indicate that fulicin and other
peptides derived from the fulcin precursor could regulate male reproductive behaviors that are altered during the course of infection in this host-parasite system.

Identification of inflammatory biomarkers in dengue disease severity in eastern India.
A. Patro1, B. Prusty1, S. Gaikwad2, D. Singh2, S. Mohanty2, B. Das2, B. Ravindran1;
1Infectious Disease Biology Group, Institute of Life Sciences, Bhubaneswar, India, 2Medicine, SCB Medical College, Cuttack, India

Background: Dengue is the most common arboviral infection with an estimate of 390 million infection per year and about 3.6 billion people at risk. Notably, 34% of the total global infections of dengue reported is from India alone. The detail mechanisms of dengue pathogenesis are not established yet. Host immune response could contribute to disease severity. There are four serotypes of dengue virus (dengue-1, -2, -3 and -4). There are limited data on the circulating strains in this region. Information on the circulation strains and identification of inflammatory biomarkers will help in devising effective interventionalal strategies. Objective: To determine the dengue virus circulating strains, immune biomarkers involved in disease severity in eastern India Methodology: Eight nine subjects of suspected dengue subjects (WHO criteria) presented to the SCB Medical College & Hospital, Cuttack, India, during the 2016 outbreak, were enrolled in the study. Dengue virus detected by serology and RT-PCR. Dengue serotype discrimination and was made by types-specific PCR and Sequencing. Multiplex cytokine bead array for 41 cytokine panel was used to measure the expression of the inflammatory biomolecules.
Results: RT-PCR for dengue detected in 49% samples. Dengue serotype-2 was predominant (58%) followed by serotype-1 (24 %), serotype-3 (8 %) and serotype- 4 (in 10 %) subjects. Mixed infections were seen in 39% subjects. Mixed infections were seen in 39% subjects. The levels of IFN-γ, GM-CSF, IL-10, IL-1Rα, IL-6 TNF-α, MIP-1β and MCP-1 were significantly elevated in severe dengue. Conclusions: Dengue virus serotype-2 was predominant type in this outbreak. This study demonstrated the association of serotype specific immunity in determinants of severe dengue. The involvement of the host inflammatory biomarkers, could serve as potential predictor for therapeutic interventions. The pathogenic yeast, Cryptococcus neoformans, alters the transcriptome of host macrophages.
L.M. Siricy1, K.D. Cunningham2, R.L. Seipelt-Thiemann1, E.E. McClelland1, D.E. Nelson1;
1Biology, Middle Tennessee State University, Murfreesboro, TN, 2Chemistry, Middle Tennessee State University, Murfreesboro, TN

Cryptococcus neoformans (Cn) is a ubiquitous fungal pathogen that is a leading cause of mortality among the immunocompromised with almost 625,000 deaths per year worldwide. While Cn infections usually begin as acute pulmonary infections that can progress to fungal meningitis, Cn can also establish long-lasting chronic infections by residence inside host macrophages. However, the mechanisms Cn utilizes to circumvent the host immune response are only partially understood. Some intracellular pathogens, including Cn, are able to attenuate the innate immune response through inhibition of host cell protein synthesis, altering host cellular functions, or by compromising macrophage polarization. Classically-polarized (M1) macrophages exhibit enhanced microbicidal activity and are associated with a more
favorable clinical outcome in cryptococcal infections, while alternatively-activated (M2) macrophages are less able to destroy ingested pathogens. However, the mechanisms intracellular Cn uses to disrupt host macrophage function to survive are poorly understood. Although altered host macrophage function by intracellular Cn could be explained as a byproduct of cellular stress, we hypothesized that there would be Cn-induced changes in the gene expression of host macrophages that lead to the attenuated immune response. Using RNA sequencing to assess the transcriptome profile of M1-polarized Cn- and non-infected RAW 266.7 murine macrophages, we first analyzed the data using R-based tools to generate hierarchical clusters and multidimensional scale plots to visualize similarities of overall gene expression. The data were then analyzed for differential gene expression between Cn-infected and non-infected macrophages. Gene ontology enrichment analysis was then used to determine over-represented functional pathways and processes. Our data suggest that there are unique gene expression profiles, and that intracellular Cn causes altered expression of ribosomal and mitochondrial oxidative phosphorylation genes. These differences corroborate previously reported inhibition of host cell translation and mitochondrial dysfunction upon Cn-infection. Furthermore, our data show that even in an M1-polarized environment, there is an up-regulation of M2-specific markers, including M2-associated Arg1 and M2-exclusive Myc, after 24 hours of infection. Additionally, using western blotting, our data show an up-regulation of c-Myc after 24 hours of infection. Therefore, our data suggest that intracellular Cn alters macrophage function through changes at the transcriptional level to attenuate fungicidal activity and survive long-term within host cells.

Role of Viperin Interaction with Human Cytomegalovirus Tegument Protein pp28 in Virion Assembly.
J. Lee1, H. Jeon1, J. Seo1;
1Severance Biomedical Science Institute, Brain Korea 21 PLUS Project for Medical Science, Yonsei University College of Medicine, Seoul, Korea, South

Viperin is a multifunctional interferon (IFN)-inducible protein that is directly induced in cells by human cytomegalovirus (HCMV) infection. Viperin normally localizes to the endoplasmic reticulum (ER) and has antiviral activity. However, this protein re-localizes from ER to mitochondria by interacting with a HCMV protein vMIA at early stage of infection and modulates cellular metabolism to enhance viral infectivity. Viperin finally localizes to the virus assembly compartment (AC) at late stage of infection, although its function remains unexplored. Viperin interaction with HCMV viral proteins is the key factor to determine viral replication status. Nevertheless, HCMV viral proteins which interact with viperin have not yet been identified except for vMIA. Here, we screened interacting partners for viperin using yeast two hybrid assay. We selected a HCMV tegument protein pp28 that is accumulated at the AC at late stage of infection and essential for viral replication. The pp28 contains a stretch of acidic amino acids (aa 44-59) that is required for its trafficking to the AC and the virus assembly. Recently, we have shown that this acidic cluster of pp28 has distinct functional domains. The first half (aa 44-50) of the acidic cluster is sufficient for pp28 trafficking and the native acidic cluster containing the second half (aa 51-59) is required for the virus assembly. We confirmed that viperin interacts with pp28 in transient transfection and viral infection and co-localizes with pp28 to the AC at late stage of infection. We generated a panel of pp28 mutants and identified a binding domain (aa 51-61, the second half of acidic cluster of pp28) of pp28 interacting with viperin. Recombinant viruses expressing this pp28 deletion mutant (delta aa 51-61) but not pp28 acidic cluster deletion mutant (delta aa 44-59) produced infectious virions. We also observed that the pp28 deletion mutant (delta aa 51-61) localizes to the AC at late stage of infection.
However, the recombinant viruses exhibited delayed viral growth kinetics and decreased viral yield. The results suggested that viperin interaction with pp28 plays a critical role in the virus assembly and the production of infectious viruses, and the second half of acidic cluster of pp28 is required for their interaction.

Computational analyses of the ExoS protein, a component of Sinorhizobium meliloti ExoR-ExoS/ChvI pathway.

E. Wiech¹, H. Cheng², S.M. Singh¹;
¹Biology, Brooklyn College, City University of New York, Brooklyn, NY, ²Biological Sciences, Lehman College, City University of New York, Bronx, NY

The Sinorhizobium meliloti periplasmic ExoR protein and the ExoS/ChvI two-component system form a regulatory mechanism, the RSI Invasion Switch, which directly controls the transformation of free-living to host-invading cells. In the absence of crystal structures, understanding the molecular mechanism of interaction between ExoR and the ExoS sensor, which is thought to drive the key regulatory step in the invasion process, remains a major challenge. Here we present for the first time a three-dimensional representation of S. meliloti Rm1021 ExoS periplasmic sensing domain generated through computational methods. Our model suggests the Per-ARNT-Sim (PAS)-like fold for ExoSp. Even though ExoSp shares a similar overall structure as other PAS domains, it does not bind small ligands and therefore probably uses a different mechanism to recognize and bind the periplasmic binding protein, ExoR. We suggest that elongated structural elements that are unique to ExoSp might provide flexibility to this fold to accommodate binding of ExoR, an elongated multi-repeat protein. This study lays the foundation for future work including experimental analysis that target key proposed functional sites of ExoSp and the interface of the ExoSp-ExoR complexes so as to validate the ExoSp model and uncover the essential residues employed in ExoSp-ExoR interactions.

SERINC5 Inhibits HIV-1 Fusion Pore Formation by Promoting Functional Inactivation of Env Glycoproteins.

M. Marin¹, C. Sood¹, A. Chande², M. Pizzato², G.B. Melikian¹,³;
¹Pediatrics, Emory University, Atlanta, GA, ²Centre for Integrative Biology, University of Trento, Trento, Italy, ³Children’s Healthcare of Atlanta, Atlanta, GA

SERINC5 (SER5) is a newly discovered multi-transmembrane domain protein that inhibits HIV-1 infectivity upon incorporation into budding virions in the absence of HIV/SIV Nef expression. The cellular functions of SER5 and the mechanism by which this protein restricts HIV-1 infection are poorly understood. The SER5-sensitivity maps to the HIV-1 envelope (Env) glycoprotein, with different isolates exhibiting a broad range of sensitivities to this host factor. Based upon the earlier observation that SER5 more potently blocks viral infection than fusion, it has been proposed that SER5 impairs enlargement of the fusion pore and thereby prevents the release of viral nucleocapsid. Here, by using live imaging assays, we show that incorporation of SER5 into virions in the absence of Nef inhibits the formation of small fusion pores between viruses and cells. We also demonstrate that SER5 restricts both virus-mediated fusion between adjacent cells (“fusion-from-without”) and cell-cell fusion between Env-expressing and CD4/coreceptor-expressing target cells. Importantly, we found that SER5 promotes
spontaneous functional inactivation of sensitive, but not resistant Env glycoproteins, an effect that phenocopies the SER5 resistance phenotype. We found that the accelerated loss of Env function upon SER5 incorporation occurs through exposure of the conserved domains of the transmembrane gp41 subunit of Env, as evidenced by the enhanced virus sensitivity to neutralizing antibodies against cryptic gp41 epitopes and to gp41-derived inhibitory peptides. Together, our results imply that SER5 blocks HIV-1 infection at a step upstream of small fusion pore formation by selectively inactivating Env and delaying conformational transitions of the HIV-1 gp41 en route to fusion. Efforts are on the way to detect SER5-Env interactions within virions and to assess the possibility that this restriction factor interferes with the formation of functional Env clusters on the viral envelope. This work was partially supported by the NIH R01 grant GM054787 to G.B.M. The first two authors contributed equally to this work.

Behavioral Response of Caenorhabditis elegans with Pseudomonas aeruginosa Infection Controlled by Iron Variables.
Q.N. Robinson¹, R.E. McFarlane¹, J.A. Jordan¹;
¹Department of Biology, Clayton State University, Morrow, GA

Caenorhabditis elegans is a model organism that has a life span of 2 to 3 weeks; it’s widely studied within laboratories because of its host pathogen interaction. This organism expresses unique characteristics such as defense mechanism against pathogenic virulence. A known resistant pathogen is Pseudomonas aeruginosa, a common bacteria found in various amounts of environments such as plants and animals. P. aeruginosa thrives and colonizes to form clusters of biofilm that affects patients with a disease known as cystic fibrosis. Cystic fibrosis is a disease where mucus builds up in the lungs in which affects the respiratory system. Previous studies have shown that three mechanisms are known to killing C. elegans; NG medium, increase the iron concentration of high-osmolality, and brain- heart infusion medium. Studies have shown that the NG medium has a “slow killing” of this organism and high osmolality has a “fast killing.” In this research, we are studying the environmental behavior that interacts between the biofilm and C. elegans when being exposed to various levels of the medium. Current studies suggest that increasing the osmolality of iron would extend the slow killing process of C. elegans.

Multiple Epstein-Barr viral microRNAs downregulate human NF-kB pathway transcripts.
L. Parsley¹, D. Kolakada¹,², K. Riley¹;
¹Department of Chemistry, Rollins College, Winter Park, FL, ²Immunology Microbiology, University of Colorado Denver, Denver, CO

The Epstein-Barr virus (EBV) is a gamma-herpesvirus infecting nearly 95% of humans worldwide. EBV infection is the primary cause of infectious mononucleosis and has been linked to specific malignancies including Burkitt’s lymphoma and nasopharyngeal carcinoma. Through divergent expression of 49 mature microRNAs (miRNAs), EBV disrupts cellular mechanics to enable pathogenesis. The targets of the EBV miRNAs are not completely understood. High-throughput sequencing and crosslinking immunoprecipitation (HITS-CLIP) and bioinformatic predictions identified targets of EBV and human miRNAs in Burkitt’s lymphoma cells and demonstrated a significant enrichment of at least seven NF-kB pathway transcripts. To confirm the extent of downregulation and specificity of miRNA base pairing to
these transcripts, luciferase reporter assays and endogenous protein western blots were conducted for each potential miRNA-mRNA pair. Many, but not all predicted, EBV BART miRNAs significantly downregulate NF-kB pathway proteins, most likely to fine tune expression of the pathway.

Adhesion of Providencia stuartii onto Cultured Bladder Epithelial Cells.
N. Kurmasheva1, M. Sharipova1, A. Mordanova1;
1Institute of Fundamental Medicine and Biology, Kazan (Volga region) Federal University, Kazan, Russia

Providencia stuartii are opportunistic bacteria related to the pathogens of nosocomial urinary tract infections. However, so far little is known about the mechanisms of pathogenesis used by these bacteria. The initial step of the infectious process is the ability of microorganisms to adsorb or to adhere onto sensitive cells and such interaction involves the specialized structures on their surfaces. According to modern concepts, adhesins are surface proteins or glycoproteins of the bacterial cell. Data on the adhesive potential of P. stuartii are not widespread in the literature and some basic questions remain unanswered. The purpose of this work is to study the adhesiveness of opportunistic bacteria P. stuartii using bladder epithelial cell line. The clinical isolate of P. stuartii NK has been used in the work. First of all, by using quantitative adhesion assay it has been demonstrated that the bacteria are able to adhere onto T24 eukaryotic cell line. To determine the nature of the bacterial components responsible for binding to eukaryotic cells, the microbial culture was treated with trypsin. It has been established that a preliminary 10-minute enzymatic treatment of P. stuartii NK at 37°C ensured the reduction of adhesion index by 94% compared to the control. The adhesion of P. stuartii NK onto eukaryotic cell line has been visualized by scanning electron microscopy (Carl Zeiss, Germany). The cell culture was grown on coverslips until a subconfluent monolayer was reached and infected with the daily culture of P. stuartii NK. Samples were taken after 30, 60, 90 minutes of incubation at 37°C and fixed in 1% glutaraldehyde solution. Microphotographs have showed the presence of bacterial cells on the eukaryotic surface and the formation of contacts between them. Thus, it has been shown that bacteria P. stuartii NK are able to adhere onto the bladder epithelial cells. The adhesion index of P. stuartii NK has been significantly reduced after the pretreatment of bacteria with trypsin, which indicates the participation of protein substances in the attachment process onto eukaryotic cells. The work is performed according to the Russian Government Program of Competitive Growth of Kazan Federal University.

Viperin exerts antiviral function against Junín mammarenavirus at different subcellular localizations.
M.L. Morelli1, J.R. Peña Cárcamo1, C.A. Vázquez1, S. Vatansever2, A.S. Upadhyay3, A.K. Överby3, S.M. Cordo1, C.C. García1;
1Biochemistry Department, Antiviral Strategies Laboratory, School of Sciences- University of Buenos Aires, Buenos Aires, Argentina, 2Graduate School of Science and Engineering, Koc University, Istanbul, Turkey, 3Department of Clinical Microbiology, Laboratory for Molecular Infection Medicine Sweden (MIMS), Umeå University, Umeå, Sweden

Junín arenavirus infections are associated with high levels of interferons in both severe and fatal cases. Upon Junín virus (JUNV) infection a cell signaling cascade initiates, that ultimately attempts to limit viral

Tuesday-526
replication and prevent infection progression through the expression of host antiviral proteins. The interferon stimulated gene (ISG) viperin has drawn our attention as it has been highlighted as an important antiviral protein against several viral infections. The studies of the mechanistic actions of viperin have described important functional domains relating its antiviral and immune-modulating actions through cellular lipid structures. In line with this, through silencing and overexpression approaches, we have identified viperin as an antiviral ISG against JUNV. In addition, we found that lipid droplet structures are modulated during JUNV infection, suggesting its relevance for proper virus multiplication. Furthermore, our confocal microscopy images, bioinformatics and functional results also revealed viperin-JUNV protein interactions that might be participating in this antiviral pathway at lipid droplet level. Altogether, these results will help to better understand the factors mediating innate immunity in arenavirus infection and may lead to the development of pharmacological agents that can boost their effectiveness thereby leading to new treatments for this viral disease.

Synaptotodin-2, a novel promyogenic marker required for the development of sarcomeric Z-disk in zebrafish.
N. Margam¹, F. Kai², V. Rajan¹, J.N. Berman¹,³, R. Duncan¹,³,⁴;
¹Microbiology and Immunology, Dalhousie University, Halifax, NS, ²Department of Surgery, University of California, San Francisco, San Francisco, United States, ³Department of Pediatrics, Dalhousie University, Halifax, NS, ⁴Biochemistry and Molecular Biology, Dalhousie University, Halifax, NS

Myogenesis is a differentiation-dependent cell-cell fusion process that involves migration and fusion of uninucleated myoblasts to form multinucleated myotubes that develop further into striated contractile myofibers. This multi-step process also takes place during muscle regeneration and muscle injury, and several proteins have been identified to play a role in these processes. Deficiency or mutation in muscle-related proteins leads to different kinds of muscular dystrophies leading to weakened and non-functional muscle. Individual muscle cells have to migrate to the site of regeneration and fuse with existing muscle fibers to repair them. Both the migration and fusion process requires extensive remodeling of the actin cytoskeleton. We have discovered a new pro-myogenic actin regulatory protein, Synaptotodin-2 (SYNPO2), that differentially affects myoblast migration and myotube formation. Three isoforms of SYNPO2 was isolated from the mouse myoblast cell line, C2C12, and its functional role in the different stages of myogenesis was studied. Both ectopic expression and knockdown did not affect the expression of myogenic-specific markers, suggesting that the SYNPO2 isoforms function downstream of these proteins, and does not alter the differentiation pathway. Ectopic expression of SYNPO2As enhanced myotube formation, whereas SYNPO2A and SYNPO2B inhibited myotube formation. Knockdown of SYNPO2As, but not SYNPO2A or B, reduced myotube formation by 50% when compared to mock transduced cells. SYNPO2A and SYNPO2B significantly increased directional migration and SYNPO2As decreased directional migration pre-differentiation, and SYNPO2As, significantly decreased migration post-differentiation when compared to mock transduced cells. Therefore, SYNPO2As acts as a negative regulator of myoblast migration increasing the chances of cell-cell contact, thereby acting as a positive regulator of myoblast fusion. To gain further insights into the in vivo function of SYNPO2As, we identified the zebrafish homolog, synpo2b. CRISPR knockout of synpo2b in zebrafish resulted in developmental defects such as tail-coiling and bending of the body axis. When examined by fluorescent actin staining, knockout embryos showed disorganized actin fibers and reduced myotube formation.
Ultrastructural analysis of the knockout tail muscles by electron microscopy showed shortened myofibres, disorganized Z-disk filaments, accumulation of mitochondria and ribosomes between muscle fibers, and aggregation of autophagic vacuoles, the pathologies seen in a muscular dystrophy model. These results suggest that synpo2b is an essential promyogenic protein required for the normal development and maintenance of muscle integrity and function.

Role of metavinculin in actin reorganization and force transmission.
H.T. Lee1, L.Y. Kim2, M. Sarker1, M. Lu1, G.M. Alushin2, K. Burridge3, S.L. Campbell1;
1Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC, 2Cell Biology and Physiology, NHLBI, Bethesda, MD, 3Cell Biology and Physiology, University of North Carolina at Chapel Hill, Chapel Hill, NC

Vinculin (Vcn) is an essential cytoskeletal protein that acts as a scaffold to link transmembrane receptors to actin filaments, thereby playing a crucial role in cell adhesion, motility, and force transmission between cells. While Vcn is ubiquitously expressed, metavinculin (MVcn), a larger isoform of Vcn, is selectively expressed in smooth and cardiac muscle cells. Similar to Vcn, MVcn can directly associate with actin and remodel the actin cytoskeleton. However, distinct from Vcn, MVcn contains an additional exon which encodes a 68-residue insert. Point mutations in the 68-residue insert have been associated with altered actin organization and heart disease, notably dilated cardiomyopathy (DCM) and hypertrophic cardiomyopathy (HCM). Both DCM and HCM are diseases of myocardium, or the heart muscle, that prevent the heart from pumping blood normally because of disruption in force transmission. MVcn expression is higher in muscle cells that require greater force transmission. Given these observations, we postulate that MVcn plays an important role in force generation and transmission through its interaction with the actin cytoskeleton. We have now verified that the wild-type (WT) MVcn tail domain (MVt) does not bundle actin filaments and that the cardiomyopathy-associated MVt mutant ΔL954 shows slightly enhanced actin bundling in vitro through actin cosedimentation assay and negative-stain electron microscopy (EM). We are expanding these studies to investigate how MVcn regulates actin organization in the presence of Vcn. We have observed that WT MVt inhibits Vt-mediated actin bundling via negative-stain EM and actin cosedimentation assay. We have additionally succeeded in expressing MVcn in Vcn null mouse embryonic fibroblasts (MEF) and observed that MVcn localizes to focal adhesions, similar to Vcn. In Vcn null MEFs that transiently express MVcn, focal adhesion size was slightly larger and focal adhesion number per cell slightly fewer compared to cells transiently expressing Vcn. Cell area, on the other hand, did not seem to differ significantly between the cells transiently expressing each isoform. We have more recently generated stable Vcn null MEFs that express either MVcn or Vcn, and are currently conducting similar studies to determine differences between the two isoforms. We also plan to make MVcn disease-associated mutant expressing stable cells to determine differences in adhesion, motility, and force transmission compared to WT MVcn expressing cells. Results from these studies will provide the groundwork for how Vcn and MVcn differ and how MVcn disease mutants contribute to associated cardiomyopathies.

Altered cardiac expression of genes involved in iron metabolism is driven by an iron-independent process in heart failure.
J. Petrak1, M. Krijt2, D. Vyoral2, M. Behounek3, V. Melenovsky3;  
1BIOCEV, First Faculty of Medicine, Charles University, Prague, Czech Republic,  
2Institute of Hematology and Blood Transfusion, Prague, Czech Republic,  
3Department of Cardiology, Institute for Clinical and Experimental Medicine, Prague, Czech Republic

Chronic heart failure (HF) is a multi-system disease characterized by primary cardiac dysfunction associated with neuro-humoral and systemic inflammatory responses to diminished blood flow that affect other organ systems. Systemic iron deficiency was observed in 50 percent of HF patients and myocardial iron levels have been shown to be decreased in HF patients. This suggests that relative deficiency of iron might play an important role in the pathophysiology of HF. To understand the connection between cardiac iron metabolism and heart failure we studied expression of genes involved in iron metabolism in a rat model of HF. In this model, HF is induced by volume overload due to surgically created aorto-caval fistula (ACF). We manipulated iron status of ACF and control (sham-operated) animals using defined diets with different iron content - LOW iron diet (5 ppm Fe), NORMAL iron diet (50ppm Fe) and HIGH iron diet (500 ppm Fe).

Heart failure developed in all ACF cohorts regardless of diet, cardiac function and morphology were not significantly affected by iron content. Animals fed LOW iron diet (both control and ACF) were anemic and had markedly reduced liver iron levels compared to animals fed NORMAL iron diet. Animals fed HIGH iron diet had markedly increased liver iron compared to rats fed NORMAL diet. We observed only very mild increase (cca 10-20 percent) in myocardial iron content in response to increased iron content in diet. Cardiac iron content tended to be marginally lower in ACF animals compared to control sham-operated rats fed the same diet. Despite comparable iron content, mRNA expression of most genes critical for iron metabolism was significantly increased in ACF rats compared to control sham-operated animals. Most of the iron-related genes were upregulated in ACF animals (hepcidin, ferrooxidases ceruloplasmin and hepehaestin, iron exporter ferroportin, iron reductase Dcytb, Tfr2, mitoferrin1 and Voltage-dependent L-type calcium channel subunit alpha-1D) regardless of nutritional iron status.

Upregulation of reductase Steap 3, Hfe, and mitoferrin 1 was significant in ACF animals in NORMAL and HIGH iron cohorts. Expression of H-ferritin and neogenin mRNA was not affected by presence of heart failure neither by iron status. Expression of Tfr1 mRNA positively responded to low iron in diet. The observed marked dysregulation of most genes involved in iron metabolism in failing myocardium suggests presence of an iron-independent process driving the expression. Hypoxia, stress response or other processes and pathways can be hypothesized. Increased expression of Bmp6 mRNA (the key regulator of hepcidin expression) in ACF suggests involvement of TGF-beta/Smad signaling.

Analysis of fusion-related genes in ethanol-treated C2C12 muscle cells.
M.E. Boyle1, C. Brough1, O.M. Kielbasa1;  
1Biology Program, Department of Science and Mathematics, Alvernia University, Reading, PA

A significant event in the formation of skeletal muscle is the fusion of myoblasts to form multinucleated muscle fibers. Fusion of myoblasts with existing muscle fibers continues to be essential throughout life for successful growth and repair of damaged skeletal muscle. Long-term alcohol use has been
associated with the development of skeletal myopathy, which is characterized by progressive muscle weakening accompanied by atrophy of skeletal muscle tissue. In the first part of this study, we assessed the effect of ethanol on the differentiation of C2C12 skeletal muscle cells in culture, utilizing the fusion index calculation as a measurement of differentiation. Our results demonstrate a significant reduction in the fusion of myoblasts to form multinucleated myotubes when treated with a physiologically relevant concentration of ethanol at the start of differentiation. This is consistent with additional published evidence demonstrating that ethanol reduces the differentiation capability of skeletal muscle cells, in part by preventing fusion of myoblasts to form mature muscle fibers. In the second part of this study, we are investigating the expression of fusion-related genes to determine if there are specific factors that are impacted by ethanol treatment. We performed a literature search to identify potential gene candidates involved in the fusion process and are examining their expression in ethanol-treated C2C12 cultures. For these experiments, RNA was extracted from cultures that were either untreated or treated with 100 mM ethanol over five days of differentiation. RNA was converted to cDNA and PCR was performed using gene-specific primers. For the gene candidates analyzed so far, preliminary results do not indicate consistent expression changes in ethanol-treated cultures as compared to untreated cultures. In continuing work, we are refining this analysis to contribute to a more comprehensive understanding of the effect of ethanol treatment on fusion-related gene expression in C2C12 muscle cell culture. Results from these studies may provide further insight into the mechanism by which ethanol exposure leads to the development of skeletal myopathy.

**SNP analysis of a mixed population reveals associations with osteoarthritis.**

H. Xia¹, T. Hua¹, J.L. Myers², M.Y. Caballero¹, J. Park³, S. Valtier³, G.J. Chaudry¹;
¹Center for Advanced Molecular Detection, 59 Medical Wing, San Antonio, TX, ²Medicine, University of Texas Health Science Center, San Antonio, TX, ³Science and Technology, 59 Medical Wing, San Antonio, TX

Of the arthritic disorders, osteoarthritis is the most common. In the United States, an estimated 30 million adults have osteoarthritis of varying degrees. The etiologic factors that determine susceptibility to osteoarthritis and the subsequent course of the disease are quite varied. Generally, genetic, acquired, and environmental factors together determine susceptibility to the disease. Single nucleotide polymorphisms (SNPs) constitute one type of genetic variations that have been explored as players in osteoarthritis and many other diseases. For the current report, we analyzed 32 SNPs located in 19 genes, and putatively linked with arthritic disorders. Using the TaqMan genotyping assay (Life Technologies), we conducted this analysis on a gender and race mixed population of 1000 individuals, 500 osteoarthritis patients and 500 healthy (control) individuals. Multiple regression logistic models controlled for gender, age, and race were employed to reveal any SNP associations with osteoarthritis. For the overall population, three SNPs showed statistically significant association with osteoarthritis (p < 0.05): rs2294984 (COL9A3, G>A, missense, G17E), rs1800629 (TNFA, G>A, promoter), and rs1800796 (IL6, G>C, promoter). In comparison to its homozygous G/G genotype, the G/A of rs2294984 showed significant association with osteoarthritis (OR = 1.36; p = 0.049). Likewise, in comparison to the G/G genotype of rs1800629, the G/A had significant association (OR = 1.39; p = 0.03). The homozygous genotype A/A for both SNPs had p-values greater than 0.05, suggesting lack of association, a result that is likely due to the small sample size in this genotype category. For rs1800796, the G/C and C/C genotypes in comparison to G/G had odds ratios of 0.67 and 0.34, respectively, suggesting negative association with osteoarthritis, although only the G/C genotype had statistical significance (p = 0.03).
In the age group 40-59 years (n = 536), rs2227306 (IL8) homozygous T/T associated with osteoarthritis, with odds ratio of 2.59 in comparison to C/C (p = 0.008). Among the Hispanic population (n = 118), rs143383 (GDF5) homozygous C/C associated with the disease (OR = 4.93; p = 0.005), but not among the White subjects (n = 561). Overall, 17 SNPs showed association with osteoarthritis in the total population or various subgroupings (gender, race and age).

Cell Size and Nuclear Scaling Relationships in Multinucleated Muscle Fibers.
S.E. Windner¹, A. Manhart², A. Mogilner², M.K. Baylies¹;
¹Developmental Biology, Memorial Sloan Kettering Cancer Center, New York, NY, ²Courant Institute, New York University, New York, NY

Different cell types can be identified by their overall size and the relative size, i.e. scaling, of their organelles. In particular, nuclear size and position are characteristic features and reflect cell state and activity. Both, the intrinsic regulation of cell size and nuclear scaling, and the contribution of physical dimensions to cell function are poorly understood – specially in skeletal muscle fibers, which are among the largest cell types and can contain hundreds of nuclei. We have developed a *Drosophila* system to analyze cell size and nuclear scaling relationships in fully differentiated multinucleated muscle fibers *in vivo*. With this system, we are further able to genetically manipulate individual cellular components, and to quantify the impact of these manipulations on muscle size and function. We find that, while nuclear number and DNA content increase with muscle cell size, the cumulative size of all nuclei in the cell is the most precise global nuclear scaling parameter. Combining our *in vivo* data with mathematical modeling further suggests that size scaling relationships are established locally by coordinating the size and the position of individual nuclei within a cell. However, differences in nuclear size scaling and transcriptional/translational activity in distinct sub-cellular domains indicate that cell size regulation might differ dependent on nuclear position along the length of each muscle fiber. We confirm these observations using genetic manipulations to alter nuclear size and DNA content. Moreover, our data show that changes in nuclear size scaling affect locomotion and thus correlate with reduced muscle function. Our study provides the first comprehensive approach to unraveling the intrinsic regulation of size and scaling in multinucleated muscle fibers. Ultimately, identifying the underlying molecular mechanisms will provide insights into how disruption of sub-cellular organization results in muscle disease.

Genes Differentially Expressed During Reversion of Androgen-Dependent Skeletal Muscle Atrophy.
M.D. Gomes¹, F.A. Flavia A. Guarnier², L.B. Figueiredo³, L.S. Zaramela¹, R.O. Godinho³, P.O. Coelho¹;
¹Biochemistry and Immunology, Ribeirão Preto Medical School, University of São Paulo, Ribeirao Preto, Brazil, ²Laboratory of Pathophysiology and Muscle Adaptation, State University of Londrina, Londrina, Brazil, ³Pharmacology, Escola Paulista de Medicina, Universidade Federal de São Paulo, Sao Paulo, Brazil

Muscle wasting or atrophy is a condition associated with major human systemic diseases including, diabetes, cancer, and kidney failure, among others. There is accumulating evidence from comparison of transcriptional profiles that a common set of genes, termed atrogene, are modulated in atrophying muscles. However, the transcriptional changes that trigger reversion or attenuation of muscle atrophy
have not been characterized at the molecular level. To identify key factors involved in the recovery of skeletal muscle mass, we have used cDNA microarrays to investigate genes differentially expressed during the atrophy reversion of the androgen-sensitive levator ani muscle (LA), in the well-established model of castration and testosterone replacement. As expected, most of the differential expressed genes behave as atrogenes and responded to castration-induced atrophy. Strikingly, 7 genes did not respond to castration but exclusively to the testosterone replacement. Considering that almost all proteins encoded by these genes are associated to reversion of atrophy and may function as regulators of cell proliferation/growth, our results open new perspectives in signaling pathways on atrophy-related syndromes field.

High throughput screening to identify mechanisms regulating endothelial fatty acid uptake.
A. Ibrahim1, Z.P. Arany1;
1Cardiovascular Institute, University of Pennsylvania, Philadelphia, PA

Type II diabetes is marked by hyperglycemia brought on by severe insulin resistance, a condition caused in part by intramuscular lipid accumulation. We have recently uncovered that the muscle-borne paracrine metabolite 3-hydroxyisobutyrate (3-HIB) plays a novel role in transporting serum fatty acids across the endothelium both in vitro and in vivo. However, the molecular mechanisms behind both 3-HIB-mediated and basal endothelial fatty acid uptake remain unclear. To begin understanding how this regulation works, I conducted a high-throughput screen in which a large chemical compound library was administered, along with 3-HIB and luciferin-tagged fatty acids, to luciferase-expressing endothelial cells. Through the inhibition of various intracellular pathways, some of these drugs inhibited or enhanced fatty acid uptake, as measured by luminescence. I then carried out secondary screening on the top 1% hits, and further orthogonal assays for validation. These ongoing studies will help us uncover the pathways modulating endothelial fatty acid uptake and transport, and holds promise for developing novel therapeutics against insulin resistance.

Determining the role of endothelial Notch signaling in vascular regeneration in the mouse hindlimb ischemia model.
J. Hyun1, K. Pajcini1, A.B. Malik1;
1Pharmacology, University of Illinois at Chicago, Chicago, IL

Ischemic disease such as peripheral arterial disease predicts to be a major cause of morbidity in the future; with few late stage treatment options. Emerging therapeutic approaches involve the transplantation of endothelial progenitors or localized release of pro-angiogenic factors to enhance neovessel formation and to re-vascularize ischemic tissue. Our previous work revealed the significance of the Hif1a-Etv2-Notch signaling axis in differentiation of functional arterial endothelial cell from embryonic stem cells. Hypoxic differentiation of embryonic stem cells led to increased differentiation of arterial endothelial cells and improved outcomes when transplanted in both myocardial infarction and hindlimb ischemia models in mice. As Notch signaling is situated downstream, compared to Hif and Ets signaling pathway, during vascular development, and is a gatekeeper in maintaining endothelial identity, i.e. tip vs stalk cell, we looked to investigate if modulating Notch signaling in existing vasculature could enhance regeneration by preferentially specifying the generation of arterial endothelial cells following
acute hindlimb ischemia. Notch signaling was conditionally inhibited in 8-12week old male, DNMAML:Cdh5/CReRT, mice prior to inducing ischemia. We observed decreased functional recovery, as measured by Laser Doppler Imaging, in hindlimbs of DNMAML:Cdh5/CReRT mice compared to DNMAML:Cdh5/CReRT negative littermates. This lead us to hypothesize that Notch signaling is required to adaptively generate new or remodel pre-existing vessels to perfuse ischemic tissue. Ongoing studies characterizing the temporal regulation of Notch signaling will help delineate the role of Notch signaling in therapeutic arteriogenesis and angiogenesis.

Optogenetic stimulation of pericytes lacking alpha smooth muscle actin produces a decrease in capillary blood flow in the living mouse brain.
D.A. Hartmann1, R.I. Grant1, S.A. Harrill1,2, T. Noonan1,2, A.Y. Shih1;
1Neuroscience, Medical University of South Carolina, Charleston, SC, 2Undergraduate Biology, College of Charleston, Charleston, SC

Vascular mural cells surrounding the cerebrovasculature are responsible for modulating blood supply in accordance with the metabolic demands of the brain. Although it is accepted that vascular smooth muscle cells on arterioles can regulate blood flow, the capacity for pericytes on capillaries to regulate blood flow is debated. Contributing to this debate is the finding that only some pericytes express alpha smooth muscle actin, a protein believed to be required for the ability to change blood vessel diameter (Grant, et al. JCBFM 2017). This has led to a burning question in the field: Does alpha smooth muscle actin expression in pericytes dictate their ability to modulate blood flow? To answer this question, we stimulated channelrhodopsin (ChR2) in individual pericytes using two photon illumination, as done previously (Hill, et al. Neuron 2015). Although we used offspring of PDGFRBeta-Cre and Ai32 mice, which possess ChR2 in both smooth muscle cells and pericytes, the spatial specificity of two photon excitation allowed selective stimulation of individual pericytes, thus avoiding incidental activation of nearby vascular smooth muscle cells that also express ChR2. Simultaneously, with the same two photon laser used for excitation of ChR2 in pericytes, we measured capillary diameter and red blood cell velocity using intravenous dextrans. We found that pericyte excitation for 60 seconds produced, on average, a ~20% reduction in diameter and velocity throughout the cortical microvasculature. Surprisingly, the magnitude and kinetics of this decrease in blood flow did not differ between pericytes with and without alpha smooth muscle actin expression. Importantly, identical stimulation parameters did not produce hemodynamic changes in control mice with cytosolic YFP or membrane-bound GFP in vascular mural cells, indicating that our observed reductions in blood flow in ChR2 mice were not an artifactual result of animal movement or tissue damage. Further, the observed decrease in velocity and diameter in response to pericyte ChR2 stimulation was inhibited when we applied fasudil, a Rho kinase inhibitor and vasodilator, to an intact dura (dose of 10 mM). Our results to date suggest that pericytes, even those without alpha smooth muscle actin, have the capacity to modulate blood flow. These findings will advance our understanding of mural cell biology, and could be relevant for disease processes known to involve deficits in capillary blood flow, such as stroke and dementia.

The necroptosis machinery in normal gut development, and in the pathogenesis of neonatal necrotizing enterocolitis (NEC).
A.D. Werts\textsuperscript{1}, E. Banfield\textsuperscript{2}, M. Ladd\textsuperscript{3}, W. Fulton\textsuperscript{3}, C. Gosztlya\textsuperscript{3}, B. Johnson\textsuperscript{3}, L. Martin\textsuperscript{3}, H. Jia\textsuperscript{3}, P. Lu\textsuperscript{3}, T. Prindle\textsuperscript{3}, Y. Yamaguchi\textsuperscript{3}, J. Sung\textsuperscript{3}, C. Sodhi\textsuperscript{3}, D.J. Hackam\textsuperscript{3};
\textsuperscript{1}\textit{Molecular and Comparative Pathobiology, Johns Hopkins University, Baltimore, MD, \textsuperscript{2}\textit{Human Genetics, Johns Hopkins University, Baltimore, MD, \textsuperscript{3}\textit{Surgery, Johns Hopkins University, Baltimore, MD}}

Necrotizing enterocolitis (NEC) is a devastating disease that causes the breakdown of the gastrointestinal barrier of infants, leading to sepsis and death in up to 50\% of cases. NEC is characterized by extensive cell death and inflammation in the intestine, which the Hackam Lab has shown is mediated in part by toll-like receptor 4 (TLR-4)-dependent apoptosis. However, since apoptosis is generally a non-inflammatory form of cell death, we seek to investigate alternative, more inflammatory forms of programmed cell death that may contribute to NEC and may be targets for prevention and treatment of NEC. Necroptosis, a receptor-interacting protein kinase 1 and 3 (RIPK) and mixed lineage kinase domain-like protein (MLKL)-dependent pathway is a key mediator of cell death which is also activated downstream of TLR4, and is a strong candidate for involvement in the pathogenesis of NEC. Here, using a combination of pharmacologic and genetic inhibition of the necroptosis signaling pathway both in vivo in mice and in vitro in enteroid culture, we show that necroptosis gene expression is dynamically regulated in the gut during the transition from late prenatal to early postnatal development, and that inhibiting RIPK1 function with Nec-1s or by using an mlkl-deficient mouse in our NEC model both result in decreased inflammation as measured by inflammatory cytokine production, leading to partial attenuation of disease.

Levels of CSF amyloid-\textit{β} 40 and 42 are decreased in amyloid PET (-) normal pressure hydrocephalus patients.
Y. Kim\textsuperscript{1}, H. Kim\textsuperscript{2}, T. Kim\textsuperscript{1}, T. Yim\textsuperscript{2}, J. Chang\textsuperscript{1};
\textsuperscript{1}\textit{Department of Biomedical Sciences, Ajou University School of Medicine, Suwon, Korea, South, \textsuperscript{2}\textit{Department of Neurology, Ajou University School of Medicine, Suwon, Korea, South}}

Coexistence of Alzheimer Disease (AD) in Normal Pressure Hydrocephalus (NPH) is known to be associated with shunt unresponsiveness and usually suspected by a decrease in the CSF Aβ42 level. In the recent studies, it has been reported that the well-established CSF AD biomarkers could be misled in NPH. In this study, we investigated levels of CSF AD biomarkers in amyloid PET (+) AD, amyloid PET (-) NPH, and cognitively normal (CN) subjects. Ten patients diagnosed with probable AD, 10 probable NPH, and 8 CN subjects were included in the experimental groups. 18F-florbetaben PET was performed and CSF was collected and analyzed for Aβ40, Aβ42, total tau and phosphorylated tau (p-tau) by ELISA method. All AD subjects were amyloid (+) and all NPH subjects were amyloid (-). Levels of CSF Aβ40 and Aβ42 were significantly decreased in NPH subjects compared to CN subjects. The level of Aβ42 was significantly decreased in the AD group compared to NPH and CN groups while there was no significant difference in the level of Aβ40 between AD and NPH groups. Total tau and p-tau levels were significantly increased in the patients with AD compared to NPH and CN. There was no statistical difference in the levels of total tau and p-tau between NPH and CN groups. This study demonstrates for the first time that CSF Aβ40 and Aβ42 are decreased in amyloid PET (-) NPH.

Control of high-fat-diet induced obesity by the mouse mSeg1 salivary protein.
M. Hu1, Y. Bai1, J. Wang1, Z. Yang2, S. Ye2, J. Chen1, J. Peng1;
1college of animal science, Zhejiang University, HangZhou, China, 2Model Animal Research Center, Nanjing Biomedical Research Institute, Nanjing University, HangZhou, China, 3Life Sciences Institute, Zhejiang University, HangZhou, China

Abstracts: The increasing incidence of obesity is a growing global public health concern, potentially controlled by therapeutic reductions in fatty acid biosynthesis. Here we report that the mouse Seg1 (mSeg1) salivary protein controls obesity. We show that mSeg1 null mice (mseg1Δ/Δ) do not exhibit the increases in fatty acid biosynthesis or obesity characteristically induced by high-fat diets. We also show that mSeg1 activates the Srebp pathway to regulate liver lipogenesis genes. Whilst the native mSeg1 is a glycosylated protein, a non-glycosylated recombinant E. coli-expressed mSeg1 antagonizes the function of native mSeg1. Most importantly, feeding wild-type mice with recombinant mSeg1 protects them from high-fat-diet induced obesity. In conclusion, mSeg1 is a novel salivary liver lipogenesis regulatory factor and a potential therapeutic target for the prevention of obesity.

1Davis Heart and Lung Research Institute, The Ohio State University Wexner Medical Center, Columbus, OH, 2College of Medicine, University of the Philippines Manila, Manila, Philippines, 3Division of Pulmonary, Allergy, Critical Care and Sleep, Department of Internal Medicine, The Ohio State University Wexner Medical Center, Columbus, OH, 4Department of Neuroscience, The Neurological Institute, The Ohio State University Wexner Medical Center, Columbus, OH

Obstructive sleep apnea (OSA), characterized by cyclic intermittent hypoxia (IH) during sleep, is associated with systemic inflammation. Adipose tissue is now recognized as an endocrine organ that secretes a wide variety of bioactive peptides. We previously showed that IH suppressed the secretion of adiponectin, an anti-inflammatory adipokine and that hypoxia-inducible factor 1α (HIF-1α) increased interleukin-6 (IL-6) adipose secretion. Here, we hypothesized that IH will induce inflammation in adipocytes via stabilization of HIF-1α. 3T3-L1 adipocytes cultured in 100 mm dishes were exposed to IH at 12 cycles/h for 8 h/d to simulate the hypoxic stress similar to that encountered in OSA. Control adipocytes were exposed to 21% O2 under identical conditions. After 48 h, 3T3-L1 cells exposed to IH have increased HIF1α mRNA expression, which was associated with an increase in mRNA expression and protein secretion of the inflammatory cytokine IL-6 (p < 0.05). There were no significant changes in tumor necrosis alpha (TNF-α) expression or protein secretion. Pre-treatment of adipocytes with PX-478, a known specific inhibitor of HIF-1α, reversed the inflammatory phenotype of IH-exposed adipocytes, with a decrease in IL-6 expression and protein secretion to control levels. These findings suggest a mechanism of how IH directly leads to adipose tissue inflammation through HIF-1α stabilization and subsequent IL-6-upregulation. The HIF1α pathway appears to be a promising target to reduce adipose tissue inflammation in OSA patients.
Kidney disease is the ninth leading cause of death in the U.S., with an estimated 26 million adults afflicted with chronic kidney disease. Chronic kidney disease is a significant public health problem due to the high incidence rate of causal comorbidities, the scarcity of kidneys for transplants, and the growing needs for dialysis. Unfortunately, neither the tools for early detection of renal decline nor clinical interventions to preserve kidney function exist, due to a limited repertoire of molecular markers of the mammalian kidney. Using an unbiased screening approach, we combined peptide phage display technology and high-resolution imaging techniques to identify molecular signatures and spatial localization patterns of ligand:receptor interactions in normal kidney and decellularized renal scaffolds. Three iterative selection rounds were performed to enrich for peptide ligands that bound components within the renal extracellular matrix (ECM). A separate protocol was performed in vivo to compare enriched peptide phage populations between whole kidney and decellularized kidney matrices. The ECM- and in vivo-enriched libraries demonstrated robust binding throughout the renal matrices and whole kidneys, respectively. Importantly, phage were internalized by renal tubules under in vivo conditions, suggesting that phage can traverse the glomerular filtration barrier and/or migrate through ECM to target epithelial components. We next evaluated individual clone enrichment and chose three unique peptide phage candidates from the ECM library for in vivo delivery. Clones and control, fd-tet insertless phage were individually injected via tail vein, and kidneys and control organs were harvested to compare ex vivo and in vivo binding patterns. In decellularized scaffolds, Ligand 1 revealed intense binding to glomerular vascular poles, Ligand 2 bound robustly throughout glomerular matrices, and Ligand 3 decorated the vascular network. These data demonstrate the utility of the approach for identifying distinctive molecular regions within the renal ECM. In vivo, Ligands 1, 2, and 3 displayed binding within the renal interstitium, with Ligand 2 also demonstrating internalization by tubular epithelia. We predict that glomerular targeting may require injury-induced exposure of the ECM; these studies are ongoing. In sum, our strategy has potential to lead to applications such as the basic evaluation of renal cell structure-function relationships, identification of diagnostic biomarkers, and ligand-directed targeting of small molecules to specific sub-cellular regions of the kidney for diagnostic and treatment purposes.

GENERATION OF AN EGFR ISOFORM D SPECIFIC KNOCKOUT MODEL.
N. Maihle¹, S. Yee², T. Ackley³, G. Gronowicz⁴, C. Dealy⁵;
¹Georgia Cancer Center, Augusta University, Augusta, GA, ²Cell Biology, University of Connecticut Health Center, Farmington, CT, ³Pharmacy, University of Connecticut, Storrs, CT, ⁴Surgery, University of Connecticut Health Center, Farmington, CT, ⁵Reconstructive Sciences, University of Connecticut Health Center, Farmington, CT

The Epidermal Growth Factor Receptor (EGFR) is a receptor tyrosine kinase that is a clinically validated target in cancer and arthritis patients. In addition to the full-length receptor, the human EGFR gene encodes three shorter variants known as isoforms B, C, and D, that are comprised of the EGFR extracellular domain along with short regions of unique aa sequence not found in EGFR. EGFR Isoform-D is produced from a 3.0 kb EGFR transcript that arises from an alternate splice event. The alternatively spliced Isoform D transcript encodes a unique 78 aa carboxyl-tail and 3' UTR sequences. The Isoform-D transcript is expressed in normal adult tissues where its expression is tightly regulated to maintain a constant high ratio of full-length to Isoform-D. In cancer cells, Isoform-D expression is regulated by the Inc-AS-1-RNA, and is linked to ‘super responsiveness’ to EGFR-targeted inhibitors (i.e., gefitinib). Both the human and murine homologs of EGFR Isoform-D are intrinsic membrane proteins expressed on the cell surface. This Isoform-D membrane protein, p110 sEGFR, is proteolytically released from the cell surface into the bloodstream, where it is the major circulating EGFR isoform. Quantitative assays suggest that changes in blood concentration of EGFR Isoform D have diagnostic potential in certain cancer and rheumatoid arthritis patients. The extraordinary level of regulation imposed on EGFR Isoform D synthesis, cell-surface expression, and proteolytic release into the circulation suggest this protein has unsuspected functions in systemic maintenance of health and homeostasis in the body. We have shown that an antibody directed against the unique 78 aa domain of human Isoform D promotes cell:cell and cell:matrix interactions, in vitro. However, the endogenous functional roles of this novel EGFR isoform in normal and diseased tissues remain unknown because no animal model has been available to study its function. This is because generation of isoform-specific mouse knock out models has not been feasible using standard homologous recombination approaches.
Here, we used CRISPR gene editing to selectively delete the 2.8 kb transcript that encodes the murine homolog of EGFR Isoform D. This new animal model offers opportunities to test the functional roles of this highly-regulated normal serum protein (i.e., a matriline) and putative serum biomarker. It also provides an in vivo system for exploring the mechanism of action of certain EGFR-directed therapeutics, including the ability of some patients to exhibit exceptional responsiveness to EGFR-targeted drugs.

Effects of rho-associated protein kinase inhibitor Y-27632 on scarring formation after glaucoma filtration surgery.
J. Ko¹, D.G. Ibrahim¹, Y. Kiuchi¹;
¹Ophthalmology, Hiroshima University, Hiroshima, Japan

Glaucoma filtration surgery usually fails because of post surgical scarring, a process in which fibroblasts play a prominent role. To elucidate the effects of rho-associated protein kinase (ROCK) inhibitor Y-27632...
in post surgical scarring (fibrosis), we have now investigated the molecular mechanisms with human tenon fibroblasts. So, human tenon fibroblasts were cultured with Y-27632 or various antiglaucoma drugs for indicated periods. After cultivation, we have prepared total RNA and protein samples from tenon fibroblasts. Using Multi RT-PCR array, we examined the factors respond to Y-27632. Also, we have examined the three-dimensional collagen gels cultivation for gel contraction by various antiglaucoma drugs. Collagen gel contraction by tenon fibroblasts was blocked in the presence of Y-27632. In Multi RT-PCR array using fibrosis-related genes, the expression of MMP-3 was down-regulated in tenon fibroblasts by additional Y-27632. Furthermore, Immunoblot and immunofluorescence analysis revealed that the expression of fibrosis markers was down-regulated in the presence of Y27632. These results suggest that the rho-associated protein kinase inhibitor Y27632 may block scarring formation with interaction MMP-3 after glaucoma surgery. And, it will be possible that ROCK inhibitors and MMP-3 may have potential to be developed for treatment of glaucoma and other ocular diseases.

Metformin ameliorates progressive nephritis in a mouse model of Alport syndrome.
S. Kaseda1,2, K. Omachi1,2, T. Yokota1, J. Kuwazuru1, M. Kamura1,2, K. Teramoto1,2, K. Kojima1, M. Suico1, T. Shuto1, S. Otsuki3, H. Kai1,2;
1Molecular Medicine, Kumamoto University, Kumamoto, Japan, 2Leading program HIGO, Kumamoto University, Kumamoto, Japan, 3Pharmaceutical Microbiology, Kumamoto University, Kumamoto, Japan

Alport syndrome (AS) is a hereditary kidney disease caused by a dysregulation of type IV collagen, a crucial component of the glomerular basement membrane (GBM). Abnormal GBM structure due to a mutation in one of the type IV collagen (COL4A3, COL4A4, and COL4A5) genes leads to glomerular aberration, which eventually results in chronic progressive nephritis and end-stage renal disease (ESRD). Importantly, early inhibition of Renin-Angiotensin-Aldosterone-System (RAAS) in AS delays renal failure and improves life expectancy; however, most AS patients finally develop ESRD and have higher risk of hyperkalemia, a life-threatening side effect of RAAS inhibitors. Therefore, identification of novel therapeutic targets and agents that have different mechanisms from RAAS inhibitors is crucial to establish therapeutic approaches for progressive nephritis such as AS. Here, we isolated glomerulus from AS model mice (Col4A5-G5X) and analyzed global protein expression by LC-MS/MS. Proteomics analysis showed a dysregulation of metabolic pathways in AS glomerulus. Notably, treatment of AS model mice with metformin (6-11 wk; 5 mg/mL, 12-20 wk; 2.5 mg/mL, free drinking water), a metabolic stressor and popular anti-diabetic drug, significantly suppressed proteinuria and glomerular injury as well as renal fibrosis to the same extent as a RAAS inhibitor losartan (6-11 wk; 250 μg/mL, 12-20 wk; 125 μg/mL, free drinking water). Consistently, metformin also reduced the expression of kidney injury markers (Lysosome, Kim1), pro-inflammatory cytokines (Il-6, Il-1β, KC) and pro-fibrotic genes (Tgfβ, Mmp9/12), and the effects was better than losartan, possibly due to alteration of a variety of metabolic signals by metformin but not losartan. Finally, metformin also suppressed proteinuria and ameliorated kidney injury in a mouse model of acute progressive nephritis induced by adriamycin treatment (10 mg/kg, i.v.), implying that metformin directly targets glomerulus to protect against progressive nephritis. Together, the study provides a novel concept that dysregulation in metabolic pathways may play important role in the pathogenesis of progressive nephritis of AS, and suggest that metformin treatment is a novel therapeutic option for AS.

Beneficial effect of midazolam against vascular endothelial growth factor-induced vascular leakage in the retinas of diabetic mice.
J. LEE¹, Y. Lee², H. Jeon³, Y. Kim¹, K. Ha¹;
¹Molecular and Cellular Biochemistry, Kangwon national university school of medicine, Chuncheon, South Korea

Anesthetics, including midazolam, are widely used for induction and maintenance of anesthesia, anxiolysis, and sedation; however, their preventive effects against diabetic complications, including diabetic retinopathy, are unknown. Here, we investigated the beneficial effects of midazolam against vascular endothelial growth factor (VEGF)-induced vascular leakage and its mechanism of action in human retinal endothelial cells (HRECs) and the retinas of diabetic mice. Midazolam inhibited VEGF-induced elevation of intracellular Ca2+, generation of reactive oxygen species (ROS), and transglutaminase activation in HRECs; these effects were reversed by the GABAA receptor antagonist flumazenil, but not by the translocator protein antagonist PK11195. Midazolam also prevented VEGF-induced disassembly of adherens junctions and in vitro permeability. Intravitreal injection of midazolam prevented hyperglycemia-induced ROS generation, transglutaminase activation, and subsequent vascular leakage in the retinas of diabetic mice, and these effects were reversed by flumazenil. The roles of flumazenil were further supported by identifying GABAA receptors in mouse retinas. Thus, midazolam prevents hyperglycemia-induced vascular leakage by inhibiting VEGF-induced intracellular events in the retinas of diabetic mice, suggesting that midazolam has a therapeutic potential for treating diabetic retinopathy.

Protective effects of chrysin on visual cycle impairment in diabetic retina.
M. Kang¹;
¹Food Science and Nutrition, Hallym University, Chuncheon, South Korea

Diabetes-associated visual cycle impairment has been implicated in diabetic retinopathy and chronic hyperglycemia causes detrimental effects on visual function. Chrysin, a naturally occurring flavonoid found in various herbs, carrot and propolis, has anti-inflammatory, antioxidant and anti-cancer properties. The current study investigated retinoprotective effects of chrysin on visual cycle-related proteins and photoreceptors in 33 mM glucose-exposed human retinal pigment epithelial cells (HRPEC) and db/db mouse retinae. HRPECs treated with glucose temporally reduced retinal pigment epithelium-specific 65 protein (RPE65), a critical enzyme in the visual cycle located in retinal pigment epithelium. When 1-20 μM chrysin was treated to HRPEC, the RPE65 level was near-completely restored. In addition, oral administration of 10 mg/kg chrysin enhanced tissue levels of RPE65, cellular retinol-binding proteins, interstitial retinol-binding protein, and cellular retinaldehyde-binding protein diminished in db/db mouse eyes. Furthermore, chrysin enhanced the level of rhodopsin present in outer segments of visual cells and involved in visual signal transduction. These results demonstrated that chrysin restored the levels of visual cycle-related proteins in glucose-exposed HRPEC and diabetic mouse eyes. Therefore, chrysin may be a potent agent combating diabetes-associated retinal visual cycle impairment.

Protective effect of cysteamine against vascular leakage by inhibiting VEGF-induced transglutaminase activation in diabetic mice.

Y. Lee1, J. LEE1, H. Jeon1, K. Ha1, Y. Kim1;
1molecular and cellular biochemistry, kangwon national universit school of medicine, chucheon, South Korea

Cysteamine (an aminothiol), which is derived from coenzyme A degradation and metabolized into taurine, has beneficial effects against cystinosis and neurodegenerative diseases; however, its role in diabetic complications is unknown. Thus, we sought to determine the preventive effect of cysteamine against hyperglycemia-induced vascular leakage in the retinas of diabetic mice. Cysteamine and ethanolamine, the sulfhydryl group-free cysteamine analogue, inhibited vascular endothelial growth factor (VEGF)-induced stress fiber formation and vascular endothelial (VE)-cadherin disruption in endothelial cells which play a critical role in modulating endothelial permeability. Intravitreal injection of the amine compounds prevented hyperglycemia-induced vascular leakage in the retinas of streptozotocin-induced diabetic mice. We then investigated the potential roles of reactive oxygen species (ROS) and transglutaminase (TGase) in the cysteamine prevention of VEGF-induced vascular leakage. Our findings suggest that cysteamine protects against vascular leakage through inhibiting VEGF-induced TGase activation rather than ROS generation in diabetic retinas.

Chrysin inhibits advanced glycation end products-associated glomerulosclerosis in glucose-exposed mesangial cells and db/db mice.

L. Eun Jung1, Y. Kang1;
1Food Science and Nutrition, Hallym University, Chuncheon, South Korea

Diabetic nephropathy (DN) is one of the major diabetic complications and the leading cause of end-stage renal diseases, which is characterized by glomerular hypertension and basement membrane thickening, and mesangial expansion due to matrix protein deposition in kidneys. Advanced glycation end products (AGEs) play a causative role in the development of DN via induction of extracellular matrix accumulation. The present study investigated the effects of chrysin (5, 7-dihydroxyflavone) present in bee propolis and herbs, on glomerulosclerosis in glucose- or AGE-exposed renal mesangial cells and db/db mice. The in vitro study employed human mesangial cells exposed to 33 mM glucose for 72 h in the absence and presence of chrysin nontoxic at 1-20 μM. Chrysin suppressed the induction of collagens, α-smooth muscle actin (α-SMA) and fibroblast-specific protein-1 (FSP-1) enhanced by glucose. In addition, chrysin inhibited the induction of AGEs and receptor for AGEs by glucose that led to increased production of mesangial collagens and matrix metalloproteinases. The in vivo study explored the demoting effects of 10 mg/kg chrysin on glomerular fibrosis in a type 2 diabetic model. Oral supplementation of chrysin inhibited the collagen fiber accumulation in damaged renal tissues of db/db mice, evidenced by PAS staining and masson trichrome staining. The induction of α-SMAand FSP-1 was blunted in chrysin-treated diabetic glomeruli. Moreover, treating db/db mice with chrysin diminished the level of AGEs increased in diabetic glomeruli. These results demonstrate that chrysin attenuated the acquisition of myofibroblast phenotype of glucose- or AGE-exposed mesangial cells and the glomerular accumulation of extracellular matrix proteins in diabetic kidneys. Therefore, chrysin may be a potential renoprotective agent targeting glucose-mediated AGEs-associated glomerulosclerosis and fibrosis.

Upregulation of glucose uptake by (+) lariciresinol, a lignan isolated from Rubia philippinensis, through the activation of AKT and AMPK/GLUT4 pathway in C2C12 cells.
J. Ra¹, H. An¹, J. Lim¹, S. Lee¹;
¹Food Science and Biotechnology, Kyungpook National University, Daegu, South Korea

Diabetes is one of the most prevalent diseases worldwide, and plays the pivotal role in developing various life threatening diseases such as stroke, hyperlipidemia, and cardiovascular disease. In the present study, we investigated that the upregulation of glucose uptake by (+)lariciresinol (LRS), a lignan isolated from Rubia philippinensis, along with the molecular mechanisms. The α-glucosidase inhibitory activity was found to be 80% at 50 μM dose by functioning as noncompetitive inhibitor, and improved the glucose uptake in a dose-dependent fashion which is confirmed by 2NBDG assay in C2C12 cells. RT-PCR analysis revealed that, LRS treatment was augmented the mRNA expression of Irs-1, Glut4, and Ppar, whereas mitigated the mRNA expression of As160. Moreover, the protein level of GLUT4 was increased by LRS treatment, which was confirmed by western blot analysis. Furthermore, LRS treatment also activated the phosphorylation of both AKT and AMPK. Taken together, the present data show that LRS stimulate AKT and AMPK phosphorylation, which led to upregulate the GLUT4 expression, and increase the glucose uptake in C2C12 cells.

Upregulation of the GLUT4 expression by Spatholobus suberectus extracts via the activation of AMPK and AKT signaling and mitigates the type II diabetic symptoms.
P. Zhao¹, M. ALAM¹, M. Ju¹, K.Y. Gyung¹, S. Lee¹, H. Kim¹, S. Lee¹;
¹Food Science and Biotechnology, Kyungpook National University, Daegu, South Korea

Nowadays, the rapid increases in the incidence of diabetes have severely threatened in human health. In the present study, we investigated the antidiabetic effect of Spatholobus suberectus (Ss) Dunn belongs to Leguminosae family which is used as a Chinese traditional herb medicine. Foremost, the aqueous (AeSs) and ethanolic (EeSs) extract showed strong antioxidant activities in various in vitro methods in a concentration-dependent manner. Moreover, both extracts had a potent α-glucosidase inhibitory activity with an IC50 value of 6.42 ± 1.45 and 2.81 ± 0.48 g/ml for AeSs and EeSs, respectively. Treatment of EeSs significantly enhanced the glucose uptake, mediated through the upregulation of GLUT4 via the stimulation of AKT and AMPK pathways in C2C12 cells. Moreover, EeSs significantly lowered the postprandial blood glucose levels in STZ-induced diabetic mice, associated with increased the expression of GLUT4 and the activation of AKT and/or AMPK-mediated signaling cascade in skeletal muscle. Furthermore, RT-PCR analysis revealed that administration of EeSs significantly boosted up the expression of various antioxidant enzymes such as Sod-1, Gpx-1, Nox-1 and Ho-1, and also mitigated the gluconeogenesis enzyme such as Pepck and G-6-Pase enzyme expression in liver tissue of a STZ-induced diabetic mice model. Taken together, all these data indicated that Ss extract has potential application in preventing and/or treating type 2 diabetes.

Increased C-reactive protein (CRP) by placenta-derived mesenchymal stem cells is involved in angiogenesis and Wnt signaling pathway in hepatic failure model.
J. Jun¹, J. Choi², J.J. Kim², S. Bae³, S. Hwang⁴;
¹Biomedical Science, CHA University, Seongnam-si, South Korea, ²Dermatology, Northwestern University, Chicago, IL, ³Internal Medicine, Catholic University Medical College, Seoul, South Korea, ⁴Internal Medicine, CHA University, Seongnam-si, South Korea

Hepatic failure is a severe and irreversible disease although the liver has a certain regenerative capacity. This disease is associated with dysfunction of the liver vessels. Placenta-derived mesenchymal stem cells (PD-MSCs), which originate from the fetus, have their distinctive features such as recycling of the placenta removed as waste after birth, ease of accessibility, abundant cell numbers and strong immunosuppressive properties. Recently, we demonstrated that PD-MSCs can regenerate the liver in hepatic failure through anti-fibrotic and autophagic mechanism. Furthermore, the β-catenin is a key molecule for homeostasis in a number of tissues, regulating the Wnt signaling pathway through transcriptional activity. C-reactive protein (CRP) is produced in the hepatocytes and secreted via vessel for metabolism. Therefore, the objectives of this study were to compare the expression of CRP, vascular and Wnt signaling-related factors in hepatic failure model (bile duct ligation and CCl4-injured rat model) by PD-MSCs transplantation and evaluate their correlation between CRP, Wnt signaling and angiogenesis. The expression of CRP in transplanted PD-MSCs (TTX) group was increased compared with control (p<0.05) and non-transplanted (NTX) group in protein level of rat hepatic failure model. Moreover, Wnt signaling and vascular-related factors significantly increased in TTX group than control and NTX group (p<0.05). Likewise that of in vivo model, CRP, vascular-related and Wnt signaling factors were significantly increased in co-cultured PD-MSCs rat hepatocytes (WB-F344) treated CCl4 or LCA. Furthermore, the proliferation of WB-F344 was higher in co-cultivated PD-MSCs group than non-co-cultured PD-MSCs group through BrdU staining. The findings suggest that increased CRP by PD-MSCs promotes angiogenesis in hepatic failure through Wnt signaling and involves in proliferation of the hepatocytes. Therefore, CRP enhanced by PD-MSCs has therapeutic potential for regeneration in degenerative disease. This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (HI17C1050020017).

INTRODUCTION AND OBJECTIVES: Preclinical studies suggested that administered cultured stem cells protected kidney function against renal IRI. The purpose of this study was to determine the therapeutic effects of hypoxic preconditioned hBMSC and the optimal route for cell delivery in a rat model of renal IRI. METHODS: Sixty male Sprague-Dawley rats were randomly divided into 6 groups (10 animals per group): sham, nephrectomy control, IRI control, renal arterial injection, renal parenchymal injection and
tail venous injection. To induce renal IRI, the left renal artery was clamped with a vascular clamp for 40 minutes, and the right kidney was removed. Serum creatinine, BUN and glomerular filtration rate were evaluated 1 day prior to IRI, and 1, 2, 3, 4, 7 and 14 days after IRI. For histological studies, the kidney was removed 14 days after IRI. RESULTS: Two and one of mortality cases were observed in the renal parenchymal and tail venous injection groups, respectively. All hBMSC injections significantly reduced the extent of elevation in serum creatinine compared with the IRI control group 1, 2, 7 days after IRI. Renal arterial injection significantly reduced the extent of elevation in serum BUN compared with the IRI control group 1, 14 days after IRI. Renal arterial injection significantly reduced the extent of decrease in glomerular filtration rate compared with the IRI control group 2, 4, 7 days after IRI. Sirius red stain for the degree of fibrosis showed that kidney of renal arterial injection group was significantly less fibrotic than that observed in the IRI control group. The number of TUNEL positive cells increased after IRI, suggesting apoptosis or necrosis had occurred. TUNEL assay showed significantly decreased apoptosis in renal arterial, renal parenchymal and tail venous injection groups compared to the IRI control group. A greater increase in glutathione reductase and glutathione peroxidase was observed in renal arterial, renal parenchymal and tail venous injection groups than in the IRI control group. These findings further suggest that anti-oxidative responses were elicited by IRI and hBMSC treatment contributed to further anti-inflammatory and anti-oxidative effects after IRI in this study. CONCLUSIONS: Our study showed that renal function is most effectively rescued from renal IRI through renal arterial injection of hypoxic preconditioned hBMSC. Source of Funding: This research was supported by a grant of the Korea Health Technology R&D Project through the Korea Health Industry Development Institute (KHIDI), funded by the Ministry of Health & Welfare, Republic of Korea (grant number: HI15C0925).

Efficacy analysis of functional enhancement human mesenchymal stem cells depends on gene delivery systems.
J.J. Kim1, J. Choi2, S. Lee3, S. Jin1, J. Jun1, G. Kim1;
1Department of Biomedical Science, CHA University, Seongnam-si, South Korea, 2Department of Dermatology, Northwestern University, Chicago, IL, 3Department of Oral Pathology, Gangneung-Wonju National University, Gangneung-si, South Korea

Mesenchymal stem cells (MSCs) have significant potential for regenerative medicine because of self-renewal, differentiative and immunomodulatory effect. Nevertheless, powerful MSCs generation via gene manipulation by viral or non-viral gene delivery systems should be enhanced the therapeutic effect in degenerative medicine. Recently, we reported that increased phosphatase of regenerating liver-1 (PRL-1) promotes migration of MSCs into injured target tissues as well as liver regeneration in hepatic failure models. Therefore, the major objectives are to generate stable placenta derived MSCs (PD-MSCs) and bone marrow derived MSCs (BM-MSCs) overexpressed with PRL-1 (PRL-1+) using lentiviral and AMAXA system, which is non-viral gene delivery system. Their characterizations by comparing between naïve and PRL-1+ were analyzed. The expression of stemness markers, differentiation potential and teratoma formation were analyzed by qRT-PCR, IF and chemical staining. Cells surface markers for CD34, 13, 90, 105, HLA-family in naïves and PRL-1+ cells were analyzed by FACS. Moreover, migration ability through Rho family by qRT-PCR and mitochondrial function by Western blotting, ATP assay, XF mito stress assay were evaluated in both PRL-1+ cells. The expression of stemness markers was observed in PRL-1+ cells compared to naïves in gene delivery systems (p<0.05). Differentiation abilities into multilineages and surface markers in the PRL-1+ cells are similar to those of naïves regardless of transfection system. There is no teratoma formation in NOD/SCID mice until 14 weeks after PRL-1+ cells

Tuesday-543
transplantation. Moreover, migration ability of PRL-1+ cells was improved through Rho family. Interestingly, MSCs with PRL-1+ using viral and non-viral systems have a significant increase in mitochondrial DNA (mtDNA) copy number and ATP production in cell lysate (p<0.05). In addition, the protein expression of mitochondrial respiration-related genes (e.g. PD, SHDA, VDAC etc.) is higher than naïves. Furthermore, although BM-MSCs were relatively influenced metabolic state than PD-MSCs and PRL-1+ using lentiviral system, PRL-1+ in PD-MSCs using AMAXA system have more energetic mitochondrial function by upregulating ATP production and spare capacity for cellular respiration in live conditions than PRL-1+ in BM-MSCs. Taken together, functional enhancement MSCs with PRL-1+ were successfully not only generate using lentiviral and AMAXA systems but up-regulation of PRL-1 can improve self-renewal ability and significantly increased mitochondrial function compared to naïves. Furthermore, these data suggest that gene delivery system using non-viral AMAXA system provides a useful and safe strategy on MSCs manipulation based on gene reinforcement for degenerative medicine.

Attenuation of UVB-induced skin senescence by Nypa fruticans bud extract: involvement of the suppression of MMP activity through downregulation of NF B & AP1 signaling via the activation of MAP kinase.
H. Choi1, H. Son1, C. Jeong1, H. Lee1, S. Lee1;
1Food Science and Biotechnology, Kyungpook National University, Daegu, South Korea

Ultraviolet (UV) radiation is one of the major causative factors to develop extrinsic skin aging and to change the various pathological condition of skin such as thickening, wrinkling, erythema, and dryness. The mechanisms underlying skin photo-aging are related to the degradation of collagen via activation of matrix metalloproteinase (MMP) activity, which is induced by reactive oxygen species (ROS) production. Nypa fruticans belongs to Arecaceae family and traditionally, used to treat asthma, tuberculosis, sore throat, and liver disease. The present study was undertaken to investigate the protective effect of Nypa fruticans bud (NFB) extract on skin aging induced by UVB irradiation in vitro and in vivo along with the mechanistic study. The results revealed that NFB dose-dependently inhibited the elastase activity. Pretreatment of NFB has increased the cell viability compared to non UVB-irradiated group along with dose dependent suppression of UVB-induced cellular ROS generation without showing any cellular toxicity in HaCaT cells. In addition, topical application of NFB was attenuated lesions of UVB-induced photoaging such as skin erythema and skin thickening in photo-aged BALB/C mice dorsal skin. Treatment of NFB also restored the UVB-induced decrease of collagen contents in dermis along with the augmentation of SIRT-1 expression as well as mitigation of the MMP-1 and IL-1 expression. Furthermore, RT-PCR analysis revealed that NFB treatment was markedly downregulated the mRNA expression of MMP-1, 8 and 13, whereas Col1a1 and Sirt-1 were upregulated. Moreover, western blot analysis revealed that treatment of NFB drastically suppressed the protein expression of MMP-1, NF- B and p-c-Jun compared to UVB-induced control group. In addition, NFB treatment has also regulated the activation of MAP kinase protein such as p-38, JNK, and ERK1/2. Together, we demonstrated that NFB had potential in attenuating UVB-induced skin senescence through the suppression of MMP-1 activity along with the down-regulation of NF- B and AP-1 signaling via the activation of MAP kinase proteins, suggesting that NFB is a promising natural agent to protect against skin photo-aging.

Mushroom anti-tyrosinase activities of Nymphaea nouchali flower extract attenuates melanogenesis in vitro and in vivo: involvement of cAMP/p-CREB, MAPKinase and proteasomal degradation machinery.

M. ALAM¹;

¹Food Science and Biotechnology, Kyungpook National University , Daegu, South Korea

Medicinal plants are employed in the treatment of human ailments from time immemorial. Several studies validated the use of medicinal plant products in hyperpigmentation disorder. The aim of the present study was to investigate the anti-melanogenic effects of Nymphaea nouchali flower extracts, the mechanisms responsible for its inhibition of melanogenesis in in vitro and in vivo. Ethyl acetate fraction of Nymphaea nouchali flower (NNFE) significantly inhibited mushroom tyrosinase activity in both mono- and di-phenolase activities, and markedly inhibited melanin production and intracellular tyrosinase activity in in vitro and in vivo. In addition, NNFE abolished the expressions of tyrosinase, TYRP-1, TYRP-2, and MITF, thereby blocking melanin production and interfering with cAMP/p-CREB as well as the phosphorylation of ERK1/2, JNK, and p38. Furthermore, specific inhibitors of ERK1/2, JNK and p38 prevented melanogenesis inhibition by NNFE, and the proteasome inhibitor (MG-132) prevented NNFE-induced reductions in cellular tyrosinase levels. Taken together, NNFE was found to suppress intracellular CAMP production with subsequent down-regulation of phosphorylation of CREB as well as stimulate MAP-kinase (ERK1/2, JNK and p38) phosphorylation and the proteolytic degradation pathway, which led to the degradations of MITF and tyrosinase, and to suppress the productions of melanin in both in vitro and in vivo demanding further attention.

The aim of the present study was to investigate the anti-melanogenic effects of 3,8-dihydroxyquinoline (jineol) isolated from Scolopendra subspinipes Mutilans in melan-a cells along with its molecular mechanism of action. Jineol exhibited significant, dose-dependent antioxidant effects in various in vitro methods. Jineol significantly inhibited mushroom tyrosinase activity by functioning as an uncompetitive inhibitor with an inhibition constant of 103 M⁻¹. Treatment of jineol markedly abolished melanin production and intracellular tyrosinase activity in melan-a cells. In addition, jineol lessened the expressions of tyrosinase, TYRP-1, TYRP-2, and MITF, thereby hindering melanin production and interfering with the phosphorylation of ERK1/2 and p38. Furthermore, specific inhibitors of ERK1/2 and p38 prevented melanogenesis inhibition by jineol, and the proteasome inhibitor (MG-132) prevented jineol-induced decreases in cellular tyrosinase levels. Taken together, jineol was found to stimulate MAP-kinase (ERK1/2 and p38) phosphorylation and the proteolytic degradation pathway, which led to the degradations of MITF and tyrosinase resulting in to quench melanin production.
Bioactive oligopeptides are a promising class of therapeutic molecules, which possess diverse activities, high specificity and low toxicity. The use of oligopeptides as potentially selective and safe antioxidants is of particular interest in treatment and prevention of inflammatory, cancer, and degenerative diseases. Conjugation of bioactive oligopeptides with carrier molecules is an effective approach to improving their pharmacokinetic properties at tissue and cellular levels and enhancing a specific action. We studied the effect of triphenylphosphonium (TPP) moiety as an established intracellular and mitochondria-directed carrier on antioxidant and cytoprotective properties of a model tetrapeptide composed of repetitive aromatic and basic amino acids, e.g. Tyr-Arg-Phe-Lys. The tetrapeptide and its N-derivatives with different carboxyalkyl TPP compounds were obtained by a solid phase peptide synthesis from Fmoc-protected amino acids. Antioxidant activity of the starting oligopeptide and the modified ones was assessed in the Fenton-type reaction of cobalt chloride (CoCl$_2$) and hydrogen peroxide (H$_2$O$_2$). It was found that the modified oligopeptides at a concentration of c.a. 1 mM completely inhibited generation of oxygen radicals in the reaction similarly to the tripeptide glutathione, whereas the unmodified tetrapeptide was inactive at a concentration as high as 5 mM. Introduction of the TPP moiety into the tetrapeptide increased its antioxidant effect towards PC-12 rat pheochromocytoma cells subjected to H$_2$O$_2$-induced oxidative stress upon short-term exposition. During culturing of PC-12 cells in the presence of CoCl$_2$ as a hypoxia-mimicking agent, the modified oligopeptides effectively prevented cobalt-induced cytotoxicity to a higher extent compared with the initial tetrapeptide or glutathione at the same concentration. Our results suggest that modification with TPP moiety can enhance antioxidant and cytoprotective activity of oligopeptides for mammalian cells, presumably, due to promoting their anti-radical capacity and cellular availability.

This work was co-funded by the Russian Foundation for Basic Research (project No. 16-33-60146) and performed according to the Russian Government Program of Competitive Growth of Kazan Federal University.

Senility and obesity are often associated with dysfunction of various biological systems, including the male reproductive apparatus. Jabuticaba, a Brazilian fruit rich in phenolic compounds with antioxidant, anti-inflammatory and anti-carcinogenic activities, could potentially counteract disorders related to
aging and weight gain. In the present study, we evaluated the testicular function, using stereological, spermatological and physiological methods, in senile mice after high-fat diet intake and investigated the possible beneficial effect of the treatment with jabuticaba peel extract (JPE). For that, 140 FVB mice were distributed in 7 groups: YG (Young), SE (Senile), SHD (Senile+Hyperlipid diet), SJI (Senile+Jabuticaba peel extract [JPE], [0.003mL/gJPE]), SJI (senile+0.006mL/gJPE), SHJI (Senile+Hyperlipid diet+JPE [0.003mL/gJPE]), and SHJII (senile+hyperlipid diet+0.006mL/gJPE). After 60 days, the animals were euthanized and their testes were collected for several analyses. Histological sections, stained with HE, were photographed with an Olympus BX41 microscope coupled to the Olympus Q Color 3 digital camera to be used for stereological and spermatologic analysis. Analysis of oxidative stress was performed using commercial kits read on the SynergyHT, Bioktek (Winooski, USA). The data were analyzed with Gen5™2.0 data analysis software. Other analyses applied the IMAGE PRO PLUS 6.0 software, while the statistical analysis was done with the PRISM 5 STATISTIC software. Considering oxidative stress evaluation, the treatment with JPE significantly increased the activity of GSH, GPx, GR and SOD in SJI and SJII groups in comparison with SE levels. In relation to SHJI and SHJII, we observed an increase in the activity of GR, SOD and Catalase, but lower GSH activity, when compared to SHD group. In conclusion, our data corroborate the anti-inflammatory activity of phenolic compounds attributed to the JPE and suggest that this JPE can prevent the deleterious effects of senility and obesity on male reproductive function.

Inflammatory bowel disease (IBD) is a complex chronic intestinal human disease composed of genetic, environmental and host immune factors. Establishing a robust and predictive in vivo animal model to study cellular function during acute and chronic inflammation has been challenging. Our previous genome-wide association study (GWAS) showed strong association of increased IBD risk with SNPs in innate immunity and autophagy. Live in vivo imaging of intestinal innate immunity can be uniquely performed on zebrafish because of their transparency and the presence of solely innate immunity over its initial weeks of life. For these reasons, we examined the effects of intestinal injury on time-course and cell-type dependent responses, with a particular focus on prostaglandin E2 (PGE2). Dextran sodium sulfate (DSS) induces chemical intestinal inflammation and has been extensively utilized to study intestinal innate immunity. We compared the effects of single and repeated DSS treatment in zebrafish.
and reported the mortality, lysosomal function and mucin production. Using previously reported doses, we observed dose-dependent mortality with repeated injury (Oehlerls et. al., 2012, 2013). Since neutral red accumulation indicates normally functioning acidic lysosomes, we quantified neutral red intensity in the mid gut with single and repeated DSS treatment for one and two days post DSS. Our results showed that the initial damage to lysosomal function fully recovered in two days after single injury but remains impaired after repeated injury. Mucin production was quantified from alcian blue stained fixed zebrafish. Alcian blue intensity increased in single injury but decreased from 60 to 40% after repeated injury. We observed high mortality with impaired recovery of lysosomal function and mucin production after repeated injury. We then applied PGE2 to the single injury model. By adding 1μM PGE2 for 1, 3, and 6 hours after DSS removal, PGE2 promoted recovery of neutral red intensity, positively correlated to earlier PGE2 treatment. PGE2 treatment dose-dependently increased alcian blue intensity. We further applied fluorescent killed E. coli to the single injury model and detected a high mortality rate similar to repeated injury. 90 minutes after E. coli treatment, fluorescence signals were detected in the dorsal aorta and the posterior cardinal vein of DSS-treated zebrafish, suggesting that high mortality may be due to sepsis. The bacteria-induced mortality was significantly decreased with PGE2 treatment during recovery or co-treatment with DSS. Phagocytosed E. coli co-localized with autophagosome in mFAP4+ intestinal macrophages. Together, we showed that PGE2 prevents sepsis by increasing mucin production and recovering lysosomal function in intestinal macrophages.

**Hepatocyte exosomes are anti-fibrotic in the liver.**

L. Chen\(^1\), R. Chen\(^1\), S. Kemper\(^1\), D.R. Brigstock\(^1,2\);

\(^1\)Nationwide Children's Hospital, Columbus, OH, \(^2\)The Ohio State University, Columbus, OH

Exosomes are nanovesicles that arise by inward budding of multivesicular bodies and which are released extracellularly when multivesicular bodies fuse internally with the plasma membrane. Exosomes contain a complex mixture of miRs, mRNAs and proteins that reflect the transcriptional and/or translational activity of the donor cell. Following their release, exosomes traverse the intercellular space and may be taken up by neighboring cells into which the components of their molecular payload are delivered, resulting in epigenetic re-programing and phenotypic alterations. In this study, we have investigated how experimental liver fibrosis is regulated by exosomes from normal hepatocytes. Exosomes were purified by ultracentrifugation from the conditioned medium of mouse AML12 hepatocytes cultured under serum-free conditions for 48 hrs and identified by nanoparticle tracking analysis and Western blot for CD81. In a short-term in vivo model of liver fibrogenesis in which BAC reporter transgenic connective tissue growth factor-enhanced green fluorescent protein (CCN2-EGFP) Swiss Webster mice expressing EGFP under the control of the CCN2 promoter received 30μl CCl4/25g i.p. every other day for 10 days, expression of EGFP, CCN2, or αSMA in the liver was dose-dependently blocked following administration of purified exosomes over the last 6 days (20-80 μg exosomal protein i.p., q.o.d). In a long-term in vivo model of liver fibrosis in which wild-type Swiss Webster mice received 30 μl CCl4 /25g, i.p. 3 times/wk for 5 wks, collagen deposition and expression of CCN2, αSMA, or collagen α1 were blocked following administration of purified exosomes over the last 10 days (80 μg exosomal protein i.p., q.o.d). Target cells in mouse livers were identified as hepatocytes and hepatic stellate cells (HSC) based on the in vivo localization of iv-administered PKH26- or PKH67-labelled exosomes. When tested in vitro, hepatocyte exosomes diminished expression of fibrosis-associated molecules (αSMA, collagen α1(I)), CCN2) in HSC and reversed ethanol-mediated cytotoxicity in hepatocytes. Thus hepatocyte exosomes carry a payload that is instrinsically anti-fibrotic and reverses HSC fibrogenesis or toxin-mediated hepatocyte damage.

Gomisin N inhibits an early stage of adipogenesis in 3T3-L1 preadipocytes.
M. Jung1;
1School of Korean Medicine, Pusan National University, Yangsan, South Korea

Gomisin N (GN) is a physiological lignan derived from Schisandra chinensis. In the present study, we investigated the inhibitory effects of GN on differentiation of 3T3-L1 preadipocytes. Incubation with GN significantly inhibited the differentiation of 3T3-L1 preadipocytes in a dose-dependent manner. This inhibitory effect primarily occurred at an early adipogenic stage through impairment of mitotic clonal expansion (MCE) caused by cell cycle arrest at the G1/S phase transition. GN inhibited the extracellular signal-regulated kinase and phosphoinositide 3-kinase/protein kinase B signaling in the MCE process and activated AMP-activated protein kinase. Furthermore, GN downregulated CCAT/enhancer-binding protein β (C/EBPβ) and histone H3K9 demethylase JMJD2B during early stages of adipogenesis, and therefore repressed the expression of C/EBPβ-targeted cell cycle genes. Collectively, these findings suggest that GN has potential as a novel agent for the prevention and treatment of obesity.

Shockwaves decrease PPARgamma and suppress adipocyte differentiation.
W. Cho1, M. Jeong1, Y. Park1;
1Molecular Medicine, Ewha Womans University, Medical School, Seoul, South Korea

ObjectiveWhite adipose tissue is a fat storage organ for keeping energy and an endocrine organ secreting adipokines such as leptin, adiponectin, and resistin. Adipogenesis which generates mature adipocyte is important in obesity. Shockwaves are mechanical pressure disturbances which transmit signals for biological responses. The goal of this study is to investigate the effect of shockwaves to adipocyte differentiation.

MethodsMouse fibroblast cell line, 3T3L-1 was (American Type Culture Collection (ATCC, CL-173)) cultured following the manufacturer’s instruction. 3T3L-1 cells at confluency were treated with insulin (1ug/mL), dexamethasone (DEXA, 1uM) and 3-isobutyl-1-methylxanthiane (IBMX, 0.5 mM). After 48 hours, the media was replaced with DMEM containing insulin (1ug/mL). Then, the medium was replaced with adipocyte maintenance medium (DMEM supplemented with penicillin and streptomycin) every 2-3 days until terminal differentiation into adipocytes Shockwaves (0.04mJ/mm2, 5Hz, 1000 impulses) were applied to the cells at the time when we changed the medium.

ResultsWe revealed that intracellular lipid accumulation was 20 % less in shockwave-treated 3T3L-1 than untreated control cells after adipocyte differentiation. Key adipogenic transcriptional factors, PPARgamma and C/EBPalpha were 40 % less in shockwave-treated cells compared to the untreated 3T3L-1 after 14 days of differentiation process. Shockwave treatment decreased other adipogenesis markers such as Perilipin, FAS, ACC in 3T3L-1 derived adipocytes. We found that shockwave-treatment activated Wnt signaling pathway and induced stabilization of beta-catenin and decreased PPARgamma which finally suppressed preadipocyte differentiation into adipocytes.

ConclusionsShockwaves suppressed 3T3L-1-derived preadipocyte differentiation into adipocytes by decreasing PPARgamma. These findings may provide a new therapeutic strategy for the treatment of obesity.
